By using permanently acting clamping and guide elements (Figure 1) which are precisely matched to the engine in question, it is possible to optimize the chain drive in such a way that its service life corresponds to that of the engine.

Chain tensioner

The chain tensioner (Figure 7), mechanically or hydraulically acting, assumes a range of tasks in the timing drive. On the one hand, the timing chain is pre-tensioned in all operating conditions on the loose side under a defined load, even in the event of wear elongation that occurs during operation. Slack run refers to the non-pulled, as it were load-free chain section. A damping element – either friction or viscous damping – reduces vibrations to an acceptable level.

Mechanical chain tensioners without additional hydraulic damping are used, as

a rule, in oil-pump drives which are subject to low load. In special cases, this mechanical chain tensioner can even be omitted completely.

Tensioning and guide rails

Simple rails made of plastic or metal (aluminum or sheet steel) with plastic covering and which are flat or bent - depending on the chain route - are sometimes used as tensioning and guide elements. In the case of newer types, the rails are for the most part inexpensively injection-molded from plastic and manufactured as a two-component design (base carrier and sliding lining).

Here, in the case of the tensioning rail, a friction lining of glass-fiber-free polyamide is sprayed or clipped onto a carrier of heat-resistant polyamide with 30 to 50 % glass-fiber content. The sliding rails are usually designed in plastic as one-component rails, and are used for chain guidance. Figure 8 shows some types of tensioning and guide rails.

Engine cooling

The process of converting any type of energy into mechanical energy to drive a vehicle creates heat as a waste product, whether it be by friction of different engine components against each other or by the combustion of fuel in the engine. In order to optimally utilize the conversion of the chemical energy of fuel into kinetic energy, this process must take place under controlled conditions and, to protect the engine and its components, also under controlled temperatures. The waste heat that is generated must be reliably dissipated to atmosphere under all operating and ambient conditions.

Figure 1: Principle of air cooling

2 Cooling-air fan,
3 Cylinder with cooling fins,
4 Oil pan,
5 Pressure-relief valve,
6 Oil pump (gear pump),
7 Lube-oil filter,
8 Thermostat.

Air cooling

Design and operating principle

Cooling air is routed by dynamic pressure or a fan around the external walls of the cylinder casing (Figure 1). These walls are finned in order to achieve better cooling results thanks to the increased surface area. The cooling-air quantity can be controlled for example by specifically restricting its flow at the vehicle's cooling-air inlets, which is achieved for example with thermostat-controlled flaps or by means of the rotational speed of a load- or temperature-dependent fan.

Heat absorbed by the engine oil is dissipated via cooling fins on the oil pan which are also located in the air stream.

Advantages and disadvantages of air cooling

The advantages of air cooling are simple and cost-effective construction, reliable operation, and lower weight when compared with water-cooling systems.

The disadvantages are higher noise generation, lower temperature consistency of all engine parts, and poorer thermal behavior at high specific power outputs.

Air-cooled engines struggle to comply with the currently required exhaust-emission limits.

Applications

Today, air cooling is mainly used for motorcycle and aircraft engines and in special applications. Extra-small engines in model-making applications also use air cooling.

The expected operating conditions for a vehicle can only dictate which cooling principle is chosen. In Arctic regions, where temperatures down to −50 °C are experienced, water-cooled engines cannot be used owing to the risk of the water freezing; for this reason air cooling must be used in these regions.

Water cooling

Design and operating principle

Cooling circuit

In contrast to air cooling, with water cooling the waste heat from the engine is not dissipated directly to the ambient air. Instead, the waste heat is absorbed by the coolant and transported via this medium to the main coolant radiator (Figure 2). Here, heat is exchanged between the coolant and the ambient air. The cooling-air flow rate is controlled by a fan, and the coolant is circulated in the circuit by a coolant pump.

Coolant cooling, also called water cooling, has become the standard in both passenger cars and commercial vehicles.

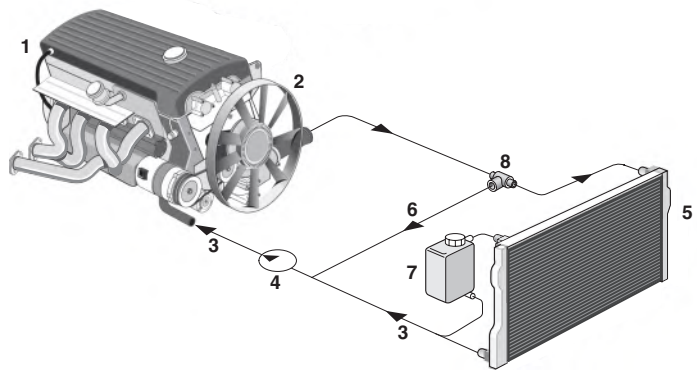
Coolant

Coolants are a mixture of water, antifreeze (mostly ethylene glycol), and corrosion inhibitors. The inhibitors prevent the components through which coolant flows from corroding (see Coolants). Adding antifreeze in concentrations of 30 to 50 % firstly stops the coolant from freezing even at temperatures down to – 25 °C and secondly raises the coolant boiling temperature to allow coolant temperatures of up to 120 °C at a pressure of 1.4 bar in passenger cars.

Radiator designs

The cores of the coolant radiators in modern passenger cars are almost exclusively made of aluminum. Aluminum radiators are also being used to an ever-increasing extent in a wide range of commercial vehicles and trucks throughout the world. There are two assembly variants: brazed radiators and mechanically joined or assembled radiators.

Flat-tube/corrugated-fin systems



For cooling high-performance engines, or when space is limited, the best solution is a brazed flat-tube and corrugated-fin radiator layout with minimized aerodynamic resistance on the air-intake side.

Construction

The radiator core consists of series of flat tubes with corrugated fins located in between (Figure 3). The flat tubes lead into the openings in the radiator base. During the manufacturing process the tips of the corrugated fins are soldered to the

Figure 2: Passenger-car cooling system

8 Thermostat.

flat tubes and the flat tubes to the radiator base in an oven. The solder material is applied as a layer to the materials.

The radiator tank ensures that the coolant is distributed throughout the core. These tanks are made of fiberglass-reinforced polyamides, and are injection-molded with all connections and mountings in a single unit. They are flange-mounted to the radiator core and sealed by an integrated elastomer sealing element.

Operating principle

The coolant is routed through the radiator tank to the radiator core. It flows through the flat tubes before emerging again from the opposite radiator tank. The hot coolant in the flat tubes dissipates heat to the corrugated fins, while the cooling air flowing through the radiator core cools the corrugated fins. The soldered connections guarantee a good heat transfer from the tubes to the fins. Gills in the corrugated fins, which are brought together in gill fields, bring about additional swirling of the cooling air. This results in improved heat dissipation.

Radiator tanks are designed in such a way as to distribute the coolant as uniformly as possible to all the flat tubes. The tubes have minimal depth (approx. 2 mm with wall thicknesses of 0.2 to 0.3 mm) so that the full coolant flows past the tube walls as closely as possible, thereby ensuring a good heat transfer to the fins.

Tube/fin systems

The less expensive, mechanically assembled tube/fin system is generally employed for applications with less powerful engines or when more space is available.

Construction

When the radiator is assembled mechanically, the cooling grid is formed by mounting stamped cooling fins around round, oval or flat-oval tubes (Figure 4). The distance between the cooling fins is maintained by trapezoidal cutouts. In the manufacturing process the tubes are

Figure 3: Flat-tube/corrugated-fin system

initially inserted loosely into the cooling fins and flared with a tool. This creates an internal connection between the tubes and the fins. The connection is established exclusively by the mechanical flaring of the tube. However, the heat transfer between the tubes and the fins is much worse than in the soldered systems.

Operating principle
The cooling air flows through the radiator core between the cooling fins. These are corrugated or slotted at right angles to the direction of air flow. They are – like the corrugated fins in soldered radiators – also fitted with turbulators and gill zones, inducing air turbulence and improving the cooling effect.

Options for increasing radiator performance
Gills and a larger number of corrugations are integrated into the cooling fins on the cooling-air side to enhance thermal transfer. The gills induce turbulence in the cooling air flowing through, and the larger number of corrugations produces a larger surface area. These measures increase the quantity of heat that can be dissipated.

Further measures to increase cooling efficiency include the use of tubes with the lowest possible width and wall thickness, and turbulators on the coolant side, provided the attendant pressure losses remain within acceptable limits. The negative effect of these performance-enhancing measures is the higher pressure drop on both the cooling-air and coolant sides, which must be compensated by a higher-capacity fan and on the coolant side by a more powerful coolant pump.

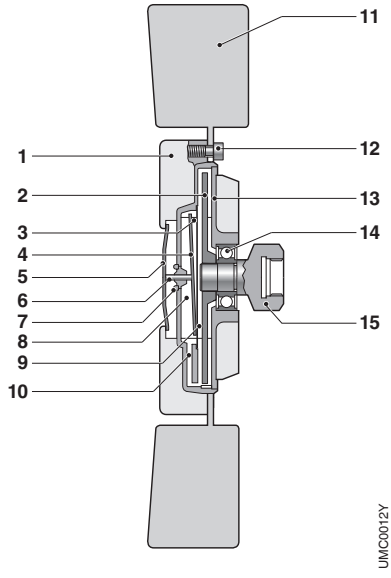
Coolant expansion tank
Mounted at the highest point of the cooling circuit is the airtight expansion tank; this tank has a filler neck through which coolant is poured into the cooling system. When the engine is running the expansion tank takes up excess coolant that expands due to heating. Where necessary, it returns it to the cooling circuit. As the coolant heats up, so too the system pressure in the cooling system increases. This causes the coolant boiling point to rise.

The expansion tank's air volume must be large enough to absorb the coolant's thermal expansion during rapid pressure buildup, and prevent the coolant from boiling over under the permitted operating conditions. At excessively high operating temperatures and thus also excessively high operating pressures the expansion tank protects the cooling circuit by means of a pressure-relief valve.

The expansion tank also provides a reliable escape channel for pressurized gases, preventing cavitation of the kind that tends to occur on the intake side of the coolant pump.

Expansion tanks are injection-molded in plastic (generally polypropylene), although simple designs can also be blow-molded to shape. A system of hoses is normally used to connect the expansion tank to the cooling system. The expansion tank is mounted in the engine compartment at the location representing the highest point in the cooling system to ensure air is expelled effectively. In some cases, the expansion tank can form a single unit with the radiator tank, or the two can be joined by means of a flange or plug connection.

The position and shape of the filler neck can be used to limit capacity, thus preventing overfilling. An electronic level sensor can be fitted to monitor the level of the coolant. The coolant level can also be monitored by manufacturing the expansion tank completely or partially in natural-color, transparent plastic with molded level markers. However, colorless polypropylene is sensitive to ultraviolet rays. For this reason, the transparent part of the expansion tank should not be exposed to direct sunlight.



Cooling-air fan
Design
Since motor vehicles also require substantial cooling capacity at low speeds, force-air ventilation is required for the radiator. Injection-molded plastic fans with drive-power ratings extending up to 30 kW are now used as standard in commercial vehicles. A fan of this type is driven by a mechanical coupling with the internal-combustion engine, for example via a belt drive. The fan can also be mounted directly on the crankshaft.

Single-piece injection-molded plastic fans are generally used in passengers cars; these are usually driven by DC brush motors or brushless DC motors. These motors are installed in the fan hub. The electrical drive power is around 400 W in the small-car segment, and extends up to 1 kW in the luxury-class segment and in offroad vehicles. Although blade design and arrangement can be selected to provide relatively quiet running, these fans have considerable noise levels at high rotation speeds.

In some passenger-car applications, in particular offroad vehicles with very high engine power outputs in combination with equipment options for operation in hot climates and equipment variants for diesel engines and air-conditioning systems, the capacity of the electric drive is no longer sufficient to provide the volume of air necessary to ensure effective cooling. Fan-output figures in excess of 1 kW can only be achieved when the fan is driven mechanically by the engine. However, this is only possible with a longitudinally installed engine.

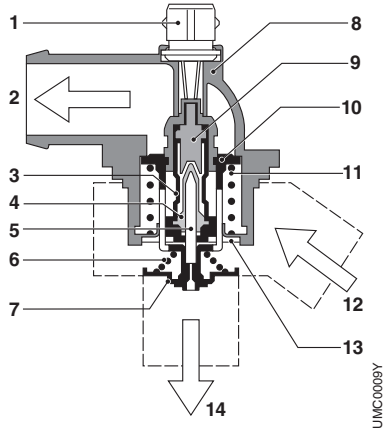
Control of electrically driven fans
Depending on vehicle and operating conditions, the unassisted air stream can provide sufficient cooling up to 95 % of the time. It is thus possible to economize on energy that would otherwise have to provide the power to drive the fan. For this purpose, electric fans use a multistage or continuous control system that specifically adapts the operating periods and speed of the fan to the required cooling capacity. A multistage control system may consist of relays and series resistors, while continuous variable control necessitates the use of power electronics. Electric thermostatic switches or the engine control unit supply the input signals for the control system.

Drive of mechanical fans
The fluid-friction clutch (viscous clutch) is a mechanical-drive arrangement of proven effectiveness for use in commercial vehicles. It essentially consists of the following assemblies (Figure 5):
– Input or primary section (flanged shaft and primary disk)
– Output or secondary section (cover, basic body)
– Control facility for controlling and regulating the oil filling (working fluid)

The secondary section of the viscous clutch is divided into a working chamber and a supply chamber. When the viscous clutch is not cut in, only a small amount of working fluid is in the working chamber, such that only a very small amount of torque can be transmitted due to the high degree of slip between primary disk and secondary section. The viscous working fluid is a silicone oil.



As the temperature increases, the bulging of the bimetallic strip causes the operating pin to open the valve. Silicone oil flows from the supply chamber into the working chamber. This reduces the slip between primary disk and secondary section – in turn increasing the fan speed. The fan speed and thus the cooling capacity are infinitely increased.

As the temperature decreases, the bimetallic strip cools and causes the operating pin to close the valve slowly. The silicone oil flows through the pump body back into the supply chamber. The fan speed decreases. The amount of silicone oil located in the working chamber determines the output power transmitted by the clutch and therefore the speed of the fan.

A distinction is made between types of viscous clutch, based on how the valve is actuated: Firstly, as already described, the temperature-dependent, self-governing clutch which varies its speed infinitely by means of a bimetallic element, an operating pin, and a valve lever. The controlled variable is the temperature of the air leaving the radiator, and thus indirectly the temperature of the coolant. The electrically activated clutch is now used in 95 % of heavy-duty commercial vehicles. In this clutch type the valve lever is electromagnetically actuated and thus the oil quantity in the working chamber is regulated. Instead of just one controlled variable, a wide range of input variables is used for control purposes. These are usually the temperature limits of the various cooling media.

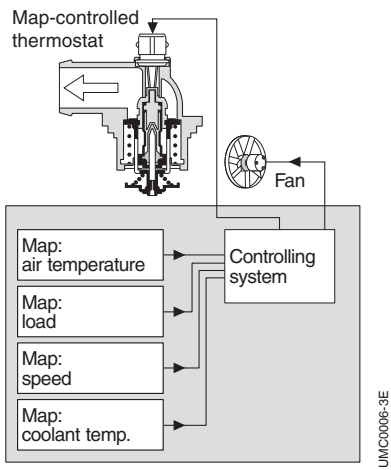
Regulation of coolant temperature

A motor vehicle's engine operates in a very wide range of climatic conditions and with major fluctuations in engine load. The consequences of this are significant variations in coolant and engine temperatures, which in turn result in increased engine wear, unfavorable exhaust-gas composition, higher fuel consumption, and unreliable vehicle heating. The temperature of the coolant must be regulated in order to counteract these unwanted side effects and to keep the coolant and engine temperature as constant as possible.

Expansion-element-regulated thermostat

A temperature-sensitive thermostat incorporating an expansion element proves to be a robust regulator operating independently of the changing pressure conditions in the cooling system. It is very similar in design to the map-controlled thermostat (Figure 6), but does not have a heating resistor. The expansion element used in this type of thermostat actuates a double-acting disk valve (main valve), which – until the operating temperature is reached – closes the connection to the radiator while simultaneously releasing coolant flow from the engine outlet to the bypass line (see Figure 2). The coolant flows uncooled back into the engine ("secondary cooling circuit").



Both sides of the double-acting disk valve are partially opened within the control range of the thermostat. This allows a mixture of cooled and uncooled coolant to flow to the engine at such a rate as to maintain a constant operating tempera-

ture. At wide-open throttle (full load) the opening to the radiator is fully opened and the bypass line closed off ("primary cooling circuit").

Electronic map-controlled thermostat
Further possibilities to regulate the coolant temperature are permitted when a map-controlled thermostat is used. An electronically controlled thermostat differs from purely expansion-element-regulated thermostats in that the opening temperature can be controlled. A map-controlled thermostat features a heating resistor that is used to additionally heat the expansion element (Figure 6). This has the purpose of enlarge the opening of the double-acting disk valve to the radiator, thereby reducing the coolant temperature. The heating resistor is controlled by the engine management system in order to ensure that the engine operating temperature is optimally adapted to the operating conditions. The information necessary for this purpose is stored in the form of program maps in the engine-management system (Figure 7).

Raising the operating temperature in the part-load range and reducing the operating temperature at wide-open throttle provide the following benefits:

Figure 7: Electronic control of coolant temperature

– Lower fuel consumption,
– Low-pollutant exhaust-gas composition,
– Reduce engine wear,
– Improved heating efficiency of the vehicle interior.

Radiator design
The size and therefore the cooling capacity of a specific radiator can be determined by calculation, based on correlation equations derived from tests relating to thermal transfer and flow-pressure loss. The mass of air that flows through the radiator in the vehicle is a decisive factor and depends on the driving speed, the resistance to flow in the engine compartment, the resistance to flow of the radiator, and the efficiency of the fan.

The primary objective of radiator design is to maintain the coolant temperature at the engine outlet below a maximum permissible value under given operating conditions. Because at low driving speeds the dynamic pressure of the cooling air and thus the cooling-air flow rate in the radiator are very low, the cooling-air flow required for adequate cooling must be ensured either by a high-output fan or by a radiator with low flow resistance, while a high air-mass flow rate facilitates the use of smaller radiators with high flow resistance. However, the latter causes high energy consumption if the air-mass flow is generated by a powerful fan.

The task of determining the most favorable solution in terms of technical feasibility and economic efficiency is a matter of optimization that is best solved by the application of simulation tools. The most suitable and effective simulation tools describe all components that have an influence on air-mass flow. They depict the radiator as an integral heat-transfer medium or heat exchanger. The simulation results are checked by way of on-vehicle tests conducted in wind tunnels.

Intercooling (charge-air cooling)

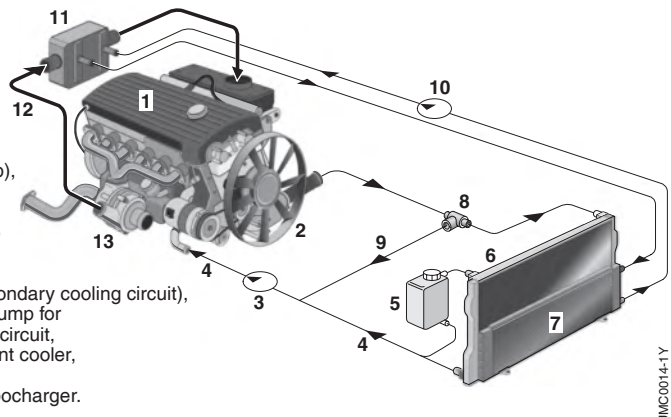
Trends in engine development show a constant increase in specific engine output power. This development goes hand in hand with the current transition from naturally aspirated engines to supercharged engines and ultimately to supercharged, intercooled engines. The need for intercooling (charge-air cooling) is attributed to the higher air density levels associated with supercharging systems and therefore the amount of oxygen available in the combustion air. Intercooling also reduces exhaust-gas emissions from supercharged diesel engines. If there was no intercooling (charge-air cooling) employed on supercharged spark-ignition (SI) engines, appropriate steps would need to be taken to prevent engine knocking attributed to mixture enrichment or retarded ignition timing. Consequently, intercooling indirectly serves to reduce fuel consumption and exhaust emissions.

Design variations

Basically speaking, both the ambient air and the engine coolant can be employed to cool the charge air. With only few exceptions, air-cooled intercoolers are now used both on passenger cars and commercial vehicles.

Air-cooled intercoolers

Air-cooled intercoolers can be mounted in front of or next to the engine radiator, or even completely separate from the adiator at a different location in the engine compartment. A separately positioned intercooler can utilize either the unassisted vehicle air stream or its own fan. With the intercooler located in front of the engine radiator, the cooling-air fan ensures sufficient air flow even at low vehicle speeds. However, a drawback of this arrangement is that the cooling air is itself heated in the process. To compensate for this effect, the higher temperature of the inflowing cooling air must be taken into account in the design of the engine radiator.



The system of corrugated aluminum fins and tubes employed for the intercooler core is similar to the design of the engine coolant radiator. Wide tubes with internal fins provide superior performance and structural integrity in actual practice. The fin density on the cooling-air side is relatively low and corresponds approximately to the density of the inner fins in order to achieve a good distribution of thermal-transfer resistance.

Wherever possible, the plenum chamber is injection-molded in fiberglass-reinforced polyamide as a single casting incorporating all connections and mounts. The plenum chambers which are subject

to increased stresses on the charge-air inlet side are injection-molded from highly heat-resistant PPA (polyphthalamide) or PPS (polyphenylene sulfide). They are flange-mounted to the radiator core and sealed by an integrated elastomer sealing element. Plenum chambers which feature undercut shapes or are intended for high-temperature applications are cast in aluminum and welded to the core.

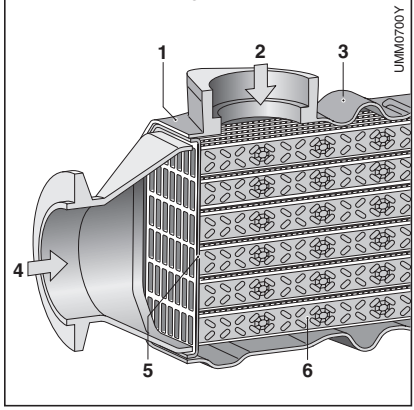
Coolant-cooled intercoolers
Coolant-cooled intercoolers can be installed in virtually any location in the engine compartment, as there are no technical difficulties to supplying the system with coolant. In addition, thanks to its modest dimensions, this type of intercooler requires substantially less space than the air-cooled intercooler. Coolant-cooled intercoolers have a high power density. However, coolant at a very low temperature must be available in order to effectively cool the charge air. This requirement is of particular significance in commercial vehicles and heavy-duty trucks as, in this case, it is necessary to heat the charge air to a level of 15 K above the ambient temperature. Because this stipulation cannot be implemented with the temperature level of the normal cooling circuit at approx. 100 °C, it is necessary, in order to cool the charge air, to install a low-temperature radiator to ensure coolant is available in a separate circuit at the required temperature level.

Diffusion rate, intercooler
The diffusion rate Φ of an intercooler is particularly important in assessing intercooler performance. It defines the relationship between charge-air cooling efficiency and the charge-air/cooling-air temperature differential:

$$\Phi = \frac{T_{1E} - T_{1A}}{T_{1E} - T_{2E}}.$$

The equation's elements are:
T_{1E} Charge-air inlet temperature
T_{1A} Charge-air outlet temperature
T_{2E} Cooling-air or coolant inlet temperature

For passenger cars: Φ = 0.4...0.7
For commercial vehicles: Φ = 0.9 – 0.95



Exhaust-gas cooling

Exhaust-gas recirculation is used in diesel engines to reduce raw nitrogen-oxide emissions (NO_x). In gasoline engines it serves both to protect components and to dethrottle in the part-load range by charge dilution (see Exhaust-gas recirculation). Exhaust-gas recirculation delivers the best results when the recirculated exhaust gas is cooled in an EGR cooler.

Design of an EGR cooler
A central aspect in the design of an EGR cooler is, as well as its output, its durability. The former is achieved either by specially shaped tubes (winglets) which generate a high level of turbulence in the tube or by internal fins in the tubes which increase the surface area for heat exchange. The essential characteristic here is the tendency of an EGR cooler towards fouling. This can be significantly influenced by a suitable design of the winglets or tube fins. Figure 9 shows such an EGR cooler in longitudinal section. The winglet tubes direct the hot exhaust gas and are themselves surrounded by coolant.

It must be borne in mind with regard to durability that the hot exhaust gas may

Figure 9: EGR cooler

2 Coolant inlet,
3 Length compensation,
4 Exhaust-gas inlet,
5 Stainless-steel cooler base,
6 Stainless-steel winglet tubes.

condense in the cooler. The condensate produced has a lower pH value and attacks the material like a strong acid. For this reason, the gas-directing parts of EGR coolers are frequently made of stainless steel.

When the EGR cooler is in operation the tubes get hotter than the housing. Suitable design measures must be used to compensate for the linear difference in the cooler.

The issue of vibration also plays an important role in view of the fact that the cooler is usually bolted directly on the engine. The EGR cooler must therefore be as rigid as possible in its design. The first natural frequency of an EGR cooler should at least be above the first natural frequency of the engine block. For this reason, the brackets of such EGR coolers are specifically very rigid and sometimes multiply ribbed in design.

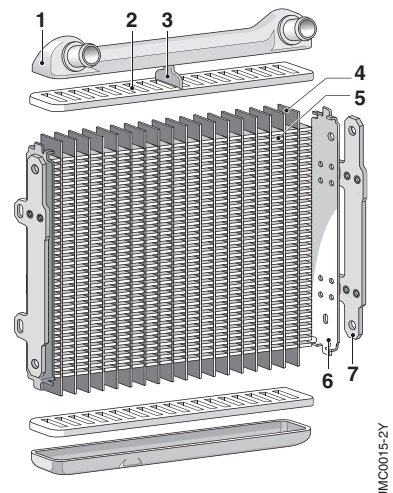
The cooler housing is often made of stainless steel, which can be strengthened further by cold-working. The exhaust pipes connected to the cooler should be isolated at the engine end. This isolation is achieved by bellows or by a comparable structure.

Cooling circuit

The coolant comes primarily from the engine cooling circuit, with the EGR cooler being cooled by coolant flowing out of the engine. A variant of this arrangement is “two-stage exhaust-gas cooling”. Here the exhaust gas is cooled in a first stage as described above. There is also a second cooling stage, which is supplied by a cooling circuit independent from the engine (low-temperature circuit). Because the temperatures in this second cooling stage are much lower (approx. 10 to 20 K above ambient temperature), the exhaust gas can also be cooled significantly below the otherwise normal values, increasing the effect of reducing nitrogen oxide. The two cooling stages are either integrated together in a single housing or designed separately as two independent components.

Oil and fuel cooling

Oil coolers are often needed in motor vehicles to cool both the engine oil and transmission oil. They are used when the heat losses from the engine or transmission can no longer be dissipated via the surface of the oil pan or the transmission with the result that the permitted oil temperatures are exceeded.



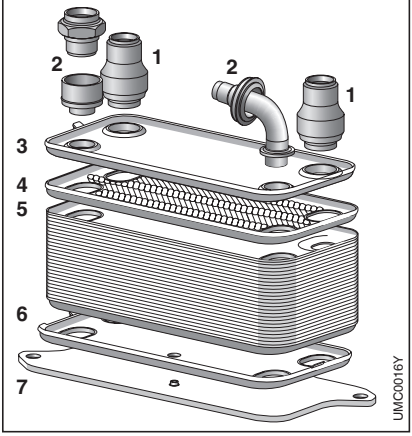
Air- or coolant-cooled oil coolers are used to suit their application profile.

Oil-to-air coolers

Oil-to-air coolers are predominantly made of aluminum. In most cases, soldered flat-tube/corrugated-fin systems (Figure 10, similar to engine radiators) with a high power density are used. Mechanically assembled systems with round tubes and fins are less commonly used. Turbulence inserts are brazed in the flat-tube system to increase cooling capacity and strength (to resist high internal pressures).

Figure 10: Oil-to-air cooler (flat-tube/corrugated-fin system)

1 Collector tank with oil connections,
2 Base,
3 Partition,
4 Flat tube with turbulence insert,
5 Corrugated fin,
6 Side section,
7 Bracket.



The principle of oil-to-air cooling is ideal for use in commercial vehicles and powerful passenger cars to cool the transmission oil. To ensure good ventilation, they are ideally mounted upstream of the coolant radiator, but can also be mounted elsewhere in the engine compartment. Oil-to-air coolers which are not located upstream of the main coolant radiator and are thus outside the range of action of the main fan must be supplied with cooling air accordingly, for example by exposure to dynamic air pressure or by a separate electric fan.

Oil-to-coolant coolers
Aluminum stack designs employed in oil-to-coolant coolers have largely replaced stainless-steel disk coolers, double-tube oil coolers, and aluminum forked-tube coolers.

Disk-stack oil coolers
Disk-stack oil coolers are made of individual disks with turbulence inserts inserted between the disks (Figure 11). The upright edges of the disks fit together in a casing. Passages connect the channels formed by the disks in such a way that coolant and oil flow through alternate channels.

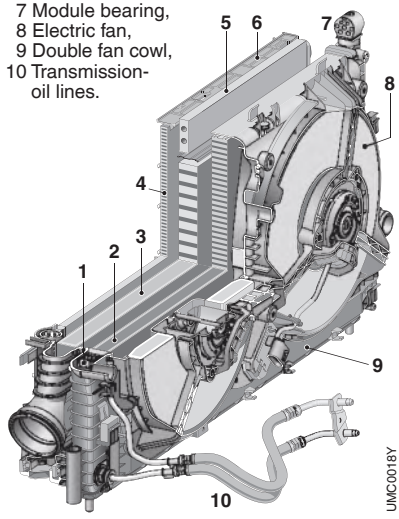
Figure 10: Oil-to-coolant cooler (disk-stack oil cooler)
1 Oil connections,
2 Coolant connections,
3 Cover,
4 Disk stack (oil passage),
5 Disk stacks (coolant passage),
6 Reinforcement plate,
7 Base plate.

Double-tube oil coolers and flat-tube oil coolers
These cooler types are mounted directly in the radiator tank on the outlet side of the main radiator (coolant radiator). The radiator tank thus assumes the function of the coolant-side housing for the oil coolers. The double tube of the oil cooler is formed by an outer tube and an inner tube inside it with a turbulence insert in between. The two tubes are soldered to each other at the ends. The transmission oil passes through the space between the inner and outer tubes, around or through which already cooled coolant flows.

Double-tube coolers are used as transmission-oil coolers in passenger cars and commercial vehicle in the lower power segment up to approx. 2.5 kW. As power requirements increase up to 4 kW the double tube is replaced by numerous flat tubes connected to each other by turbulence plates on the coolant side. The flat tubes are interconnected by openings at their ends. The flat tubes are also provided on the oil side with turbulence plates, which are soldered to increase both cooling capacity and strength.

Disk oil coolers
Disk oil coolers are mounted between the engine block and the oil filter. They have a separate casing and a central channel for the oil to pass through. The oil flowing back from the oil filter is routed through a labyrinth of perforated disks separated by turbulence inserts. This labyrinth is cooled by coolant flowing from the main circuit through the casing.

Forked-tube coolers
Forked-tube coolers are made of finned forked tubes through which the coolant flows. On the oil side, they have no casing and must therefore be integrated into the oil-filter housing or the oil pan.



Engine-oil coolers for commercial-vehicle applications
The engine oil in commercial vehicles is generally cooled by stainless-steel disk-stack coolers or aluminum flat-tube cool-

ers without a casing on the coolant side. They are accommodated in an extended coolant duct in the engine block.

Fuel coolers
Fuel coolers are installed in modern diesel engines in order to cool excess diesel fuel down to permissible levels. This excess diesel fuel heats up during the injection process as the result of compression in the high-pressure pump, before it is routed back via the return line to the fuel tank. The excess diesel fuel that is returned without cooling to the tank has a temperature of well over 70 °C and heats the diesel fuel in the tank. If now the tank were almost empty, the temperature of the diesel fuel in the tank would therefore exceed the maximum permissible temperature. The excess fuel must therefore be cooled before being introduced into the tank.

The fuel can be cooled by means of an air-cooling or coolant-cooling system. Coolers operating along similar lines to oil-to-air coolers or disk-stack oil coolers are used to cool fuel.

Modularization

Cooling module
A cooling module is a structural unit which can consist of various components for cooling (e.g. main radiator, intercooler, oil-to-air cooler) and a condenser for air-conditioning a passenger car, and can include a fan unit with drive (e.g. electric motor) (Figure 12).

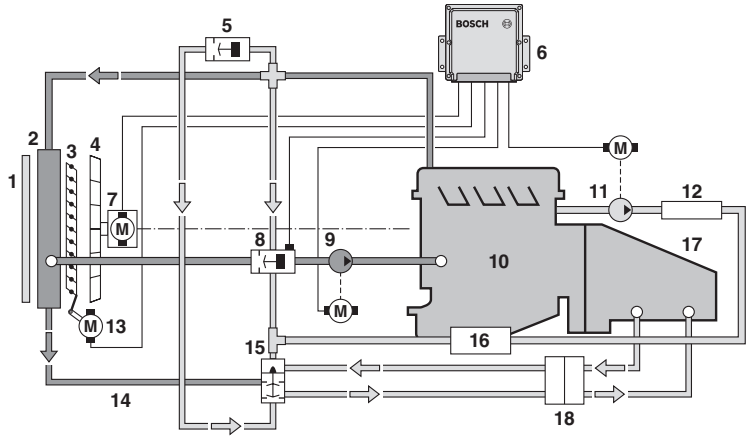
The design of a cooling module must take into consideration the interaction of the individual components, the dimensioning of the components with respect to the package space in the vehicle, and the procedure for dealing with interfaces. Important factors here are the mounting technology, the cooling-air ducts and the seals on the cooling-air side, the component connections on the fluid side, and the electrical plug-in connections.

The standard modular construction used in both passenger cars and commercial vehicles essentially offers a whole range of technical and economic benefits:
– Simplified logistics by combining components to form one structural unit,
– Reduced number of interfaces,
– Simplified mounting and assembly,
– Optimum component design by using matched components,
– Modular systems, encompassing various engine and equipment variants,
– Improved quality with regard to assembly.

Simulation and test methods are employed for the purpose of achieving optimized component design and layout in the cooling module. Assuming exact knowledge of the fan characteristics, the fan drive and the heat exchangers, simulation programs are created to replicate both the cooling-air side and the fluid side. By integrating the individual components into the simulation models, it is possible to examine the interactions of the individual components under various operating conditions. Ever greater significance is being attached to this type of virtual analysis, which is characterized by the use of computer-aided development tools. In line with this development, all geometric data are entered and processed in a CAD system (Computer-Aided Design). CFD analyses (Computational Fluid Dynamics) are con-

ducted to examine the flow of cooling air in the engine compartment, while FEM analyses (Finite-Element Method) provide statements concerning the strength and stability of the design layout. The design analysis phase concludes with verification tests that may also be performed in a wind tunnel and on vibration test rigs.

Cooling-system technology



While the cooling module comprises a structural unit of components with defined functions, the cooling system encompasses all components that are associated with the functions of the cooling system, even if they do not form complete structural units (Figure 13). This includes for example, beyond the cooling module, lines, pumps, control components, and the expansion tank, if it is not already a component part of the cooling module.

Cooling-system technology, in which all the components are matched to each other, offers a whole range of technical and economic benefits:

– Reduced parasitic losses through appropriate hydraulic design matching,
– Consideration of control systems and dynamics,
– Consideration of the passenger-compartment heating system,
– Larger scope of intervention options for the purpose of optimizing the design,
– Standardized assembly concept for all cooling-system components,
– Reduced development expenditure by cutting the number of development interfaces.

Intelligent thermal management

Function

Future trends are heading toward the system-optimized regulation of various heat and substance flows. Thermal management goes beyond cooling-system technology in that it takes into consideration all material and heat flow systems in the vehicle, i.e. in addition to the flow structures of the cooling system, it also deals with those of the air-conditioning system. The objectives of optimization consist in reducing fuel consumption and exhaust emissions, increasing air-conditioning comfort, increasing the service life of components, and improving cooling capacity in part-load states.

Optimization objectives

One of the basic principles of thermal management concerns itself with the fact that auxiliary energy employed to operate the cooling system always represents a loss for the vehicle energy balance, and component efficiency cannot be increased arbitrarily at a constant supply of auxiliary energy. To achieve the optimization objectives, the cooling system is therefore equipped with "intelligence", installed in familiar and new types of actuators, as well as in microprocessor-controlled control systems that operate these actuators. One example is demand-triggered regulation of cooling-air flow by radiator shutters and controllable fan drives so that cooling-air throughout is kept to a minimum under all operating conditions. In addition to improving the vehicle's drag coefficient (c_d), this measure also ensures that all media achieve their operating temperature more effectively during the warm-up phase after a cold start, and that the passenger compartment is heated more efficiently. Cutting back the use of auxiliary energy in this way means that auxiliary energy can be diverted for use in operating states that are critical to the cooling output, while still achieving the optimization objectives.

Another important basic principle is to maintain a constant temperature in the components to be cooled as far as possible, irrespective of the operating state and the ambient conditions. An example of this temperature control principle is to use coolant to regulate the transmission oil temperature. Heating the transmission oil during the warm-up phase and employing an efficient cooling system to prevent the transmission oil from overheating reduce friction losses in the transmission, increase the service life of the transmission, and extend the service intervals for the transmission oil.

Ultimately, considering the cooling and air-conditioning systems in their entirety opens up the option of utilizing "thermal integration". Heat flow from one of the systems can be utilized or dissipated by another system without the need for any major additional input in auxiliary energy. An example of this is the utilization of waste heat from the exhaust-gas cooling system to heat up the vehicle interior.

Applications

In the field of engine cooling thermal management is used for the following:

- Transmission-oil temperature equalization,
- Map-controlled thermostat,
- Electrically controlled viscous clutch,
- Controllable electric coolant pump,
- Cooling-air control, e.g. radiator shutter,
- Exhaust-gas cooling,
- Coolant-cooled charge-air cooling (intercooling).

Advantages

The fuel-saving potential based on the sum of all measures is in the range of approx. 5% (for passenger vehicles). On top of this, there is a range of further advantages corresponding to the above-mentioned optimization objectives. The extent to which engine management utilizes the cooling system control options is of decisive significance in leveraging this potential.

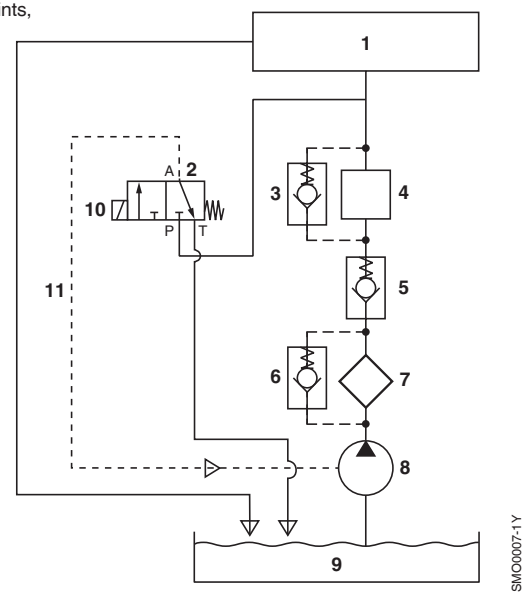
In the meantime, individual measures have been implemented to achieve system-optimized temperature equalization in motor vehicles. Nevertheless, thermal management as an all-encompassing optimization principle has to date not been fully implemented and remains the reserve of future vehicle generations.

Engine lubrication

Force-feed lubrication system

Heat and wear are produced in engines by the friction of moving parts. Small amounts of residual dirt from production and particulate ingress from the outside are also to be expected in the engine system. The engine system is lubricated with lube oil in order to minimize friction and eliminate or reduce wear and to remove particulates and heat from the engine system.

The force-feed lubrication system in combination with splash and oil mist lubrication is the most commonly used system for lubricating motor-vehicle engines. An oil pump (usually a gear pump) conveys pressurized oil to all lubricating and bearing points in the engine (Figure 1), while the sliding parts are supplied with lube oil and lubricated by splash lubrication systems and oil mist.



After flowing through the bearing surfaces and sliding parts, the oil collects below the engine in the oil pan. The oil pan is a reservoir where the oil cools, and the foam dissipates and settles. In the meantime an additional oil cooler is used in virtually all engines to regulate the oil temperature. In addition to filtration of the oil, thermal management is of particular importance.

Engine service life can be prolonged significantly by keeping the oil clean, i.e. filtration. Oil cooling by means of good thermal management makes possible current technologies such as single or multiple charge-air charging and the associated downsizing of engines.

Components

Oil filters

Function

Oil filters remove and reduce particulates (soot and other residues from incomplete combustion, metal abrasion, dust, etc.) from the engine oil, which could otherwise cause damage or wear in the lubrication circuit. Wear in this context means that the particulates can get between the moving engine components, e.g. between piston and cylinder wall. Here the surfaces can be damaged by the particulates, which in turn can cause scoring or further particulate production. Since the engine oil is constantly circulating in the lubricating oil system, inadequate filtration could cause particulates to accumulate and this would accelerate the rate of wear of components that move against each other. The oil filter does not filter out liquid or soluble constituents such as water, additives or decay products attributed to the effects of oil aging.

The typical size of particles in engine oil ranges from 0.5 to 500 µm. The fineness of the oil filter is therefore specifically adapted to the requirements of a particular engine.

Different types and designs

In principle, oil filters are based on two specific designs: easy-change filters and housing filters. In an easy-change oil filter (Figure 2), the filter element is located in a housing that cannot be opened and which is secured by means of a threaded stud to the engine block. The complete easy-change filter unit is replaced as part of the oil service.

The housing oil filter (Figure 3) is made up of a housing that is permanently connected to the engine block and can be opened to access the replaceable filter element. During the oil service, only the filter element is replaced; the housing is a permanent component. The filter element as a rule is based on a metal-free design. This means that the filter element can be completely incinerated.

3 Filter bypass valve,
4 Center tube,
5 Filter element,
6 Anti-drainback diaphragm,
7 Anti-drainback valve,
8 Filter housing.

Besides the filter element, the two filter designs normally feature a filter bypass valve, which opens at high differential pressures to ensure effective lubrication at the necessary points in the engine. Typical opening pressures range from 0.8 to 2.5 bar. Elevated differential pressures can occur in connection with high oil viscosities or when the filter element is already heavily fouled.

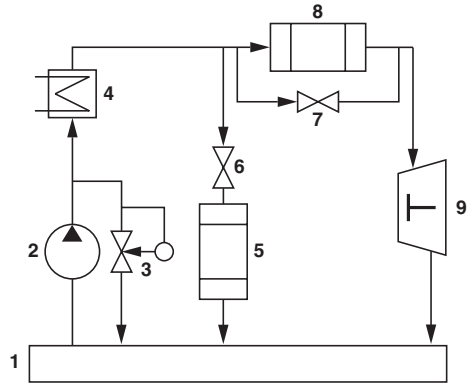
Depending on the specific engine requirements, the two filter designs may also feature a non-return or backflow check valve on the filtered or unfiltered oil side (contaminated oil side). These valves prevent the oil filter housing from draining empty after the engine is turned off.

Currently, the oil and oil-filter change intervals for passenger-car engines are between 15,000 and 50,000 km, and for commercial vehicles are between 60,000 and 120,000 km – very much dependent on the engine system, place of use and the service strategy of the car manufacturer.

Filter media

Various types of deep-bed filter media are employed in oil filtration. These are entangled-fiber structures (nonwovens) which exist in different configurations. The filter material most commonly used is flat media which, in the majority of cases, is pleated, but in some applications they are also wound or used in the form of fiber packings, especially in bypass oil filters. A mixture of cellulose with synthetic fibers is the most widely used fiber material. The synthetic-fiber content can vary markedly depending on the requirements. Alternatively, amounts of glass fibers can be mixed with the cellulose. These filter media are impregnated with resin to enhance their resistance to oil and their operational stability.

However, filter media made of purely synthetic fibers are being used even more, as they have a much greater resistance to chemicals and clear benefits in terms of differential-pressure behavior. These attributes allow for longer service intervals. They also provide better options for structuring the three-dimensional fiber matrix to specifically optimize filtration and increase particulate retention efficiency.



Full-flow oil filters

All vehicles are as a rule equipped with full-flow oil filters. Based on this filtration principle, the entire volumetric flow of oil that is pumped to the lubricating points in the engine is routed through the filter (Figure 4). Consequently, all particles which could cause damage and wear due to their size are trapped the first time they pass through the filter.

The decisive factors governing the filter area are oil volumetric flow and particulate retention capacity.

Bypass oil filters
Bypass oil filters, designed as deep-bed filters or as centrifuges, are used for superfine or microfiltration of the engine oil. These filters remove much finer particles from the oil than is possible using full-flow oil filters (Figure 5). They can remove minute abrasive particles to enhance wear protection. Soot particles are also filtered out to reduce any increase in oil viscosity. The maximum permissible soot concentration is roughly 3 to 5 %. Oil viscosity increases substantially at higher soot concentrations, resulting in a drop in the operational effectiveness of the oil. For this reason, bypass filters are used mainly on diesel engines. Only part of the oil flow (8 to 10 %) from the engine is routed via the bypass oil filter.

------- Maximum filtration efficiency for bypass or full-flow oil filter.
——— Minimum filtration efficiency for bypass or full-flow oil filter.

Thermal management

Function
Aside from its lubricating function, the engine oil also has the task of transferring or carrying off heat. At the same time the engine-oil temperature must not exceed a critical value, as otherwise there is a risk of thermal destruction, so-called cracking of the oil.

Oil-to-water heat exchangers, which are frequently combined with the oil filter module, are used to control the temperature of the oil circuit. This combination allows for a more compact construction and the reduction of interfaces. The primary task is to transfer heat from the oil circuit to the water circuit. The heat energy is then dissipated via this to atmosphere for example with an air-to-water heat exchanger.

The heat transfer must be controlled to provide optimum thermal management. To quickly heat the engine oil after cold starting, the oil-to-water heat exchanger should only be activated after an increase in temperature in the oil. This can be done by thermostatic valves which are controlled with wax elements or thermo-springs. Electric solenoid valves provide for even better control options.

Oil-to-water heat exchanger
The preferred design for an oil-to-water heat exchanger is with plates stacked on top of one another. Oil and water flow alternately through the chambers. The heat is transferred via the plates to the neighboring fluid. To achieve high heat-transfer rates the flow in the columns should be as turbulent as possible. Structures are introduced into the heat-transfer plates or turbulence plates installed in the column for this purpose.

Air-intake systems and intake manifolds

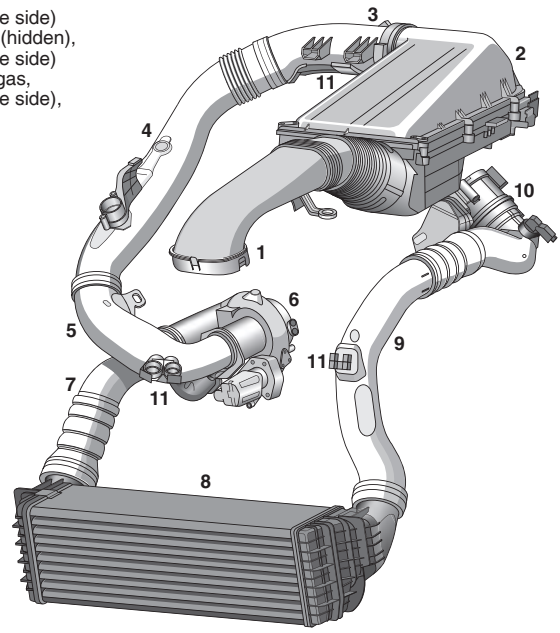
Overview

Functions

The air-intake system and the intake manifold are designed to supply the engine with air that is as cold and particle-free as possible, and to distribute this air to the individual cylinders. The main functions of the air-intake system are to direct the air from the front of the vehicle to the engine, to separate particulates contained in the intake air from the surrounding area, and to muffle the noises emitted by the engine.

Components

Basic functions



The air-intake system (Figure 1) consists of an air duct on the raw-air side, the air filter as the central components, and the lines to which the throttle valve and the intake manifold are connected. The intake manifold distributes the intake air to the individual cylinders and ensures uniform and effective combustion. The air filter prevents mineral dust and particles from being drawn into the engine and contaminating the engine oil. This reduces wear in the bearings, piston rings, cylinder walls, etc. In this way the individual system components can have a crucial positive effect on the performance and service life of the engine.

Supplementary functions

The air-intake system often incorporates further function components such as, for example, sensors (air-mass meter, pressure sensor, and temperature sensor), HC adsorber, water separator, and even anti-snow systems.

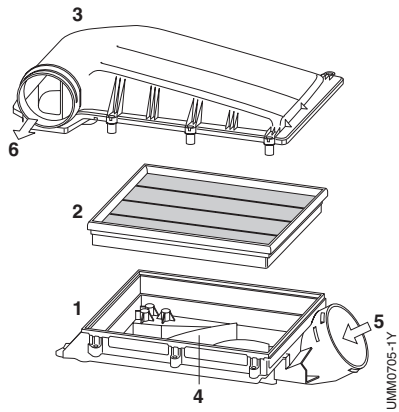
Requirements

Functional requirements



The development of the air-intake system and its components is based on numerous specifications which are shaped on the one hand by space considerations and on the other hand by functional requirements. Specifications define for example temperatures in the engine compartment which influence the choice of plastic materials and elastomers for the individual components, permissible leakage rates and pressure losses for the system or the individual components, the acoustic performance of the intake tract, and the separation performance with regard to filtration as service life and as filtration-efficiency requirement.

With regard to the intake manifold, further emphasis is placed on pressure-pulsation resistance and the level of uniform distribution of intake air. The air flow into the combustion chamber can if necessary be positively influenced by different types of flap.

Visual appearance

The visual appearance and the design of surfaces in the engine compartment gain in importance as soon as surfaces are located in the visible area of the engine compartment (e.g. design air filters or engine-mounted air filters).

Figure 2: Design of an air filter
1 Raw-air housing, 2 Air-filter element,
3 Clean-air hood, 4 Flow deflectors,
5 Raw-air connection, 6 Clean-air connection.

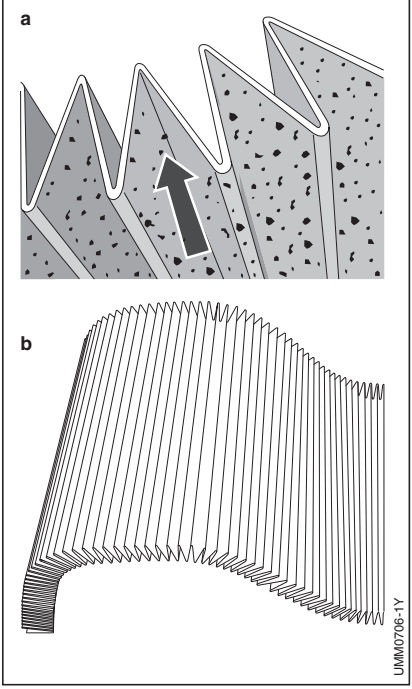
Passenger-car air-intake system

Air duct

The intake point of the raw-air line is usually located at the front of the vehicle. It is particularly important in that it has a crucial influence on the ingress of particles and the unwanted ingress of water droplets when it is raining and of snow crystals when it is snowing. However, this position is generally stipulated by the automobile manufacturers.

Classic internal-combustion engines are divided into non-supercharged naturally aspirated engines and supercharged engines, in which an exhaust-gas turbocharger for example is deployed. The air-intake system (Figure 1) in both variants consists of a raw-air line, which feeds into an air-filter housing with integrated filter element, and a clean-air line on the low-pressure side, which in a naturally aspirated engine serves as the interface to the throttle valve. In a turbocharged engine the clean-air line on the low-pressure side feeds into the turbocharger, while the charge-air lines on the hot and cold sides lead to the intercooler and to the throttle valve respectively. Low pressure losses can be achieved by large line cross-sections (this influences space and acoustics) and by optimized flow routing.

The lines are usually made of plastic and elastomer materials, while the air-filter housings are generally injected-molded plastic parts. Depending on the application, the air filter can be mounted to the body and to the engine in such a way that the lines compensate not only the tolerances between the components and their attachment points, but also above all the movement of the engine relative to the body. The components are joined with vibration isolation to the vehicle by way of rubber buffers.



Air filtration

Engine air-intake filters (Figure 2) reduce the particles contained in the intake air which can be generated for example by abrasion and incomplete combustion or condensation processes or are even of natural origin in the form of organic and mineral dust.

Composition of air pollutants
Typical air pollutants includes oil mist, aerosols, diesel soot, industrial waste gases, pollen, and dust. These particles vary greatly in size. The dust particles drawn in together with the intake air have a diameter of between 0.01 µm (mostly soot particles) and 2 mm (sand grains). Approximately 75 % of the particles (referred to the mass (weight)) are between 5 µm and 100 µm.

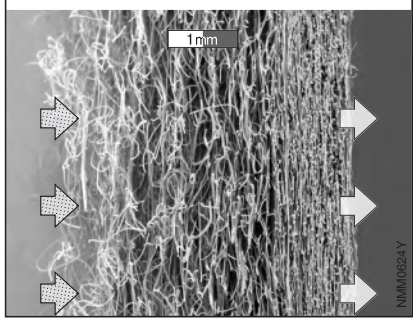
The amount of dust contained in the intake air depends heavily on the environment in which the vehicle is used (e. g. freeway/interstate or dirt track). In extreme cases, over a period of ten years, the mass concentration accumulated in a passenger car can range between a few grams through to several kilograms of dust.

Figure 3: Filter media
a) Flow through a folded/pleated filter medium,
b) Folded/pleated filter medium.

Filter elements
Filter elements which incorporate the latest technology achieve total mass filtration rates of up to 99.8 %. It is necessary to maintain these values under all prevailing conditions – also under dynamic conditions as found in the engine's intake tract. Poor-quality filters will exhibit an increased rate of dust breakdown or rupture.

Design
Filter elements are designed to meet the requirements of each individual type of engine. This ensures that pressure losses remain minimal and that high levels of filtration efficiency are not dependent on air throughput. The filter medium that makes up the filter elements in flat or cylindrical filters is installed in folded or pleated layers in order to achieve a maximum filter surface area in the smallest possible space (Figure 3). Conical, oval, stepped, as well as trapezoidal geometries complement the standard structures with the aim of optimizing the use of package space that is becoming very scarce and confined in the engine compartment. These media, mostly consisting of cellulose fibers, go through a special embossing and impregnation process to achieve the necessary mechanical and thermal strength, sufficient water stability, and resistance to chemicals. Newer applications are equipped with flame-inhibiting filter media to reduce the risk of fire caused for example by an drawn-in cigarette.

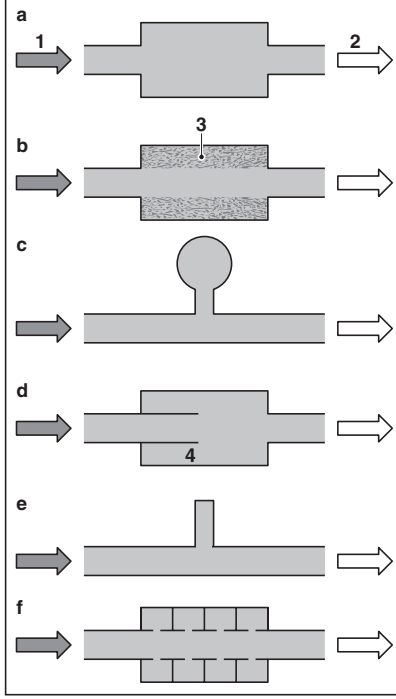
The elements are designed in accordance with the spacings and replacement intervals defined by the vehicle manufacturer. The intervals are between two and four, and sometimes even six years, or 30,000 km up to 100,000 km.



Filter media and design
The media used in passenger-car air filters are mostly part of deep-bed filters which, in contrast to surface filters, retain the particles in the structure of the filter medium. Deep-bed filters with a high dust absorption capacity are always used to advantage wherever an economic solution is required to filter large volumetric flow rates with low particulate concentrations.

The demands for compact, high-performance filter elements (with reduced package space), as well as longer service intervals, are the driving force behind the development of new, innovative air filter media. To further increase the dust retention capacity of deep-bed filters, design engineers are increasingly using media which have a gradient structure with increasing fiber density to the clean-air side.

Fully synthetic filter media
New air-filter media consisting of synthetic fibers with much improved performance data have already been phased into series production. Figure 4 shows a photograph of a synthetic high-performance filter medium (felt) with continuously increasing density and decreasing fiber diameter across the filter section from the input side to the output side.



Semi-synthetic filter media
Better results than with purely cellulose-based media can be achieved using composite materials. Here, for example, a cellulose-based paper layer is combined with a synthetic layer of melt-blown fibers. The melt-blown fibers constitute a layer of fibers formed from a polymer melt in the air flow which is either deposited directly on the paper layer or laminated on in a separate process step as a separate layer.

Figure 4: Photographic image of an air-filter medium consisting of synthetic fibers, taken with a scanning electron microscope

Acoustics
The air-intake system contributes in a similar way to the exhaust system to the overall noise of the vehicle. It is therefore necessary to introduce noise-reduction measures already in the early development stages. In the past these measures

Figure 5: Acoustic muffling measures with different resonator shapes
a) Resonator-type muffler (relatively wide-band, suitable for low and medium frequencies),
b) Absorption-type muffler (wide-band, suitable for medium and higher frequencies),
c) Resonance muffler (narrow-band, suitable for low and medium frequencies),
d) Whistle muffler (narrow-band, high muffling, suitable for medium frequencies above the Helmholtz resonance),

f) Wide-band muffler for turbocharged engines (wide-band, suitable for higher frequencies).
1 Air duct, upstream,
2 Air duct, downstream,
3 Acoustically absorbent material,
4 Inserted pipe.

were confined to designing a sufficiently sized air-filter housing as an intake muffler. In the meantime the excitation spectrum has shifted from low frequencies (f < 200 Hz) to medium to high frequencies with the result that separate measures in the form of Helmholtz resonators and $\lambda/4$ pipes are used. Computer simulation programs that determine the optimum number of resonators and their frequency are used to design these measures.

Wide-band mufflers for turbocharged engines

The increasingly widespread use of turbocharged engines has led design engineers to focus their attention on new noise sources. The whistling and whining noises are subjectively perceived to be disruptive and annoying and now measures are often integrated in the form of wide-band mufflers in the clean-air line of the air-filter system. Wide-band mufflers comprise several individual chambers through which a perforated central pipe passes (Figure 5). The individual resonant frequency of a chamber is determined by the chamber volume and the degree of perforation; a wide-band muffling effect is achieved by arranging several chambers in succession. Here too modern simulation programs are used to optimize the number.

In addition to resonator-type mufflers, absorption-type mufflers as featured in exhaust systems are occasionally used.

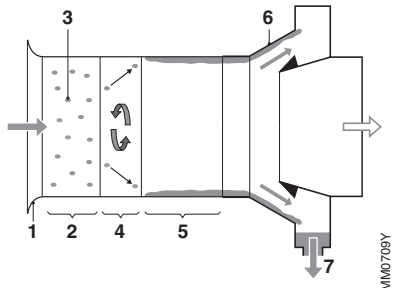
HC adsorption

For the Californian market and some other US states limits regarding the emission of highly volatile hydrocarbons are defined for vehicles (e.g. SULEV, Super Ultra Low Emission Vehicle). The US environment agency EPA is responsible for implementing the legal requirements regarding HC emission limits (High Volatile Hydro Carbons) within the framework of a multiple-stage regulation. The engine manufacturers must comply with these statutory provisions and adhere to time limits after which engines must feature pollutant-emission-reducing technologies to satisfy the emission standards.

Some of the unburned hydrocarbons (primarily fuel components) escape after the engine is turned off from the engine through the intake manifold and from the crankcase ventilation into the air-intake system, travel against the normal direction of air flow, and exit the system to atmosphere. This can mean that it is necessary to integrate an HC adsorber on the clean-air side of the system so that the hydrocarbons are separated by adsorption on activated-carbon media. An equivalent, the "Butane Working Capacity" (BWC), is defined in specifications in order to define the absorption capacity comparably. The adsorber elements can be used in the "full flow" (main path, full throughflow) or in a bypass configuration.

Unlike air-filter elements, adsorber elements according to the requirements are lifetime components which may not be removed from the system. The elements are charged while the engine is stopped with the air-borne hydrocarbons of minimal droplet size, and desorption takes place the next time the engine is operated, i.e. the hydrocarbons are returned to the combustion process in this cycle and the HC adsorber is regenerated for the next charging cycle. The adsorptive medium used is activated carbon, which is located as a single or double layer between the carrier media. These are for the most part elements which are manufactured in a process as plastic coating.

Water separation



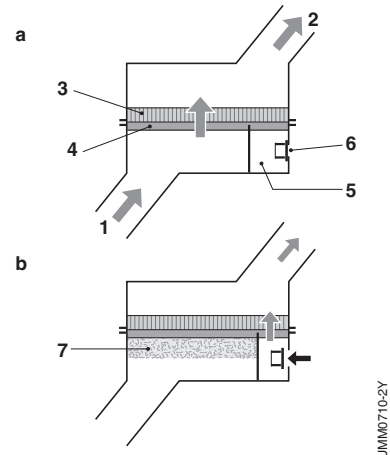
When driving in the rain, not inconsiderable amounts of water may be drawn in, depending on the position and layout of the intake fitting at the front of the vehicle. Because the filter medium only has a limited water absorption capacity, the drawn-in liquid may reach the clean-air side of the system after a certain time. Signal deviations or even damage to the hot-film air-mass meter may occur if droplets touch the hot sensor surface and result in a local, unwanted cooling of this surface. The signal deviation suggests an incorrect air-mass flow and gives rise to an incorrect setting of the mixture composition, to power losses, and ultimately to increased consumption (and increased

CO_2 emissions). The time until water penetration at the filter element can be significantly extended or even avoided entirely by way of upstream measures.

Finned separators, baffle plates or measures based on the cyclone principle such as the "peeling collar" (Figure 6) integrated in the intake air are used to separate water droplets. The shorter the raw-air line – i.e. the distance from the air inlet to the filter element – the more difficult the task. Essentially, the aim is to achieve additional flow pressure losses that are as low as possible. The measures must be combined with suitable water-discharge devices which divert the separated water from the system to atmosphere. However, separating principles are also used which carry the liquid in combination with measures on the housing side and with additional water-separating fleeces attached to the filter element from the system.

An optimized design of the raw-air line and the air-filter housing clearly enhance the above-mentioned measures such that outstanding separation results are achieved even with comparatively short raw-air lines.

Figure 6: Principle of water separation
1 Raw-air intake,
2 Raw-air line,
3 Water droplets,
4 Swirl generator (optional),
5 Wall-applied water film,
6 Peeling collar,
7 Water discharge.



Anti-snow system

In winter when it is snowing snow crystals may be drawn into the system which charge the filter element on the raw-air side. If this situation persists, the initial upshot will be an increase in pressure loss. In due course the filter element may become blocked on the raw-air side such that the engine stops receiving sufficient intake air for the combustion process. This will ultimately cause the engine to stall.

To prevent this, anti-snow systems (ASS) – essentially a second intake – are used (Figure 7). If the filter element becomes blocked, hot, dry and snow-free air is drawn in from the engine compartment, whereby this reduced air flow maintains the engine function. The supplementary intake can be opened by temperature- or pressure-controlled control mechanisms. In the case of thermal control a flap is moved by an expanding-wax element. Pressure control is based on a spring-loaded valve integrated in the

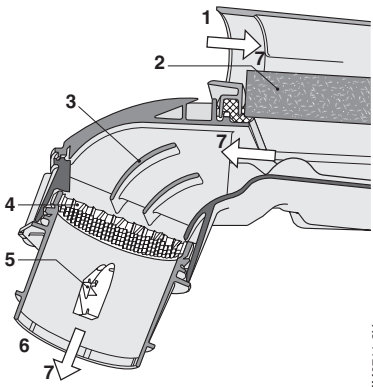


Figure 7: Anti-snow system

7 Snow block.

air filter on the raw-air side. The filter element is basically fitted with a preliminary fleece which assumes the sealing function and protects the “dry” chamber of the second intake against snow ingress.

Sensor technology
Sensors which measure the pressure, the temperature and even the air-mass flow are often integrated on the clean-air side of the air filter. The exhaust-gas-relevant air-mass flow is measured by a hot-film air-mass meter. As the emission-control legislation is tightened the requirements with regarding to signal quality are becoming increasingly stringent. Signal deviations for an air-filter system in the range of ±2.5% are difficult to achieve, but not unusual. This requires an increased simulation outlay to identify disruptive turbulent areas and instabilities in the flow close to the sensor and to minimize them by means of suitable product design and additional measures or components (e.g. air-duct grills, fins or air deflectors) (Figure 8).

Visual design of surfaces
The structuring of plastic surfaces in the visible area called for by customers for visual reasons can be achieved in a variety of ways, such as for example by erosion, blasting or photoetching of the injection-molding die. Engine-mounted design air filters are a special example here.

Interfaces
The type of connection point between the air-filter housing and the clean-air line is often geared towards customer requirements. The production plant of the automobile manufacturer often specifies the shape of the interface. If an elastomer component is called for, lines based on the material PP-EPDM with integrated bellows for isolation are manufactured by injection molding. These can be connected to a line section made using blown-part technology.

Crankcase ventilation
The clean-air line on the low-pressure side can incorporate further interfaces such as for example the blow-by introduction point from the crankcase ventilation or even the extraction point for the PCV (Positive Crankcase Ventilation). The blow-by introduction point is frequently fitted with a heating tube which is intended to prevent icing.

Low-pressure exhaust-gas recirculation
A measure specially suited to smaller diesel engines to meet the strict Euro 6 limits for nitrogen oxides (NO_x) is low-pressure exhaust-gas recirculation (see Exhaust-gas recirculation, EGR). But even larger-sized engines utilize low-pressure exhaust-gas recirculation, often in conjunction with SCR systems (Selective Catalytic Reduction). With low-pressure exhaust-gas recirculation the exhaust gas is diverted after the diesel particulate filter, cooled in an EGR cooler, and introduced into the clean-air line upstream of the turbocharger compressor. To obtain high EGR rates in wide ranges of the engine map, it is very important for the EGR system to have a low-pressure-loss

design including mixing of air with exhaust gas. For special operating points in the part-load range an additional pressure drop is generated in the EGR system by an exhaust-gas restrictor (downstream of the EGR extraction point) or by an air-intake restrictor in the clean-air line (upstream of the EGR introduction point). Configuring the mixer geometry appropriately prevents local temperature gradients from damaging the compressor and compressor efficiency from being reduced. After the EGR cooler the exhaust gas reaches maximum temperatures of 150 to 200 °C, which enable the mixing and control functions to be executed cost-effectively and space-efficiently with the aid of plastic components. However, it is important when choosing the material to ensure that it is resistant to acidic condensate (pH value of 2 to 3) which can be produced at exhaust-gas temperatures below 85 °C.

The use of low-pressure exhaust-gas recirculation is being analyzed even in gasoline engines; however, the objectives here are to reduce CO_2 and the knock tendency rather than to reduce NO_x emissions. The first applications in series production are expected in the next few years.

Validation of air filter

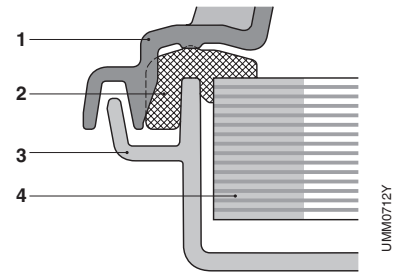
Full product validation, consisting of simulation, acoustics and component testing, is an essential part of the development process for air-filter systems in order to achieve a high degree of product maturity as early as possible. Already in the early concept phase – within the framework of virtual product validation – simulations are conducted to optimize the functions and properties of air-filter systems. Here the acoustic properties such as intake-opening noise and surface sound radiation are calculated and optimized.

As well as acoustic behavior the fluid properties such as pressure loss and approaching flow to the measuring-sensor system are analyzed and specifically improved. In addition, the vibration characteristics are tested under roadway or engine excitation using finite-element simulations to fulfill the later life test without any problems. The filtration properties among others are checked as soon as the first sample components are available. The scope of testing within the framework of component testing includes tests on individual components and on the complete system. This is rounded off by functional tests where the ambient conditions prevailing in the vehicle (such as temperature, moisture, and media pressurization) are superimposed.

The component life is tested in comprehensive vibration and pulsation tests which simulate the real load in the vehicle. In view of the strict emission-control legislation, the flow behavior in the air filter must also be very closely analyzed with a dust charge also taken into consideration. Influencing factors such as fold/pleat geometry of the air-filter element and spread of the filter medium are taken into consideration here. Component validation is rounded off by simulations of the injection-molding process to optimize component quality and the manufacturing process.

Trends – further development of air-intake systems

Three main trends can currently be observed in the market: Downsizing of engines, platform strategies to utilize synergy effects, and stricter requirements with regard to emission-control legislation.



Downsizing necessitates a higher proportion of supercharged engines with the following effects: Specifically higher air-mass flows, smaller and more complex air-filter housings, increased conflict between acoustics and pressure loss, higher temperatures in the engine compartment, and higher charge-air pressures. This necessitates a higher simulation outlay for example to optimize flow and acoustics, new air-filter media, innovative filter-element designs, and higher-quality plastic materials.

Platform strategies of the automobile manufacturers necessitate more complex package spaces and a high-grade identical-part strategy. Stricter requirements

with regard to emission-control legislation give rise to heightened specifications with regard to sensor technology, particularly the quality of the signal stability of the hot-film air-mass meter. This likewise necessitates more complex simulation tools, new test procedures, and more complex product designs and constructions.

The weights of components can be reduced with new production technologies. Air filters produced by injection molding on the basis of foamed plastics help to achieve this. A further possibility is to reduce wall thicknesses, where the acoustic behavior in particular of the air-filter housing must be observed. Structure-borne noise radiation can be countercompensated by cambering (curved geometry) surfaces and integrating ribs or beads (groove-shaped depressions), even when smaller wall thicknesses are used. New sealing concepts for the interface between filter element and housing, e.g. designed as a radial concept (Figure 9), render metal compounds superfluous, and result on the one hand in reduced costs and on the other hand in increased service friendliness when replacing the filter element. The two housing sections can be connected to each other by injected snap-on hooks.

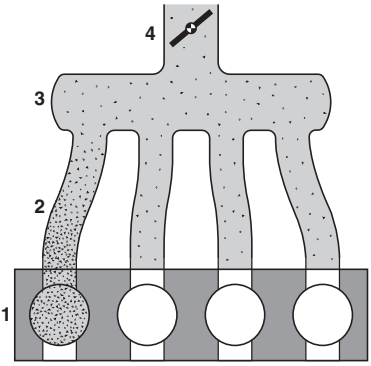
Hybrid vehicles and active noise measures



In the years to come hybridization in the automotive industry will present new challenges. Switches in operation between the internal-combustion engine and the electric motor, but also purely electric operation generate unusual acoustic states. Active systems (with ANC, Active Noise Control) constitute an interesting remedial measure in that the can not only reduce noise and thus replace passive components, but also create new degrees of freedom with regard to noise generation, e.g. for warning pedestrians in purely electric operation. Some countries have already initiated legal initiatives prescribing a warning function for purely electric operation. There are also opportunities to support a specific marque sound or for noise control in order to acoustically mask unwanted phenomena. This approach makes active systems interesting for future engine concepts.

Passenger-car intake manifolds

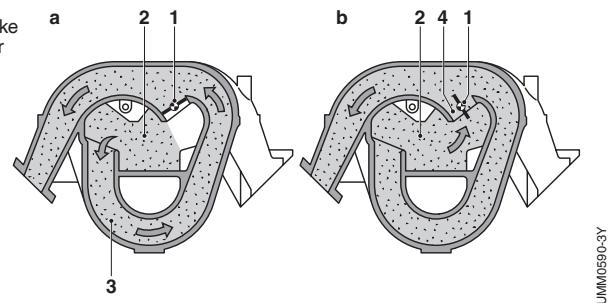
The main function of the intake manifold is to distribute the air homogeneously to the individual cylinders in order to ensure combustion that is as uniform and effective as possible in the individual cylinders. The quality of uniform distribution has a decisive effect on the engine's performance and emission characteristics.

In the case of gasoline engines a distinction is made between naturally aspirated engines and supercharged engines; in the case of diesel engines, on the other hand, only supercharged engines are still relevant. All three categories feature both passive and active intake manifolds. Active intake manifolds are usually called variable induction systems.

Figure 10: Ram-tube supercharging
1 Cylinder,
2 Individual ram tube,
3 Plenum chamber,
4 Throttle valve.

Intake manifolds for naturally aspirated engines

In these types of intake manifolds gas-dynamic supercharging effects are used to increase the air mass in the cylinder and thus the engine output or torque. There are two different supercharging effects here.



Ram-tube supercharging

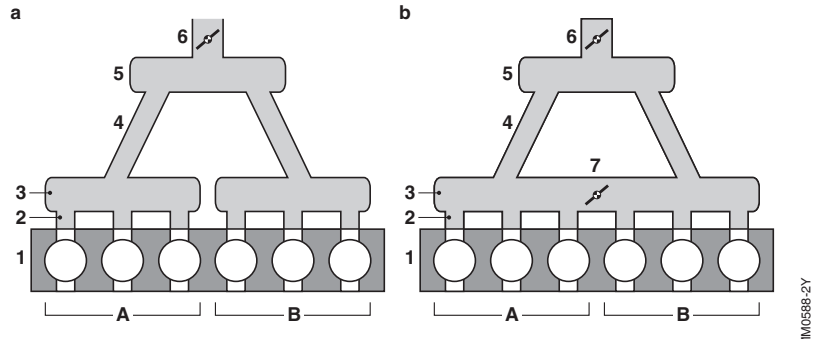
Ram-tube supercharging is based on the principle that each cylinder has its own ram tube that feeds into a common plenum chamber, also called the intake plenum (Figure 10).

The intake pulse in the induction stroke triggers a vacuum wave. This propagates in the ram tube, is reflected at the opening to the intake plenum, and returns as a pressure wave to the combustion chamber. Because pressure waves always propagate at the speed of sound, the length of the ram tubes can be used to determine the engine-speed range in which the supercharging effect is wanted.

To be able to utilize this supercharging effect in numerous engine-speed ranges, there is the option of realizing active intake manifolds of this type (variable induction system, Figure 11). The optimum solution

Figure 11: Variable induction system
a) Intake-manifold geometry with changeover flap closed (torque setting),
b) Intake-manifold geometry with changeover flap open (power setting).
1 Changeover flap,
2 Plenum chamber,
3 Long, thin oscillatory intake passage with changeover flap closed,
4 Short, wide oscillatory intake passage with changeover flap open.

would be an infinitely variable induction system in which an optimum ram-tube length is assigned to each engine-speed range. But this is barely feasible, both technically and economically. For this reason mostly two- or in rare cases also three-stage induction systems are on the market.



Tuned-intake-tube charging
Tuned-intake-tube charging is based on the principles of a Helmholtz resonator. Two groups of cylinders with the same ignition interval are established. The reason for this is that the intake pulses within the groups must not overlap. These groups are connected by short intake manifolds to the two resonance chambers (resonance plenums) (Figure 12). The two resonance plenums are connected by resonance (tuned) tubes to the common main intake plenum. The periodic intake pulses induce the gas oscillations to resonate at a specific engine speed and thereby generate the supercharging effect. The engine-speed range in which the supercharging effect acts is determined by the length and the diameter of the tuned intake tubes. This principle is preferably used in 3-, 6- and 12-cylinder engines because it is relatively easy, because of the firing order, to create independently operating cylinder groups (each consisting of three cylinders with 240° ignition interval).

Incorporating a resonance flap between the two resonance chambers creates an active system that provides further advantages. The intake manifold with closed resonance flap generates a torque increase in the lower engine-speed range. In the upper speed range this valve is opened to create an intake manifold with short ram tubes which increases power output in this speed range.

Intake manifolds
for supercharged gasoline engines
Intake manifolds for supercharged gasoline engines are in most cases passive intake manifolds. Power and torque are primarily determined via the charge-air pressure generated by the charger and thus by the air mass introduced into the cylinders. The still available, but mostly very short ram tubes are typically used for passive intake manifolds.

Active systems for this engine type have turbulence flaps (also called tumble flaps). These are situated near the cylinder head (Figure 13) and have the function of improving combustion in part-load operation. This arrangement firstly increases torque and secondly reduces emissions. In part load the flap is closed

Figure 12: Tuned-intake-tube charging

A, B Cylinder groups.

and generates a cylinder flow about the horizontal axis (tumble). In the power setting the flap is opened and the engine receives through the opening cross-section as much air mass as possible into the cylinder.

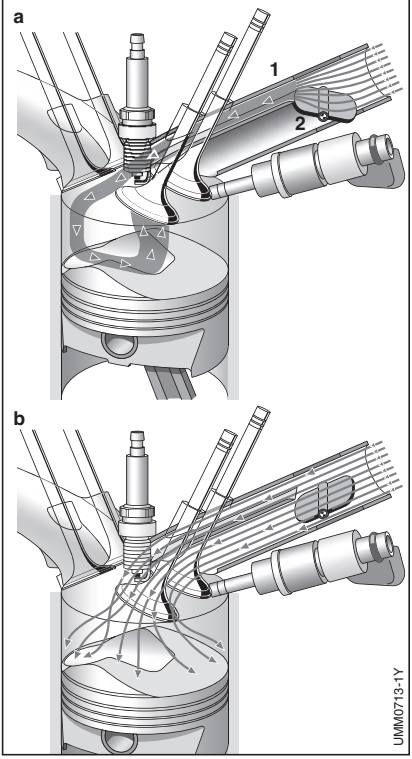
A special form here is the trough flap, which in the open setting disappears completely into the duct wall and thus ensures unrestricted flow into the cylinder.

Intake manifolds for supercharged diesel engines

In the case of intake manifolds for supercharged diesel engines there is no such clear distinction between passive and active variants. These intake manifolds practically do not have manifolds any more. All that remain are short inlet tulips that connect the intake plenum to the cylinder head.

In the case of active intake manifolds the cylinder head always has two intake ducts per cylinder, where one is a swirl duct and the other a filling duct (Figure 14). The filling duct is fitted in the intake manifold with a duct shutoff flap. The function of this flap is to fill the cylinder via the swirl

Figure 13: Tumble arrangement
a) Intake manifold in tumble setting,
b) Intake manifold in power setting.
1 Intake manifold,
2 Turbulence flap (tumble flap).



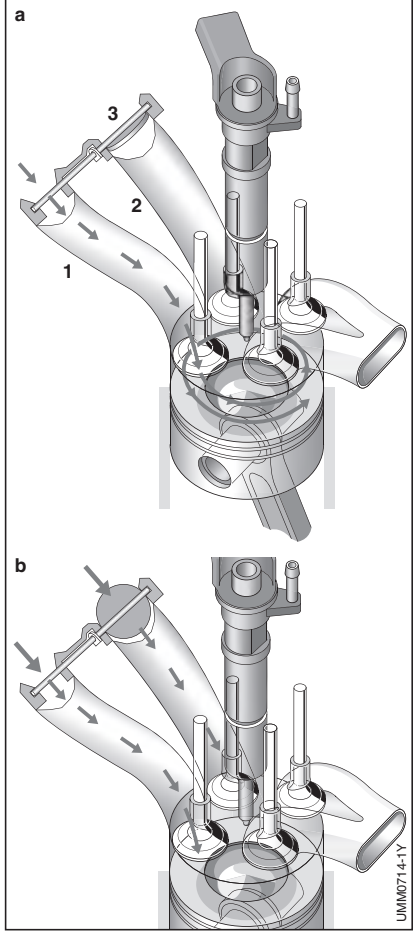


Figure 14: Swirl arrangement

1 Swirl duct,
2 Filling duct,
3 Duct shutoff flap.

duct in part-load operation and thus create a pronounced swirl about the vertical axis. This swirl ensures that air and fuel are thoroughly mixed and thereby helps to reduce emissions. In the transition to full-load operation the flap is then opened incrementally and the swirl is nullified by the filling duct. This results in as much air mass as possible being delivered to the cylinder and thus in high torque and high power output.

Actuator and sensor technology
Primarily electrical actuators or vacuum units are used to drive the different switching elements.

Electric actuators
Electric actuators are preferably used to activate swirl flaps in diesel engines. They enable any intermediate settings to be accurately and rapidly approached. Control is provided in most cases by the engine ECU.

Vacuum units (pneumatic actuators)
A vacuum unit can be used for pure two-point switchings, as are sufficient for length, resonance, and tumble switchings. These are switched by means of an electric changeover valve. The prerequisite is that the engine or a vacuum pump makes sufficient vacuum available.

Sensor technology
The sensor technology that features in variable induction systems has increased significantly in response to the OBD II legislation, which states that all exhaust-gas-relevant switching organs must be monitored by the engine ECU and that the driver must be alerted if they malfunction. Exhaust-gas-relevant switching elements are the turbulence flaps (tumble flaps in gasoline engines, duct shutoff flaps in diesel engines). Switching elements for length or resonance switching are not included.

For electric actuators the internal angle-of-rotation sensors of the actuators can be used in most cases. For vacuum units a separate sensor is required, but this can also be integrated in the vacuum unit.

For active intake manifolds, in addition to the sensor technology for angle-of-rotation monitoring, pressure, temperature, or combined pressure/temperature sensors are mounted on the intake manifolds. These are necessary to supply the engine ECU with the information from the intake manifold required for combustion.

Introduction of gases
A further function of the intake manifold is to distribute introduced gases uniformly into the respective cylinders. In gasoline engines these are primarily crankcase-ventilation and tank-ventilation gases. Fittings are attached to the intake manifold for these gases and then connected by the engine manufacturer to the relevant hoses. When crankcase blow-by gases are introduced, an additional heating tube may be required to avoid icing.

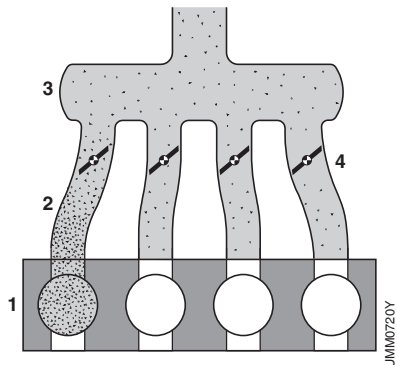
In diesel engines it is important for high-pressure exhaust-gas recirculation to be correctly introduced. Often uncooled exhaust gas is introduced into the intake manifold during the cold-start phase or diesel particulate-filter regeneration. Suitable shielding measures must be taken here where plastic intake manifolds are used. A central introduction point with adequate mixing section is beneficial to the extremely important uniform distribution here. The uniform-distribution requirement is very difficult to achieve in cylinder-selective introduction systems where the gas to be introduced (e.g. from exhaust-gas recirculation) is introduced via a distributor line with a separate introduction point for each cylinder (i.e. each cylinder is supplied with gas via a separate introduction point) at the very different operating points in the engine map.

Gaskets
A trend towards higher-quality materials can be discerned in gaskets. This is mainly because low-pressure exhaust-gas recirculation is more frequently used in diesel engines and this results in an aggressive condensate in the induction system. Peroxide-cured fluorocarbon rubber, for example, must be used in such applications. Due to the fact that the operating temperatures can extend both up and down, sometimes special low-temperature materials are required.

Validation of intake manifolds
Virtual and experimental product validation plays an increasingly important role for the intake manifold. The foundations for a flow- and weight-optimized component are already laid in the early development phase by the close interplay between design, testing and simulation. The optimum uniform distribution of air to the individual cylinders is optimized by CFD simulations in a number of iterative loops. The intake-manifold geometry is optimized with the aid of FEM simulations in such a way that maximum rigidity and strength are achieved with minimum weight. This enables the use of materials for the component to be kept as minimal as possible. The manufacturability of the component is analyzed and optimized with the aid of injection-molding simulations.
These theoretical analyses are then verified on sample and standard parts. The uniform distribution of intake air to the individual cylinders is measured on a flow-rate test rig. The structural strength of the components is ensured by rigorous pressure-pulsation and vibration tests under temperature influence. In the case of variable induction systems the durability of the switch-over elements and actuators is substantiated with endurance and fatigue tests.

Development trends for intake manifolds
Due to the switch from direct to indirect intercooling and the resulting benefits with regard to CO_2 emissions, the main trend in the intake-manifold market is towards the integration of intercoolers.

This trend has above all an effect on the intake manifolds in supercharged gasoline engines. Virtually all manufacturers pursue solutions involving full integration of the intercooler in the induction system. The cuboid-shaped intercooler must be integrated in the plastic intake manifold and, despite the large flat surfaces and sometimes for plastic extremely high temperatures (upstream of the intercooler), satisfy the requirements with regard to pressure-pulsation resistance. Materials that meet these requirements are currently in development.



The diesel-engine market is split two ways: firstly the intercooler directly integrated in the intake manifold, and secondly the arrangement of the intercooler as a “single box” upstream of the throttle valve.

Motorcycle intake manifolds

Essentially, intake manifolds for motorcycle engines have the same functions as those for passenger-car engines. However, they do have the following particularities in terms of design: While in passenger-car applications one joint throttle valve is for the most part used for a number of cylinders (see Figure 10), for motorcycles frequently individual throttle valves are used (Figure 15). This permits a significant reduction of the intake-manifold volume between throttle valve and intake valves. The smaller volume increases the dynamics and thus the response in the event of both sudden throttle-valve opening and throttle-valve closing. The dynamic response is an elementary requirement in motorcycles. The geometry permits a smaller ratio of throttled intake-manifold volume to individual-cylinder displacement. This results in, aside from an improved response, intake-manifold pressure dynamics (see Cylinder charge).

The individual throttle valves can in this design be mounted on a single shaft or on a number of shafts (e.g., in V-engines). Comparable intake-manifold configurations are used in passenger-car engines, e.g., in racing engines.

Commercial-vehicle air-intake system

Air duct

The design of the air-intake system for commercial vehicles is essentially comparable to that of passenger-car air-intake systems (see Figure 1). What must be taken into account here is the much higher service life of commercial vehicles, the higher rated volumetric flow, and the broad range of uses in local, long-distance and construction-site applications. The different volumes and types of dust must be taken into account in filter design.

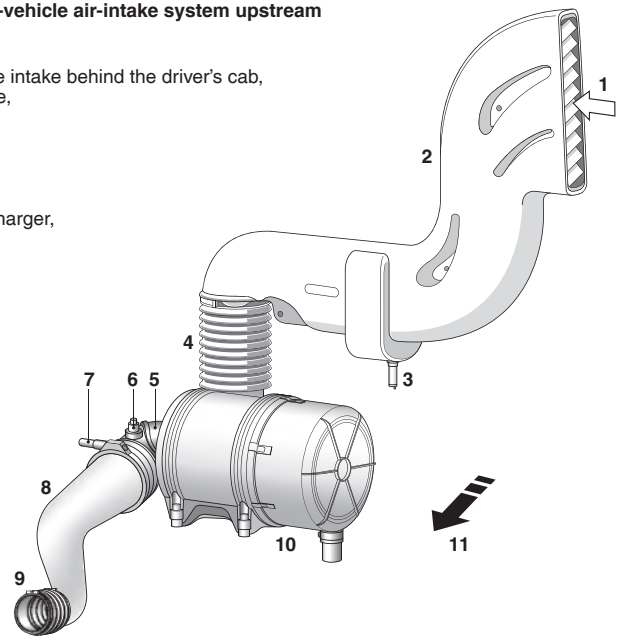
Raw-air duct, air filters and clean-air pipes up to the turbocharger are made of thermoplastics. After the turbocharger for the most part come (still) combinations of aluminum and rubber parts. However, more plastic parts will be used in future for charge-air pipes and intake manifolds (boost manifolds).

Raw-air intake

The positioning of the intake point is extremely important. A roof or side intake is usually chosen on heavy commercial vehicles. Both are generally mounted with rubber mounts for acoustic isolation to the cab rear wall. The dust and water concentrations in the air are lowest with the roof intake. There are however many raw-air duct variants to cater for the different driver's-cab heights and widths. A good compromise in terms of costs is the side intake (Figure 16): Here air is still inducted from height at the side rear of the driver's cab, irrespective of the different roof heights.

A low-height front intake or side intake, along similar lines to that used in passenger cars, is usually chosen for light utility vehicles. To keep the volumes of inducted dust a water in check, air is inducted through baffles on the vehicle sides. An air duct that delivers the best flow possible must be provided in all cases. Hot engine waste air must not be inducted as this mean a performance drop and higher fuel consumption.

Because most truck cabs are tilted forwards to access the engine for servicing, the raw-air duct is connected via bellows



to the rest of the system. The function of the bellows is to seal the interface when the cab is tilted back and to compensate the vibrating motion of the sprung cab.

Water separation
Measures for water separation are integrated in the raw-air system. Water separation prevents dust from being washed through the filter medium, which can increase engine wear, but also cause sensors to malfunction. Because as a rule cellulose-based filter media are used, at worst the filter element may be destroyed. Measures for water separation include for example using a large intake cross-section to reduce the intake velocity so that basically as little water as possible is inducted. Baffles in the system cause the water droplets in the intake air to be thrown against the inner manifold walls, where they form a film. The water droplets are then separated via a peeling collar or a change in volume and discharged via a water-discharge valve.

Dust preseparation
In vehicle applications with a higher dust concentration in the air (e.g. construction sites or operation in dusty countries) a dust preseparator is installed in the raw-air supply, either as an individual cyclone (Figure 17) or as a cell cyclone. Cell cyclones are small cyclones which are integrated in a housing to save space. These separate out a high proportion of the coarse dust contained in the intake air. The air is induced to rotate at the inlet by guide vanes; the heavy dust particles are thrown against the inner wall of the housing and discharged through the dust outlet. The precleaned air is directed by a further guide-vane assembly (optional), which rectifies the air flow again, to the air filter.

Air filters
The most widely used air filters in commercial vehicles at present are single-stage round air filters with spiral vee-shaped filter elements. They are characterized by

Figure 16: Commercial-vehicle air-intake system upstream of the turbocharger

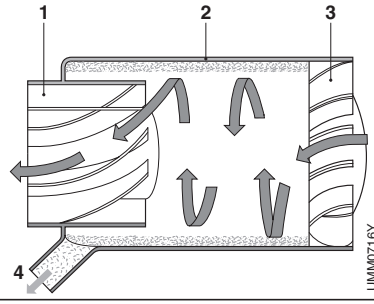
10 Air filter,
11 Direction of travel.

low pressure loss, high dust capacity, and thus long service intervals. Depending on how they are used, they can extend a typical oil-change interval by a factor of two. A further advantage of round filters is that they can also be fashioned as two-stage filters. In these variations dust separation takes place inside the air filter itself (Figure 18). The tangential air inlet generates a swirl in the housing which separates out the coarse particles.

Depending on the application, different filter media are available today which are optimized for example for maximum filtration efficiency of fine dust and soot.



A safety element is optionally fitted inside the main filter element which prevents dust from reaching the clean-air side during servicing. It also protects the engine even if the main filter element has been damaged during servicing. Basically, however, air-filter elements should be replaced and not cleaned.

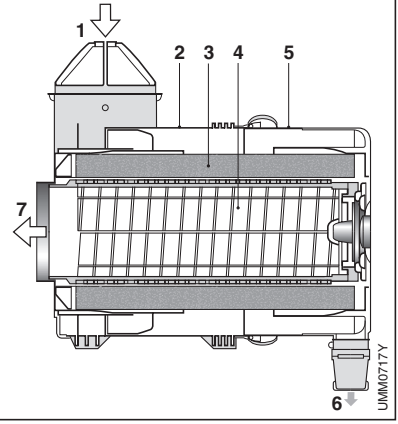
To optimize vehicle acoustics, the air filter is also fitted where necessary with resonators to minimize the opening or engine-braking noise.

Clean-air line as connection to the turbocharger

The clean-air line is as a rule a combination of metal, plastic, and rubber parts. Sensors for air mass, vacuum and air moisture can be optionally integrated. It is important for all the interfaces on the clean-air side to be permanently tight. The vacuum switch indicates to the driver that the servicing limit for the filter element has been reached. Flexible rubber connections compensate the relative movement between the engine and the frame-mounted air filter.

Figure 17: Dust preseparator (cyclone)
1 Outlet guide vanes, 2 Housing,
3 Inlet guide vanes, 4 Dust outlet.

Air filtration



Filter elements which incorporate the latest technology achieve total mass filtration rates of up to 99.95 %. Because the service life of a commercial-vehicle engine far outstrips that of a passenger-car engine, the filtration-efficiency requirements are greater accordingly.

The filter elements have to be replaced at the intervals specified by the vehicle manufacturer. Usual replacement intervals are, depending on the application, 40,000 to 320,000 km or two years. In most cases a service-interval indicator monitors when the service interval is reached.

The media used in commercial-vehicle air filters are comparable to filter media in passenger cars, but are characterized by higher filtration efficiency and are usually designed as surface-type filters. The separated particles thus precipitate mainly on the surface of the cellulose-based medium.

Better values than with pure cellulose-based media are obtained with special nanofiber-based filter media, in which

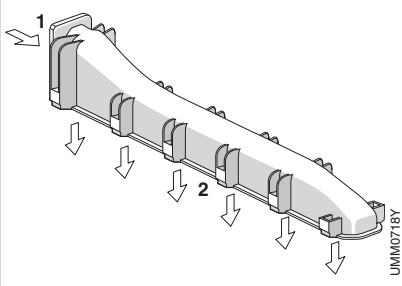


Figure 18: Commercial-vehicle air filter
1 Raw-air inlet, 2 Housing,
3 Filter element, 4 Safety element,
5 Cover, 6 Dust-discharge valve,
7 Clean-air outlet.

ultrathin, synthetic fibers with diameters of just 30 to 40 nm are applied to a relatively coarse backing layer of cellulose. The filtration-efficiency figures improved in this way enable such systems to satisfy the constantly increasing requirements of the commercial-vehicle manufacturers regarding the protection of sensors, turbochargers and other components, and by protecting these components help to comply with the ever more stringent exhaust-emissions standards.

Further development
The space allotted to the air-intake system is becoming increasingly limited, particularly due to the comprehensive exhaust-gas treatment system. For this reason, there will in future also be air filters that are flatter than round filters. This opens up the possibility of new installation positions in the vehicle, for example in front of the front wheel or underneath the driver's cab.

Figure 19: Boost manifold for commercial vehicles
1 Flange for EGR valve or auxiliary heater,
2 Flange for cylinder head.

Commercial-vehicle intake manifolds

Supercharged diesel engines require one intake manifold, usually referred to simply as a boost manifold. The air passes through the air filter to the turbocharger, and from there through the intercooler to the boost manifold. This distributes the air to the cylinders. For the most part the valve for EGR introduction (exhaust-gas recirculation) and possibly an electric auxiliary heater are flange-mounted at the inlet. The auxiliary heater helps to reach the required exhaust-gas values as quickly as possible during engine starting.

The introduced exhaust gas is mixed with the fresh air in the boost manifold and distributed as uniformly as possible to all the cylinders. The exhaust gas cooled by the EGR cooler contains, depending on the operating state and EGR rate, sulfurous acid and soot. The aluminum used for the boost manifold must be protected against the acid by for example painting. If the boost manifold is made of plastic, the plastic must be chosen so that temperature, charge-air pressure and acid do not damage the components over their service lives. The same requirements also apply to the flange gaskets.

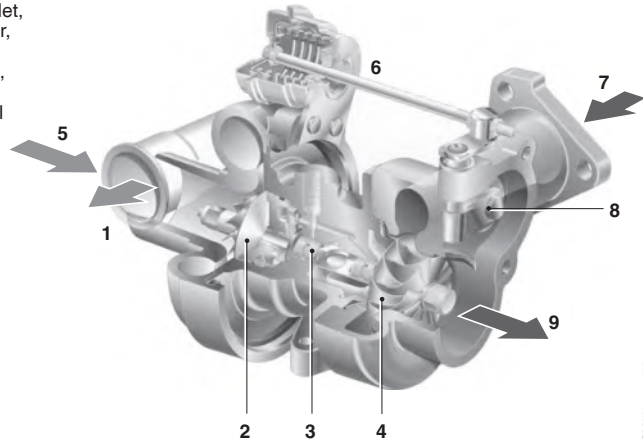
There are both simple boost manifolds (Figure 19) which can be manufactured as a single plastic injection-molded part and also parts which due to their more complex geometry are manufactured in two parts and welded. Charge-air pressure, size of the part and tolerances must be taken into account when configuring the welding. The use of plastic also contributes to the lightweight construction of the engine.

Turbochargers and superchargers

Turbochargers and superchargers for internal-combustion engines increase the air-mass flow for a given engine displacement and a given engine speed, thereby increasing the power density. These "compressors" are generally systematically divided into three different types: the mechanically driven supercharger, the exhaust-gas turbocharger, and the pressure-wave supercharger.

In the case of the exhaust-gas turbocharger (Figure 1), the drive power is generated after banking up the exhaust gas through expansion of the exhaust gas, by which part of the exhaust-gas energy is used. The exhaust-gas turbocharger has gained acceptance for use in diesel engines in both the automobile and commercial-vehicle sectors. The exhaust-gas turbocharger, particularly in conjunction with gasoline direction injection, is being increasingly used in gasoline engines as well.

But mechanically driven superchargers directly coupled to the crankshaft are also used in some vehicle models with gasoline engines. Pressure-wave superchargers on the other hand, despite having some benefits, did not enjoy widespread use in the automotive sector; only a few vehicle models were equipped with these superchargers in the 1980s and 1990s.



Superchargers (mechanically driven)

In the case of the mechanically driven supercharger, the required drive power is branched directly from the crankshaft via a belt or a gear drive from the engine output, i.e., the supercharger and the engine are mechanically coupled. Mechanically driven superchargers [1] fall into two categories: Those which operate according to the positive-displacement principle and those which compress air according to the flow principle and the principle of momentum. The internal-combustion engine drives the supercharger as a rule by means of a belt drive. It is driven either directly (continuous-running operation) or via a clutch.

Mechanical centrifugal supercharger
The compressor of the mechanical centrifugal supercharger operates according to the flow principle. This type of device is very efficient, providing the best ratio between unit dimensions and volumetric flow when compared with other mechanically driven superchargers. The pressure ratio that can be achieved is dependent on the peripheral velocity of the compressor impeller. The air flow rates typical of passenger-car engines give rise to small compressor-impeller di-

mensions. The pressure ratios required for effective engine supercharging thus require high compressor speeds.

The range of application of the mechanical centrifugal supercharger is limited technically by the high rotational speeds required and the transmittable drive power, and economically by the comparatively high costs. It is used in small numbers in performance-oriented engine concepts.

Positive-displacement supercharger

A comparatively large number of designs has been proposed for units operating according to the positive-displacement principle, but only a few have succeeded in being employed in current series applications. Positive-displacement superchargers can operate with or without internal compression. Internal-compression superchargers include the reciprocating-piston, screw-type and rotary-piston compressors. The Roots supercharger is an example of a unit without internal compression. All of these positive-displacement superchargers share certain characteristics as shown here in the program map of a Roots supercharger (Figure 2):

– The speed curves n_L = const in the p_2/p_1-$\dot{V}$ program map are very steep, i.e., the volumetric flow $\dot{V}$ decreases only slightly as the pressure ratio p_2/p_1 increases. The drop in volumetric flow is basically determined by the efficiency of the gap seal (backflow losses). It is a function of the pressure ratio p_2/p_1 and of time, and is not influenced by rotational speed.
– The pressure ratio p_2/p_1 does not depend on the rotational speed. In other words, high pressure ratios can also be generated at low volumetric flow rates.
– The volumetric flow $\dot{V}$ is independent of the pressure ratio and, roughly formulated, directly proportional to rotational speed.
– The unit retains stability throughout its operating range. The positive-displacement compressor operates at all points of the p_2/p_1-$\dot{V}$ program map as determined by supercharger dimensions.

Mechanical positive-displacement superchargers generally must be substantially larger than mechanical centrifugal superchargers in order to produce a given volumetric flow.

Roots supercharger

The Roots supercharger is a rotary-piston machine with contra-rotating twin- or multi-bladed rotary pistons mounted in rolling bearings and synchronized by a gear set. The rotary pistons mesh at identical speed without directly contacting each other in the housing (Figure 3). The gaps between these components essentially determine the machine's efficiency.

Roots superchargers operate without internal compression. Mufflers are generally fitted on the suction and pressure sides to limit their acoustic impact. Their system

Figure 2: Program map of a Roots supercharger

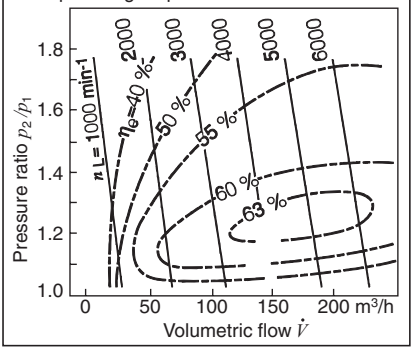

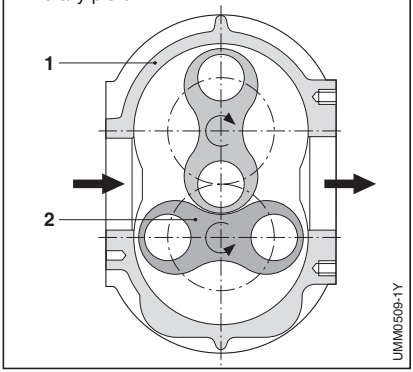

Figure 3: Cross-section through a Roots supercharger

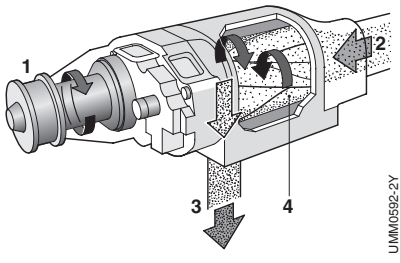
1 Housing,
2 Rotary piston.

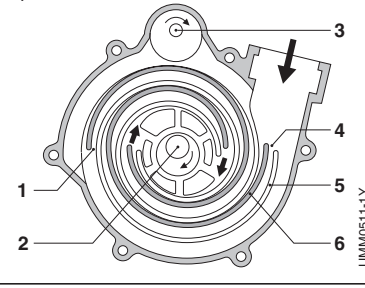


and design limits the pressure ratios that can be achieved to levels below 2. Coating the functional components has helped to improve efficiency. Current development work is focused on among other things variable-speed gearboxes on the drive side.

Screw-type supercharger
The screw-type supercharger (Figure 4) is very similar in design to the Roots supercharger, i.e., it is a twin-shaft contra-rotating rotary-piston machine. However, it differs from the Roots supercharger in that it generally operates with internal compression. It can achieve higher pressure ratios than a Roots supercharger. On the suction side (inlet) the rotation of the pistons (screws) opens a profile-gap space which fills with inducted air. As the screws continue to contra-rotate, the profile-gap space continuously decreases in size until it reaches the outlet control edges. At this point internal compression is completed and the compressed volume is forced into the pressure connection (outlet). In order to minimize internal leakage losses, the tolerances between the screws and the walls must be very closely adhered to. Measures along similar lines to the Roots supercharger were implemented for improving the function and efficiency of this type of supercharger.

Current developments are focused on the integration of electric drives primarily for fuel-cell applications. In addition to electric-only assemblies there are also variants with a power split between mechanical and electric drive.

Figure 4: Screw-type supercharger
1 Drive, 2 Air inlet,
3 Air outlet (compressed air),
4 Screws.



Spiral-type supercharger
The spiral-type supercharger (Figure 5) is a compressor in which a rotor with spiral lands eccentrically describes a circular path in a housing also with spiral lands. The spiral-type supercharger operates according to the principle of a circulatory displacer element. Working chambers in sequence open for charging, close for transport, and open once again for discharge at the hub.

The G-supercharger (G-Lader) is an example of this type. Maintaining very tight tolerances and the seal has a function-determining effect. Radial sealing is provided by the narrowest gaps possible, axial sealing by touching sealing strips inserted on the end faces. These sealing strips are subject to wear and are if necessary replaced during regular vehicle servicing. Internal compression can be achieved by an appropriate configuration of spirals.

More recent developments are heading towards a simplification of the design and the integration of a switchable clutch.

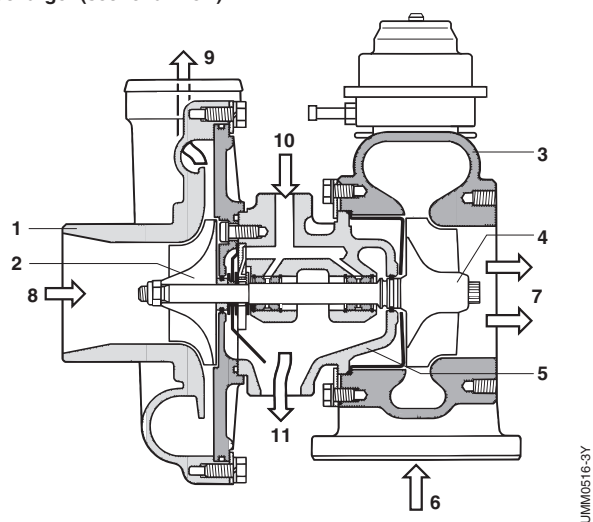
Exhaust-gas turbochargers

Of all the supercharger units in use, the exhaust-gas turbocharger is by far the most widespread. While nowadays virtually 100 % of passenger-car and commercial-vehicle diesel engines are turbocharged, the proportion of supercharged gasoline engines will continue to increase dramatically in the next few years. Here, too, the exhaust-gas turbocharger will be the dominant supercharger.



Design and operating principle
The exhaust-gas turbocharger consists of two turbo elements: a turbine and a compressor, where the impellers for the two elements are mounted on a common shaft (Figures 6 and 1). The operating concept of a turbine engine is based physically on the principle of momentum. The turbine converts some of the enthalpy contained in the exhaust gas into mechanical energy to drive the compressor. The compressor draws in fresh air through the air filter and compresses it.

The exhaust-gas turbocharger is coupled only thermodynamically, not mechanically, to the engine. Turbocharger speed does not depend on engine speed, but is rather a function of the balance of drive energy between the turbine and the compressor. The turbine generates the compressor output and the output which is essentially used up in the bearings and ultimately dissipated as heat (mechanical losses).

Applications
The exhaust-gas turbocharger in its present form can trace its roots back to the work of Alfred Büchi (1905) [2], who had already recognized the potential of combining supercharging and valve overlap to scavenge residual exhaust gas (1915). Exhaust-gas turbochargers have traditionally been used for the purpose of supercharging large diesel engines, originally being used primarily for commercial-vehicle, marine and locomotive power plants as well as for agricultural- and construction-machinery applications.

Use in diesel vehicles
The mid-1970s saw the advent of the first production diesel engines supercharged by exhaust-gas turbochargers in passenger cars. The introduction of a “wastegate” for controlling boost pressure finally facilitated a torque-oriented design and thereby improved driveability. Further increases in the performance of passenger-car diesel engines have been achieved through the

introduction of direct injection (1987) and by exhaust-gas turbocharging with variable turbine geometry (1996) or two-stage exhaust-gas turbocharging (2004). These developments have been reflected in a marked increased in the market share for diesel engines in Europe. Today in Europe all passenger-car and commercial-vehicle diesel engines are equipped with exhaust-gas turbocharging and intercooling (charge-air cooling).

Use in passenger cars with gasoline engines

Exhaust-gas turbocharging of gasoline engines was originally the reserve of only high-output sports engines for increased performance and, because of inadequate driveability ("turbo lag"), was rarely encountered on the market. In the meantime, gasoline-engine supercharging has become an integral part of engine development, predominantly in connection with small to medium-sized engines. In addition to the improvement in efficiency, one of the main objectives is to avoid the increases in the number of engine cylinders (e.g., from four to six cylinders), thus positively influencing package space and fuel consumption.

In contrast to diesel engines, mechanical supercharging was also employed and today continues to be employed occasionally on gasoline engines on account of the excellent transient build-up of boost pressure. With the introduction of direct injection in the gasoline engine the exhaust-gas turbocharger was almost on a par with mechanically driven superchargers thanks to the use of scavenging.

In addition, a combination of mechanical supercharging and exhaust-gas turbocharging (combination supercharging) was in the past employed to provide small-capacity gasoline engines with high rated output and high torque at a comparatively low specific speed. However, the current trend is towards the use of electrically driven supplementary compressors instead of combination supercharging.

The exhaust-gas turbocharger with variable turbine geometry is today the standard supercharger used in diesel engines. In the past this technology was only used on gasoline engines in niche applications due to the unmastered, thermal and technical requirements and the simultaneously high component costs. Current high-volume applications, however, are showing a trend reversal with regard to this issue, which was instigated by the series launch of the 96-kW engine version of the Volkswagen EA211 evo. The technical suitability of the turbocharger with variable turbine geometry is matched to a low-emission Miller combustion process without valve overlap (scavenging) with a simultaneously increased compression ratio. In the first generation the exhaust-gas temperature is limited to 880 °C. However, current developments cover exhaust-gas temperatures up to 1050 °C.

With regard to the statutory exhaust-emission and consumption guidelines and the existing performance figures required by customers, the importance of exhaust-gas turbocharging to the reduced-capacity and reduced-cylinder engines currently in development ("downsizing") cannot be underestimated. At present the number of turbocharged gasoline engines is increasing. The growth of this market segment is expected to continue over the coming years.

Exhaust-gas turbocharger design

The exhaust-gas turbocharger essentially consists of three assemblies: the bearing housing, the compressor, and the turbine (Figures 6 and 1). Depending on the design, there may be a fourth assembly: a boost-pressure control facility.

Bearing housing

The bearing housing accommodates the bearings and the elements for sealing the shaft. State-of-the-art designs usually feature a specially developed friction bearing both in the radial as well as the axial (thrust) bearing assembly. The radial bearings are designed either as rotating double plain bushings or as stationary plain-bearing bushings. The thrust bearing in conventional designs is made up of a multiple-spline surface bushing that is subject to load from both sides.

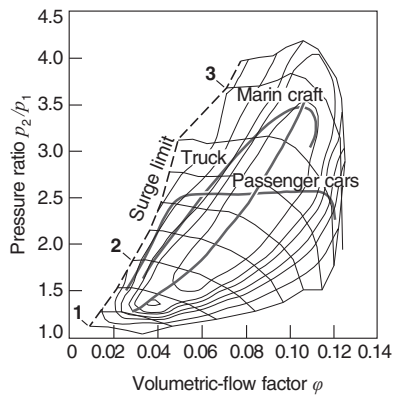
Lubricating-oil supply
The lubricating oil is supplied by connecting the turbocharger to the engine's oil circuit. The oil outlet is connected directly to the oil pan in the crankcase. Today, this type of bearing assembly is used to control rotational speeds of more than 300,000 rpm reliably.

Bearing arrangement
A rolling-bearing rotor assembly (shaft with turbine wheel and compressor impeller) can deliver consumption-related efficiency advantages which provide for a better transient build-up of boost pressure and higher boost pressures in the part-load range. However, this trend is currently falling off because significant improvements could not be achieved with the evolutionary development of the conventional, hydrodynamic-bearing version. Modern developments have a reduced friction loss with simultaneously very good acoustic properties, as demonstrated by for example the "3D-Bearing" from BMTS-Technology GmbH and the "Z-Bearing" from Garrett Motion AG. However, rolling-bearing rotor assemblies also feature in series production in the passenger-car sector. For deeper market penetration, however, further developments with regard to costs, acoustics and service life are necessary. In the commercial-vehicle sector wider deployment is expected in long-distance haulage now that the tendency to wear of the rolling elements has been sufficiently reduced.

Sealing
To seal off the oil chamber to the exterior and to minimize the entry of charge air ("blow-by") and exhaust gas to the charger interior, the shaft is equipped at the casing openings with piston rings which are tensioned in the bearing housing and with the shaft groove form a simple labyrinth. The state-of-the-art sealing technology used today limits the permissible installation location for the exhaust-gas turbocharger to a comparatively small range of inclination. Touching seals would be useful in this respect, but have not been able to be produced up to now at reasonable cost owing to the high relative speeds between shaft and housing.

Cooling
No additional cooling measures are necessary to maintain efficient operation of the bearing assemblies under suitable ambient conditions in the engine compartment, i.e., at exhaust-gas temperatures in conventional passenger-car usage up to 830 °C. The relevant temperatures can generally be maintained below critical levels using devices such as a heat shield, and by thermally isolating the hot turbine housing, supplemented by incorporating suitable design elements in the bearing housing itself. Water-cooled bearing housings are employed for higher temperatures, for example, on gasoline engines operating at up to 1080 °C exhaust-gas temperature or in certain diesel-engine applications.

Compressor
The compressor assembly in passenger car and commercial-vehicle applications consists of an axial-inflow and radial-outflow impeller (compressor impeller, centrifugal design) and a generally guide-ring-free compressor housing made of cast aluminum. However, the use of guide rings is only practical if a limited mass-flow spread of the engine operation curve can be applied without driveability limitations. The are primarily suitable for applications with high compressor pressure conditions. The flow is further slowed down in the housing, in the course of which some of the pressure build-up occurs. Having the smallest possible contour gap between the impeller and the housing is crucially important to efficiency.



Compressor impeller

The compressor impeller can be mass-produced in a special casting process from an aluminum alloy. Today, however, impellers milled from an aluminum forging alloy are mainly used. In the event of more rigorous service-life requirements, particularly in the commercial-vehicle sector with critical application profiles, impellers milled from a titanium alloy are also used. Aside from cost-intensive titanium alloys, aluminum-lithium alloys are among the preferred materials. For engines with low-pressure-side exhaust-gas recirculation, where the compressor has to deliver medium containing exhaust gas, the compressor impeller is provided with a coating. This protects the compressor impeller against erosion by particulate and droplet impingement.

Although the compressor impeller contributes much less than the turbine wheel to the rotor assembly's mass moment of inertia, a value which is as low as possible is also important on the cold side. Because of the heightened requirements with regard to performance and service life, attempts to mass-produce plastic compressor impellers for turbocharger use have hitherto failed.

Compressor program map

The characteristic of a compressor is described by a program map (Figure 7). In contrast to a positive-displacement supercharger, the program map of a flow compressor is limited by gas-dynamic, kinematic and centrifugal effects. By implementing appropriate measures, the effective range as well as the speed and efficiency characteristics of the compressor can be adapted to the required boost-pressure curve. The effective range of the compressor is determined on the "left" side of program map (i.e., maximum achievable pressure ratio for a given throughput) by the surge limit. On the "right" side (maximum possible throughput, limited by the attainment of the velocity of sound in the narrowest cross-section) the choke limit restricts the operating range. The surge limit is defined as the transition from the stable to the unstable operating range. The stability limit is dependent on the vibrational dynamics of the entire conduit system in which the compressor stage is operated. If the stability limit is undershot, delivery of the air-mass flow is as a rule periodically interrupted and re-established. The extent of the surge limit can therefore be improved among other things by means of a suitable intake-line design. The position of the surge limit is therefore not a compressor property, but rather a system property. The choke limit describes the throughput limit of a flow compressor which occurs when transonic flow velocities are reached at the narrowest compressor cross-section. The choke limit is characterized by steeply falling speed curves.

In view of the proportionality of the engine speed and volumetric air flow of the compressor, it is easy to deduce that compressors for turbocharging gasoline engines must have a substantially larger effective map width than, for instance, compressors which supply large diesel engines with air. The dimensionless compressor program map in Figure 7 shows the characteristic air requirements along the WOT

for passenger cars, commercial vehicles, and large heavy-duty engines.

The aerodynamic properties of the compressor stage are determined by the geometric properties of the compressor impeller, the diffuser, and the spiral housing. Furthermore, the compressor impeller must have a suitable mechanical design. The for the most part compromised geometric design is necessary to ensure safety again the failure modes that occur. Damage is caused by high-frequency oscillation excitations and tensile loads and shear stresses resulting from the underlying, application-specific speed horizon which act on the impeller geometries.

With the appropriate, technical requirement, recirculation channels integrated into the compressor housing or a special form of compressor inlet channel (preliminary volumes) are used to extend and stabilize the compressor program map.

Recirculation channel

The recirculation channel at suitable operating points directs some of the delivered mass flow back to the compressor inlet and thereby changes the flow condition at the compressor impeller. With suitable compressor impellers, the surge limit can mainly at pressure ratios greater than 2 be shifted to smaller mass flows. In addition, the bypass in the area of high mass flows results in a slight increase in throughput in the single-digit percentage range. The achievable efficiency levels decrease as a rule when a recirculation channel is used.

Inlet and discharge guide vanes

Variable inlet or discharge guide vanes are also used to extend the program map. The program map can also be extended in the surge-limit range by this. This means that the compressor can be operated at an operating point at which the surge limit would already be exceeded. Apart from a simple preliminary diffuser, whose vane angles twist into a specific position as the mass flow increases by means of the flow forces and are released again as the mass flow decreases, variable compressors have up to now not been series-produced.

Variable compressors

Still in development are variable compressors in which a variable cross-section constriction is arranged upstream after the narrowest compressor cross-section. This enables the surge limit to be shifted towards lower mass flows. This is consequently a further map-extending or an efficiency-increasing measure for operating points close to the surge limit.

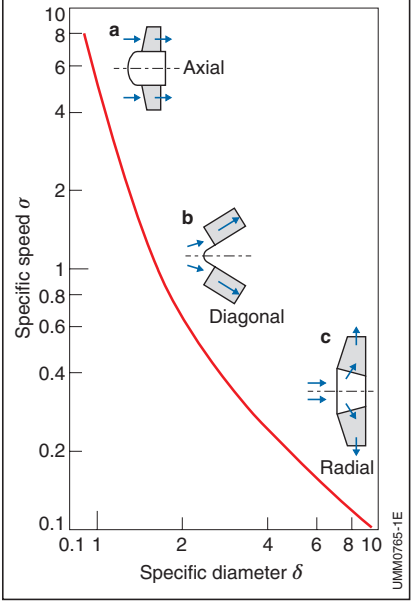
Blow-off valve

To date compressor variants for turbocharging conventional gasoline engines are equipped with a blow-off valve, whose task it is to prevent compressor surge when load is quickly removed (i.e., throttle valve closes). The blow-off valve, which was originally actuated pneumatically but is now mainly actuated electrically, for this purpose creates a bypass between the compressor outlet and inlet. In this way, the compressor pumps briefly as a blower in the circuit. Today it is possible, above all by introducing electrical actuation of the wastegate, to prevent surge without the use of a blow-off valve and guarantee reliable operation.

Turbochargers with variable turbine geometry, opening up new cutoff-strategy possibilities, are increasingly gaining acceptance in current engine applications with modern Miller combustion processes.

Turbine

The turbine consists of a diffuser and a (turbine) wheel. The diffuser of the turbocharger turbine is integrated in the flow housing (spiral housing) and for passenger-car applications, if the turbocharger is one without variable turbine geometry, is designed without vanes. Fixed-geometry diffusers with vanes are frequently used in exhaust-gas turbochargers for large engines for better fine graduation of the turbine throughput. The flow is accelerated in the diffuser and distributed as evenly as possible to the turbine wheel.



Turbine wheel

The turbine wheel is normally designed as a centripetal turbine, i.e., radial inflow and axial outflow.

Because of their favorable mass moment of inertia, turbine wheels of semi-axial design are also used. These have diagonal inflow and axial outflow. But these are not so-called diagonal turbines, which are unsuitable for these too low, specific throughputs.

Axial wheels, which have axial inflow and axial outflow, are only installed in turbochargers for medium-speed and slow-running large engines. The achievable pressure ratios are greatly limited owing to the prevailing short channel routing here with a comparatively high, specific throughput. Axial wheels have a comparatively high speed number, a dimensionless quantity that is obtained from the quotient of the peripheral velocity and the flow velocity of the turbo-machine. Without suitable matching only axial compressors can be paired with axial turbines in each case; the same applies to radial turbines.

Figure 8: Cordier diagram
a) Turbine wheel, axial design,
b) Turbine wheel, semi-axial design,
c) Centripetal turbine.

In special cases multi-flow centripetal machines are paired in order to reach a sensible level for the corresponding speed number. The interrelationship of specific mass flow and suitable design can be inferred in many available representations of the so-called Cordier diagram (Figure 8, [3], [4]). The speed number is plotted against the diameter number in the Cordier diagram. The diameter number is a dimensionless quantity for characterizing turbo-machines [5]. It relates the outside diameter of the machine impeller to the calculated diameter of an equivalent nozzle.

Exhaust-gas pipe

The arrangement of the exhaust-gas pipe plays an important role in supercharging. Classically, a distinction is made between pulse supercharging and constant-pressure supercharging. In the case of pulse supercharging, the exhaust-gas pipes are routed separately to the turbine housing. Those cylinders whose exhaust pulses influence each other minimally are brought together on the exhaust-gas side. This means that the scavenging processes of the cylinders that are brought together are subject to less hindrance. The turbine housing is designed in such a way that the separation of channels is maintained as far as possible up to the turbine-wheel inlet. The channel cross-section is the size of the exhaust cross-section. The exhaust pulses reach the turbine inlet in the form of pressure waves such that pulsating pressure is applied to the turbine. This effect must be utilized at low engine speeds where the pressure surges, due to the long interval from one exhaust pulse to the other, make up substantial power contribution of the available exhaust-gas enthalpy.

In the case of constant-pressure supercharging, the exhaust discharges are directed in a common, comparatively large-volume collector to the turbine housing. This process smooths out the individual exhaust pulses to a large extent.

With constant-pressure supercharging the more uniform enthalpy over time can be processed with greater efficiency. Pulse supercharging, on the other hand, offers advantages for the engine's part-load and accelerating performance.

Turbine housing

The design of the turbine housing differs significantly, depending on whether constant-pressure or pulse supercharging is used. Pulse supercharging for the most part is used in commercial-vehicle applications. The turbine housing is designed as double-flow housing in which the two flows join only just before the wheel inlet.

Constant-pressure supercharging is used on high-speed engines such as the diesel engines in passenger vehicles. The turbine housings are single-flow ("single-scroll") in design and partially integrated into the exhaust manifold as a single component. This provides for a particularly compact component geometry.

Gasoline engines utilize both constant-pressure and pulse supercharging. The exhaust-gas systems are configured accordingly and the housings are single-flow or twin-flow ("twin-scroll" or "dual volute") in design. Partially manifold-integrated turbine housings are also used in exhaust-gas turbochargers for gasoline engines.

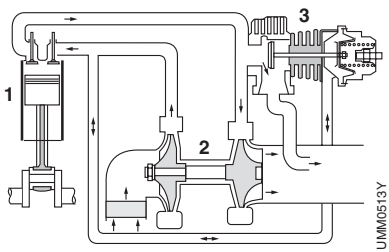
Materials

The turbine wheels are made of high-alloy nickel steels on account of the high demands imposed by temperature and mechanical loads. In view of the accuracy of shape required, procedures such as vacuum or centrifugal casting are used. The mechanical connection with the shaft is achieved by means of friction, laser or electron-beam welding.

Non-metallic and ceramic materials were analyzed as an alternative for turbine wheels. The material class titanium aluminide (TiAl) appeared promising. Due to the low density the mass moment of inertia is reduced to approx. 50 % compared with common materials like IN713C (nickel-base casting alloy). Unfortunately, the available alloys exhibited to a large extent unsuitable material properties, as a result of which the associated expensive development activities were discontinued.

The associated turbine housings are made of different casting materials depending on the thermomechanical requirements. Exhaust-gas temperatures in real applications in passenger cars range between approx. 750 °C and approx. 1100 °C. Here the spectrum of casting materials used ranges from cast iron to high-alloy cast-steel variants. Aside from the marked focus on cost, the designs are characterized by the smallest possible thermal inertia. Water-cooled turbine housings made of wrought aluminum alloys which can be operated up to an exhaust-gas temperature of 1030 °C constitute a special solution. Turbine housings for dual-flow turbines consist primarily of cast-steel materials because these alone have the requisite thermomechanical properties. Turbine housings built up from welded sheet-metal parts in single-walled or twin-walled form have also been produced in AGI versions (AGI: Air-Gap-Insulated). AGI components reduce wall heat losses and have a low thermal inertia.

So far built-up turbine housings have only been introduced in series production to a limited extent. However, these could help to meet future emission regulations in that they enable the catalytic converter to be heated up more quickly after cold starting.



Boost-pressure control

In view of the large rotational speed spread of passenger-car engines, a boost-pressure control facility is indispensable to maintain the maximum permissible boost pressure for an acceptable design torque. Standard practice presently favors turbine output control on the exhaust-gas side.

Bypass control
A simple and in gasoline and commercial-vehicle engines widely used method is that of bypass control, in which generally some of the exhaust-gas flow is routed through a flap valve ("wastegate") around the turbine (Figures 1 and 9). The flap valve is actuated by a pneumatic unit or an electric actuator. The pneumatic unit can take the form of an overpressure unit (supplied by the boost pressure itself) or a vacuum unit (vacuum supply from the vehicle system). If the boost pressure is used, the wastegate cannot however be actuated independently of the engine operating state. The control pressures are usually adjusted by using clocked-pulse valves. Because of the thermal load, the actuators are generally mounted on the compressor side and connected via a control rack to the wastegate lever.

Current developments involve almost exclusively electric actuators with position feedback, which provide for a fast and precise control response. The wastegate can therefore be actuated independently of the engine operating state. This is necessary to comply with the current statutory requirements with regard to emissions and consumption. Currently available electric actuators impress with their compact design and high actuating forces, which guarantee a better seal seat for the wastegate valve (overrun control valve) and an accelerated build-up of boost pressure.

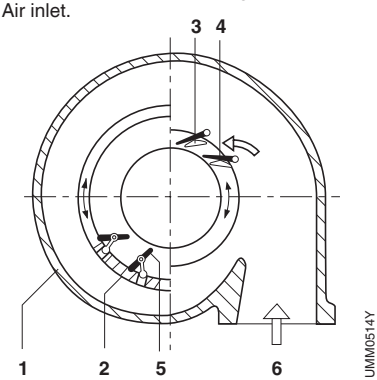


Figure 9: Boost-pressure control via exhaust-side boost-pressure control valve (wastegate)
1 Engine,
2 Exhaust-gas turbocharger,
3 Boost-pressure control valve (wastegate).

Variable turbine geometry
Compared to bypass control, variable turbine geometry (VTG) offers a more efficient method of boost-pressure control over the entire operating range. Today it is state of the art in passenger-car diesel engines and will in future also be introduced in commercial-vehicle and gasoline-engine applications. The entire mass exhaust-gas flow is routed here via the turbine, providing specific benefits in exploiting the available energy.

Of all the potential designs, adjustable blades have achieved general acceptance, as they combine a wide control range with high efficiency levels (Figure 10). The blade angle can be easily adjusted by means of a swiveling movement. The blades, in turn, are set to the required position using adjusting cams, or directly via control levers attached to the individual blades. All blades engage in an adjusting ring which can be turned by means of a lever. The lever is actuated by pneumatic or electric actuators. Where a pneumatic unit is fitted, today exclusively a position sensor is integrated in the unit, and the signal from this sensor ensures that the VTG actual blade position is clearly identified.

Figure 10: Variable turbine geometry (schematic)
1 Turbine housing,
2 Adjusting ring,
3 Control cam,
4 Adjusting blades (pivot point at front edge of blade),
5 Adjusting blades (pivot point at approx. 50 % of blade length),
6 Air inlet.

The first design variations had symmetrical blades with straight median lines. Today, profiled blades with pronounced pressure and suction sides and curved median lines are used. This helps to improve efficiency above all in the closed position, i.e., when accelerating from lower full load and in the part-load range. It is particularly important for engine performance in the lower engine speed range to adhere to the smallest possible axial gaps between the adjustable blades and the adjacent components.

Owing to the high exhaust-gas temperatures of a gasoline engine, the operationally reliable and durable implementation of an adjusting-blade exhaust-gas turbocharger involves intensive matching of thermomechanics, choice of materials, and kinematics. For this reason an adjusting-blade VTG was for a long time only available in just one gasoline-engine application of one sports-car manufacturer. In 2016, however, this technology also went into series production in mid-size passenger cars with gasoline engines. Today they also exist in price-sensitive vehicle segments in Europe and China.

A Japanese manufacturer developed, aside from adjustable-blade VTG, a comparatively simple variability in the area of the turbine spiral. However, to date it has not attained the performance levels of adjustable-blade VTG.

There is a further operating principle, the so-called sliding-sleeve principle. This is a compromise solution which generates a comparatively high degree of turbine efficiency with fewer hot parts than the adjustable-blade variant. A single actuator is used to achieve both variability of the turbine mass flow and the operation of an internal bypass to circumvent the turbine.

Exhaust-gas turbochargers with supply of additional energy

Modern exhaust-gas turbochargers are characterized by high efficiency levels and a low mass moment of inertia on the part of the rotor assembly such that a very good transient build-up of boost pressure can be achieved, particularly in conjunction with measures on the engine, such as for instance “scavenging” [6]. However, in view of current legislation, this measure is still only occasionally used because it can lead to a significant oxygen content in the exhaust gas. In combination with gasoline-engine combustion processes and the associated exhaust-gas temperatures, an oxygen excess can lead to accelerated aging of the catalytic-converter substrate and consequently to a reduction of the guaranteed conversion rate to be expected.

In the past various solutions have been proposed in order in states with little available exhaust-gas energy to supply additional mechanical, hydraulic or electrical power to the shaft for the purpose of accelerating the rotor assembly more quickly. For example, the incorporation of a gear on the turbocharger shaft allows mechanical energy to be supplied via a gearbox and a switchable mechanical connection to the crankshaft.

A further approach provides for installing on the rotor assembly between the bearings a Pelton turbine wheel which is pressurized with high-pressure oil (approx. 100 bar) from the engine circuit or separately with hydraulic fluid.

Electrically assisted exhaust-gas turbocharger

In a further approach it is proposed to install on the turbocharger shaft, for instance between the bearings, an electric motor which is supplied via power electronics by the vehicle electrical system (“electrically assisted exhaust-gas turbocharger”). The electrically assisted turbocharger is able in certain operating phases to function as a generator and thereby return electrical energy to the vehicle electrical system.

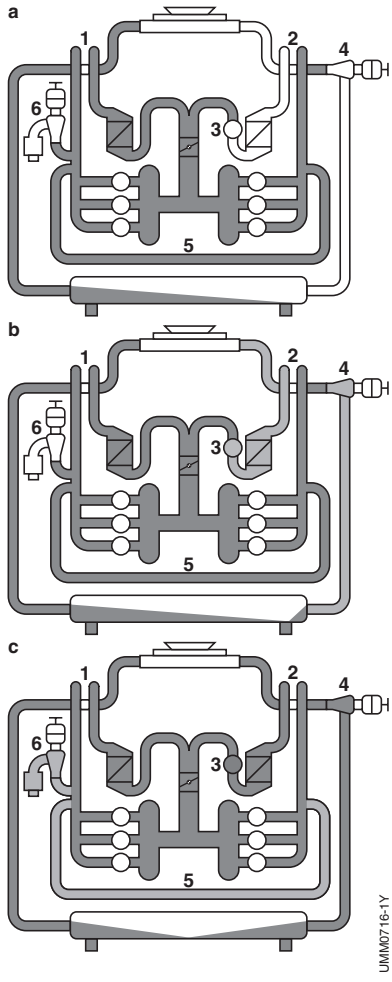
The current issues of consumption and emissions have thrown up an important additional task. The unacceptable aging of exhaust-gas treatment creates the additional requirement of high expansion performance on the part of the turbine stage at full-load speeds. The aim here is to lower the exhaust-gas temperature downstream of the turbine to as low a level as possible so that the exhaust gas permanently guarantees the conversion of the catalytic converter. A reduction of the exhaust-gas temperature to values lower than 900 °C would be desirable. This requires a particularly precise matching of the throughput and efficiency offering. A turbine bypass will not resolve the issue here, or must be able to be effectively switched off.

There are currently a number of variants of the electrically assisted turbocharger in development. There are variants without variability and without bypass valve. The recuperation potential exceeds the excess exhaust-gas enthalpy offering, by which the electrically assisted turbocharger can be braked at any time to the desired operating speed. However, this only applies to full load; a constantly sufficient electrical acceptance is the prerequisite here. This solution is a compromise which is intended to make use of a simple, cost-effective and fail-safe fixed-geometry exhaust-gas turbocharger.

Alternatively, the turbine has a wastegate so that even light-off operating modes (catalytic-converter heating-up phase until the targeted conversion of pollutants from the exhaust gas is achieved) can be supported by the turbocharger itself. Furthermore, there are electrically assisted turbochargers with variable turbine geometry. These have the distinction of being able to react much more freely to the equilibrium between available exhaust-gas enthalpy, energy recuperation demand and boost-pressure demand. With a suitably designed turbocharger a number of operating modes can be simultaneously run and can also be used in line with demand.

Compared to a conventional turbocharger, a magnet arrangement mounted on the shaft results in an increased moment of inertia on the part of the rotor assembly. The potential of these approaches does make it possible to shift the turbocharger's power balance independently of the engine, but this is limited by the program-map limits of the compressor used. Suitable measures for shifting and extending the compressor-map limits are set out in the section entitled “Compressor”.

The first series launches with the use of an electrically assisted turbocharger in passenger cars is expected from 2021.



Complex supercharging systems

With a parallel or serial/multistage connection of supercharger units the power limits can be significantly extended compared with supercharging with just one single-stage supercharger unit. Predominantly complex valves for control, for operating-point-dependent cut-in or for defined distribution of the exhaust-gas mass flow are required. The aim here is both to improve the steady-state air supply and to speed up the transient response of the build-up of boost pressure. This in turn improves both the specific consumption and the controllability of the transient operating characteristics and with it the engine emission behavior.

Bi-turbo supercharging

In the case of bi-turbo supercharging, the air supply, instead of using one large exhaust-gas turbocharger, is distributed to two or more smaller exhaust-gas turbochargers connected in parallel. These are generally permanently assigned to specific cylinders on the exhaust-gas side, for example the bank of a V-engine. Each turbocharger pressurizes the engine with air over the full rotational-speed range. The advantage of this arrangement lies primarily in the rapid transient build-up of boost pressure and in the comparatively compact routing of pipework. The turbochargers operating in parallel cannot be controlled independently of each other and should in the process always generate an identical boost pressure.

Figure 11: Sequential supercharging

c) Two-charger operation.
1 Exhaust-gas turbocharger 1,
2 Exhaust-gas turbocharger 2,
3 Compressor cut-in valve,
4 Turbine cut-in valve,
5 Transverse pipe, 6 Bypass valve.

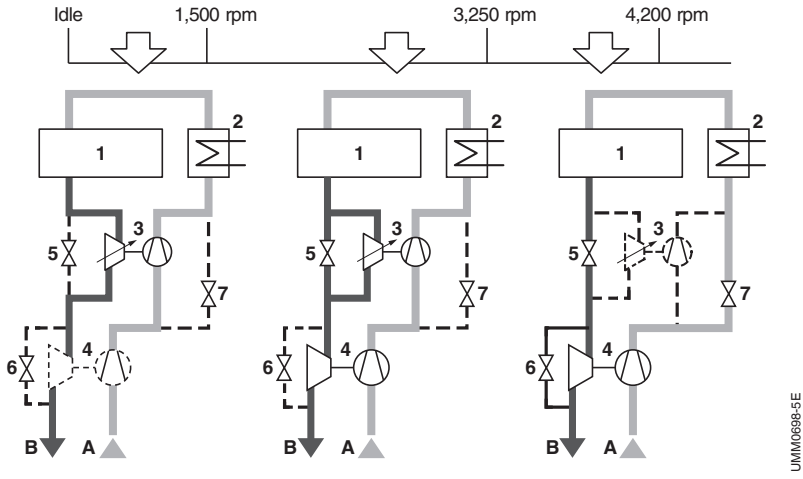
Sequential supercharging
Sequential supercharging is predominantly used in ship propulsion systems or generator drives. However, because of the high levels of power it can deliver, this arrangement variant is also used in passenger cars. In the case of passenger-car sequential supercharging, as engine load and speed increase, an additional turbocharger is cut in to the basic supercharging process (Figure 11). Thus, in comparison with mono-supercharging (i.e., a single charger which is geared to the rated output), two supercharging optima are achieved.

The sequential-supercharging system contains, in addition to the turbochargers, valves and sensors which facilitate a smooth switchover from one- to two-charger operation and back from two- to one-charger operation. When the engine is in the lower speed range, only the basic turbocharger is active, supplying all the cylinders with air. When a certain speed is reached, the second turbocharger is run up and cut in. Both turbochargers are now operating in parallel to pressurize all the cylinders. Sharing the air supply between two turbochargers helps to deliver a very wide torque plateau and high rated output. Furthermore, the significantly lower mass moment of inertia of the smaller turbocharger rotor assemblies gives rise to a dynamic response.

An integrated arrangement of both turbochargers including the switchover valves is available on the market, but is complex and only ever specifically suitable. Controlling the switchover process by means of control engineering involves a comparatively complex application of the control parameters.

Sequential supercharging is used in both gasoline and diesel engines [7].

Dual-stage controlled supercharging
In contrast to sequential supercharging, with dual-stage controlled supercharging the turbochargers are connected in such a way as to effect serial operation in certain operating phases (Figure 12). The advantage of this supercharging system over the



single-stage method lies in the increase in rated output with a simultaneous improvement in the stationary torque at low speeds and in the engine's accelerating performance thanks to the rapid build-up of boost pressure. This extremely powerful system features the use of two turbochargers of significantly different sizes. A dip in torque in the switchover range when this system is appropriately tuned and controlled is largely avoidable.

The entire drawn-in fresh-air mass flow flows through both serial compressor stages for lower full load. As a result of precompression, the relatively small high-pressure compressor works at a higher pressure level so it is able to make available the required boost pressure already for low engine speeds. Performance can be further improved by cooling the charge air after the first compression stage.

Particular importance is attached to the sealing and the control quality of the turbine bypass valve in the high-pressure stage. By way of this valve, depending on the operating point, either the entire exhaust-gas mass flow is expanded in two stages in the high-pressure turbine and then in the low-pressure turbine, or some of the exhaust-gas mass flow is diverted past the high-pressure turbine and delivered directly to the low-pressure turbine. The thermomechanical and vibrational demands placed on the valve system are very tough. This also applies to the rendering of low-loss flow routing between the compressor and turbine stages.

The bypass valves are closed in the engine's low speed range, i.e., with small exhaust-gas mass flow rates. The exhaust-gas mass flow expands primarily through the small high-pressure turbine. This results in a very good transient build-up of boost pressure. As engine speed increases, the high-pressure turbine bypass valve routes an increasing amount of the exhaust-gas mass flow directly to the low-pressure turbine until finally the low-pressure turbine too is relieved by a further wastegate. Thus for small throughputs the charge air is compressed predominantly in the high-pressure stage; however, as throughputs increase it is compressed increasingly in the low-pressure stage. When a specific engine speed is reached, the high-pressure compressor bypass valve is additionally

Figure 12: Schematic diagram of dual-stage controlled supercharging

6 Wastegate, 7 Compressor bypass valve.
A Intake air, B Exhaust gas.

opened and establishes a direct connection from the low-pressure compressor to the intercooler.

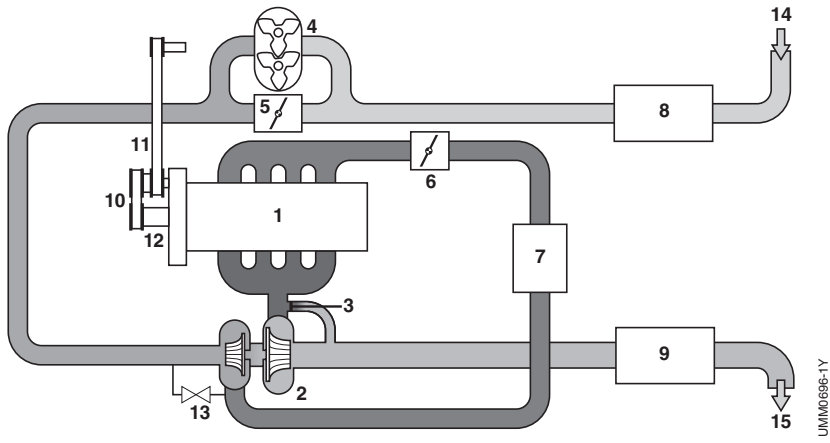
In this operating mode dual-stage controlled supercharging enables infinitely variable adaptation of turbocharging to the requirements of engine operation.

The compressor bypass valve can be designed as a (passive) non-return valve or as an actively actuated flap with actuator. With the latter variant the pressure loss in the compressor bypass can be reduced. But this involves increased control-engineering complexity.

Both fixed-geometry turbines and VTG turbines, in each case with an additional bypass valve, are used in the high-pressure stage. Either a wastegate turbine or a variable-geometry turbine (usually without an additional bypass) can be used as the low-pressure turbine.

Dual-stage controlled supercharging was introduced as standard in passenger-car diesel engines in 2004. Currently, the spread of two-stage supercharging systems for use in passenger-car diesel engines is dropping off because they negatively influence the engine emission behavior during the warm-up phase due to their high thermal inertia.

Dual-stage supercharging systems can also be used in gasoline engines and may because of the high boost-pressure requirements be of interest particularly for Miller combustion processes.



Combination supercharging

Combination supercharging combines a mechanically driven supercharger unit with an exhaust-gas turbocharger (Figure 13). This powerful supercharging system was used for the first time in a passenger car in 1985 (Lancia Delta). It can be used in comparatively small-capacity gasoline engines with high rated output and high torque already at comparatively low speeds and high dynamic response.

In the lower engine-speed range in which little exhaust-gas energy is available to drive the turbocharger turbine, the air supply is practically managed by the mechanically driven supercharger on its own. Because the exhaust-gas turbocharger is designed for the mean-speed and rated-output ranges, this results in a charger with high throughput, optimized for

Figure 13: Combination supercharging

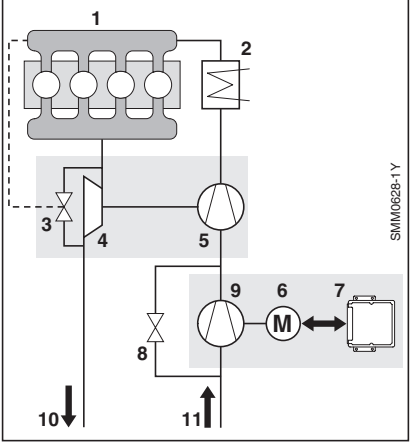
rated-output operation. In a certain operating range the system operates as a series connection of two supercharger units, i.e., the total pressure ratio is the product of the individual pressure ratios.

The mechanically driven supercharger can be positioned in the flow direction upstream or downstream of the turbocharger compressor. When the engine is in the upper speed range and there is therefore an adequate supply of exhaust-gas energy, supercharging is performed solely by the turbocharger. The mechanically driven supercharger is bypassed and mechanically isolated as otherwise, even when the mechanically driven supercharger is idling, its friction losses will be removed as drive power from the crankshaft.



Electrically driven compressor in series with an exhaust-gas turbocharger

One possible solution for obtaining the benefits of exhaust-gas turbocharging in quasi-stationary operation and in the process improving the response of a turbocharger designed for high rated output is the series connection of an exhaust-gas turbocharger with an electrically driven flow compressor ("booster", Figure 14). The advantages of this solution over the electrically assisted exhaust-gas turbocharger are that the effective program-map range is extended by the series connection of two flow compressors and the booster can be placed in thermally suitable locations in the engine compartment. The booster can be positioned in the flow direction before or after the turbocharger. A bypass allows the booster to be bypassed when it is not in operation.

This electrically assisted extension of the engine map is useful for both steady-state and dynamic engine operation. Depending on the energy availability of the vehicle electrical system used, however, different operating strategies must be chosen for a suitable charge balance of the electrical energy accumulator. Depending on the position of the combustion limits for a fault-free, reproducible combustion process, a part-load application is also useful and uncritical in terms of energy. On the basis of the current CO_2 balance and the emission legislation, non-engine-dependent boost-pressure provision is real driving operation is of significant benefit when compared with other applications. The additional function as a secondary-air pump and transient support of cost-sensitive hybrid applications are mentioned as examples.

Figure 14: Electrically driven compressor in series with an exhaust-gas turbocharger

5 Turbocharger compressor,
6 Electric motor,
7 Triggering electronics for electric motor,
8 Bypass valve for eBooster,
9 eBooster compressor, 10 Exhaust gas,
11 Intake air.

For the system to operate effectively, the booster must reach its target pressure ratio within the shortest possible time. When the acceleration of the shaft is taken into consideration, this produces a brief booster power peak. This requires a stabilization of the vehicle electrical system, especially for a vehicle system voltage of 12 to 24 V.

This supercharging system is used both in some luxury-class vehicles with 48 V vehicle electrical systems and in gasoline applications with 12 V vehicle electrical systems.

Current developments are concerned, aside from with engine applications, with the air supply and the recirculation of fuel cells. The assemblies are therefore designed for vehicle system voltages of up to 400 V and a maximum output of 20 kW.

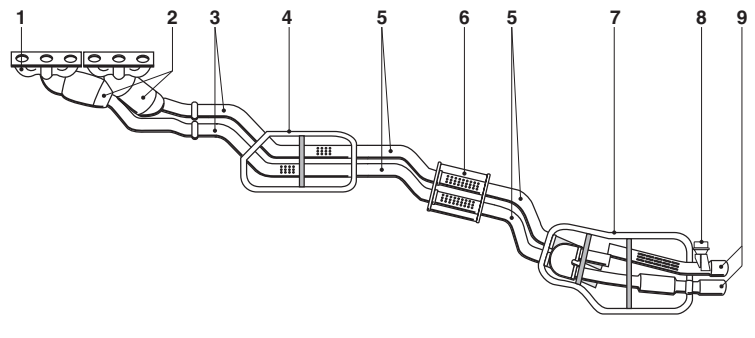
Exhaust-gas system

Purpose and design

In compliance with legal requirements, the exhaust-gas system reduces the pollutants in the exhaust gas that are generated by an internal-combustion engine. The exhaust-gas system also helps to muffle exhaust-gas noise and to discharge the exhaust gas at a convenient point on the vehicle. Engine power should be reduced as little as possible during the process.

Components
An exhaust-gas system consists of the exhaust manifold, the components for exhaust-gas treatment and for sound absorption, and the connections between these components.



The design and the layout of these components are very different for passenger cars and commercial vehicles. In the case of passenger-car exhaust-gas systems the components are usually individually connected by pipes and routed under the vehicle chassis (Figure 1). Depending on engine displacement and the type of muffler used, a passenger-car exhaust-gas system weighs between 8 and 40 kg. The components are primarily made of high-alloy steels, as they are exposed to corrosion attacks from the inside by hot gas and condensate, and from the outside by moisture and splash and salt water.

Since the introduction of Euro IV, commercial vehicles have also been required to carry components for exhaust-gas treatment. These are, however, usually integrated into a large system and secured to the frame (see Commercial-vehicle exhaust-gas systems). The individual components are explained in the following using a passenger-car exhaust-gas system as the example

Exhaust-gas treatment
The components of the exhaust-gas treatment include
– the catalytic converter to break down the gaseous pollutants in the exhaust gas, and
– the particulate filter (or soot filter) to filter out the fine, solid particulates in the exhaust gas (especially in diesel engines).

Catalytic converters are installed in the exhaust-gas system as close as possible to the engine so that they can quickly reach their operating temperature and therefore be effective even at low operating temperatures (e.g. in urban driving). The decisive factor here is the light-off temperature of the catalytic converter, i.e. the temperature at which the catalytic converter begins to break down pollutants (approx. 250 °C for three-way convert-

Figure 1: Exhaust-gas system of a passenger car (example with three mufflers)

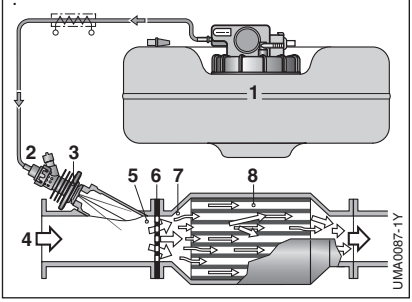
ers). Some catalytic-converter coatings, such as those for NO_x storage converters for example, are highly sensitive to temperature. These catalytic converters are therefore sooner installed in the cooler underbody area.

Diesel particulate filters are also installed in the front area of the exhaust-gas system to ensure that the soot particles they have retained are burnt off more effectively at the higher exhaust-gas temperatures.



Essentially three-way catalytic converters are used in spark-ignition engines. During engine operation with a stoichiometric air-fuel mixture ($\lambda = 1$) they convert the hydrocarbons (HC), nitrogen oxides (NO_x) and carbon monoxide (CO) present in the untreated exhaust gas by more than 99 %. An additional NO_x storage catalytic converter is only installed in lean-burn-operated gasoline direct-injection engines. This reduces the nitrogen oxides (NO_x) increasingly produced in this operating state.

Diesel engines require an oxidation-type catalytic converter to oxidize the hydrocarbons (HC) and carbon monoxide (CO) and a particulate filter to hold back the solid exhaust-gas components. For low NO_x emissions a further catalytic converter for NO_x reduction is required – an NO_x storage catalytic converter or an SCR catalytic converter (Selective Catalytic Reduction).

In order to ensure that the emissions are converted as much as possible in the catalytic converter or are well filtered in the particulate filter, it is essential to optimize the flow against these components in the exhaust-gas system. This is generally achieved by the shaping of the inflow funnel. Additional components such as swirl or mixing elements are required to optimize uniform distribution further. Especially SCR systems in which a reducing agent (Urea/water solution) is injected in liquid form into the exhaust-gas system require a mixer in order to ensure vaporization or atomization of the reducing agent to NH_3. The aim is to ensure uniform and gaseous distribution of NH_3 ahead of the catalytic converter (Figure 2).

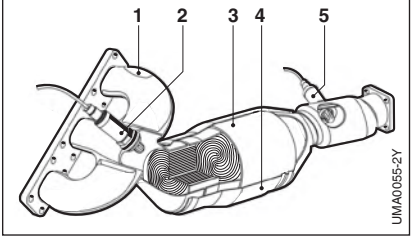
Sound absorption

The primary cause of exhaust-gas noise is the gas pulsations of the internal-combustion engine, i.e. the gas vibrations which are generated by the combustion process and by the exhaust gas being forced out through the exhaust valves during each engine power cycle. This pulsation noise is in fact damped slightly by the catalytic converters and particulate filter. But this is not sufficient to keep the noise below the pass-by limit value prescribed by law (see Vehicle acoustics). For this reason, mufflers are installed in the middle or rear section of the exhaust-gas system.



Depending on the number of cylinders and engine output, generally one, two or three mufflers are used in an exhaust-gas system. In V-engines, the left and right cylinder banks are often run separately, each being fitted with its own catalytic converters and mufflers.

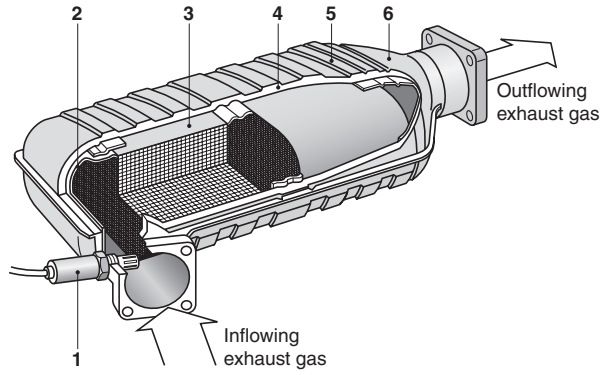
The noise-emission limit for the complete vehicle is defined by legislation. The noise produced by the exhaust-gas system represents a substantial source of noise emission in a vehicle. This fact makes it necessary to devote particular attention and resources to the development of mufflers. Although the aim is to reduce noise in compliance with the legislation, they can also create the sound specific to the type of vehicle (sound design).

Exhaust manifold

An important component in the exhaust-gas system is the exhaust manifold (Figure 3). It routes the exhaust gas out of the cylinder outlet ports into the exhaust-gas system. The geometric design of the manifold (i.e. length and cross-section of the individual pipes) has an impact on the performance characteristics, the acoustic behavior of the exhaust-gas system, and the exhaust-gas temperature. In some cases, the exhaust manifold is air-gap-insulated (i.e. double-walled) in order to achieve high exhaust-gas temperatures quickly so as to enable the catalytic converter to work at an early stage during cold start. The exhaust manifold must consistently endure very high temperatures (up to 1,050 °C in gasoline engines). It is therefore produced from very high-quality material (high-alloy casting or high-alloy stainless steel).

Figure 3: Exhaust manifold with near-engine catalytic converter
1 Exhaust manifold, 2 λ sensor, 3 Metal monolith, 4 Insulating shell, 5 OBD sensor.

Catalytic converter



A catalytic converter is made up of an inflow funnel, an outflow funnel and a monolith (Figure 4). The monolith contains a large number of very fine, parallel channels covered with an active catalytic coating. The number of channels ranges from 400 to 1,200 cpsi (cells per square inch). The functional principle of the active catalytic-converter layer is described elsewhere (see Catalytic exhaust-gas treatment). For operational reasons, several differently coated monoliths are often used in one catalytic converter. Particular attention must be paid to the shape of the inflow funnel to ensure that the exhaust gas flows uniformly through the monolith. The external shape of the monolith depends on the installation space available in the vehicle, and may be triangular, oval or round.

The monolith can be made of metal or ceramic material.

Metal monolith

The metal monolith is made of finely corrugated, 0.05 mm thick metal foil, wound and brazed in a high-temperature process. Due to the very thin walls between the channels, the metal monolith offers an extremely low resistance to the exhaust gas. It is therefore frequently used in high-performance vehicles. The metal monolith can be welded directly to the funnels.

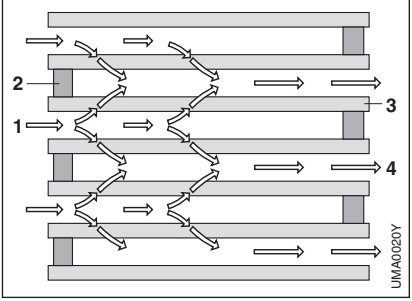


Figure 4: Catalytic converter with ceramic monolith
1 λ sensor,
2 Inflow funnel,
3 Ceramic monolith,
4 Mounting mat,
5 Metal housing,
6 Outflow funnel.

Ceramic monolith
The ceramic monolith is made of cordierite. Depending on the cell density, the wall thickness between the channels ranges from 0.05 mm (at 1,200 cpsi) to 0.16 mm (at 400 cpsi).

Ceramic monoliths have an extremely high stability to temperature and thermal shock. However, they cannot be installed directly in the metal housing and require a special mounting. This mounting is necessary in order to compensate for the difference between the thermal-expansion coefficients of steel and ceramics, and to protect the sensitive monolith against shocks. Extreme care and attention is required in the mounting and production process, particularly for thin-walled monoliths (< 0.08 mm). The monolith is mounted on a mat located between the metal housing and the ceramic monolith. The mounting mat is made up of ceramic fibers. It is extremely flexible to ensure that the pressure load exerted on the monoliths is at a minimum. It also serves as a heat insulator.

Figure 5: Ceramic particulate filter
1 Exhaust-gas inlet,
2 Ceramic plug,
3 Cell partition,
4 Exhaust-gas outlet.

Particulate filter

As with catalytic-converter monoliths, there are metallic and ceramic particulate-filter systems. The method of installing and mounting this filter in the metal housing is the same as the process used for the catalytic converter.

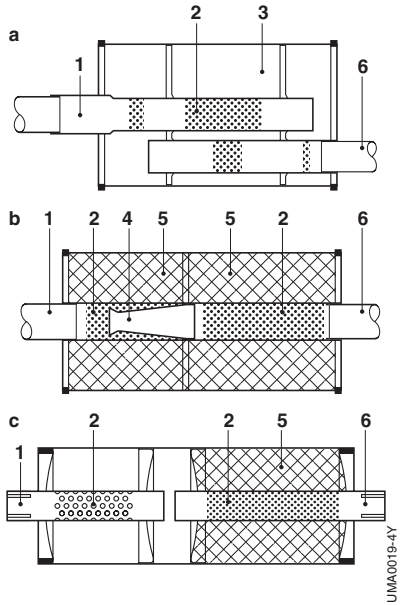
Design
In the same way as the ceramic monolith for the catalytic converter, the ceramic particulate filter is made up of a large number of parallel channels. However, these channels are alternately closed (Figure 5). Consequently, the exhaust gas is forced to flow through the porous walls of the honeycomb structure. The solid particles are deposited in the pores. Depending on the porosity of the ceramic body, the filtration efficiency of these filters can attain up to 97%.

Regeneration
The soot deposits in the particulate filter induce a steady rise in flow resistance. For this reason, the particulate filter must be regenerated at certain intervals in two different processes. Details on these processes are described elsewhere (see Exhaust-gas treatment for diesel engines).

Passive process
In the passive process, the soot is burnt off by a catalytic reaction. For this purpose, an additive in the diesel fuel reduces the flammability of the soot particles to normal exhaust-gas temperatures.

Other passive regeneration options include catalytically coated particulate filters or the CRT process (see Continuous Regeneration Trap).

Active process
In the active process, external measures are implemented to heat the filter to the temperature necessary for burning off the soot. This rise in temperature can be achieved by a burner mounted upstream of the filter or by secondary injection initiated by the engine management and the use of a preliminary catalytic converter.



Mufflers

Mufflers (or silencers) are intended to smooth out exhaust-gas pulsations and make them as inaudible as possible. There are essentially two physical principles involved: reflection and absorption. Mufflers also differ according to these principles. However, they mostly comprise a combination of reflection and absorption.

In a reflection muffler (Figure 6a) the sound waves travel through the pipes and are reflected at the pipe outlet in the chambers. In an absorption muffler (Figure 6b) the sound waves spread over the perforation in the absorption material, where they are then muffled. Figure 6c shows a combination of reflection muffler and absorption muffler.

As mufflers and the exhaust-gas system pipes together form an oscillating system with its own natural resonance, the position of the mufflers is highly significant for the quality of sound-damping. The objective is to tune the exhaust-gas systems as low as possible, so that their natural frequencies do not excite bodywork resonances. To avoid structure-borne noise and to provide heat insulation for the vehicle underbody, mufflers often have double walls and an insulating layer.

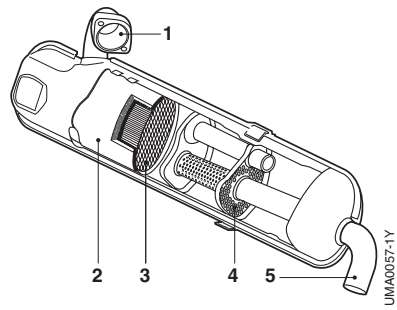


Figure 6: Muffler principles

b) Absorption muffler,
c) Combination of reflection and absorption mufflers.
1 Inlet pipe,
2 Perforated pipe,
3 Chamber,
4 Venturi nozzle,
5 Absorption material,
6 Outlet pipe.

Reflection mufflers

Reflection (resonator-type) mufflers consist of chambers of varying lengths which are interconnected by pipes (Figure 6a and Figure 7). The pipes and partitions are perforated, thereby allowing exhaust gases to pass through. The differences in the cross-sections between the pipes and the chambers, the diversion of the exhaust gases, and the resonators formed by the connecting pipes and the chambers generate superpositions of the sound waves moving back and forth, causing the sound waves to be partially extinguished. In this way, effective muffling is achieved, particularly in the middle and low frequency ranges. The more such chambers are used, the more efficient is the muffler.

Figure 7: Muffler with integrated catalytic converter
1 Inlet pipe,
2 Mounting mat,
3 Ceramic monolith,
4 Reflection muffler,
5 Tailpipe.

Absorption mufflers

Absorption mufflers are designed with one chamber, through which a perforated pipe passes (Figure 6b). The chamber is filled with absorption material (mineral wool or glass fibers). The sound enters the absorption material through the perforated pipe and is converted into heat by friction.

The absorption material usually consists of long-fiber mineral wool or glass fibers with a bulk density of 100 to 150 g/*l*. The level of muffling depends on the bulk density, the sound-absorption grade of the material, and on the length and coating thickness of the chamber. Damping takes place across a very broad frequency band, but only begins at higher frequencies.

The shape of the perforations, and the fact that the pipe passes through the wool, ensures that the material is not blown out by exhaust-gas pulses. Sometimes the mineral wool is protected by a layer of stainless-steel wool around the perforated pipe.

Because the exhaust gas in absorption mufflers essentially passes through a straight pipe, the pressure loss here is very low compared with the pressure loss at the differences in the cross-sections in reflection mufflers.

Muffler design

Depending on the space available under the vehicle, mufflers are produced either as spiral-wound casing or from half-shells.

To produce the jacket for a spiral-wound muffler, one or several metal sheet blanks are shaped over a round mandril and joined together either by the longitudinal folds or by laser welding. The completely assembled and welded core is then installed in the jacket casing. It consists of internal tubes, baffles, and intermediate layers. The outer layers are then connected to the jacket in a folding or laser-welding process.

It is often not possible to effectively accommodate a spiral-wound muffler in view of the complicated space conditions in the floor assembly. In such cases, a shell-type muffler made of deep-drawn half-shells is used as it can assume virtually any required shape.

The total volume of the mufflers in a passenger-car exhaust-gas system corresponds to approximately eight to twelve times the engine displacement.

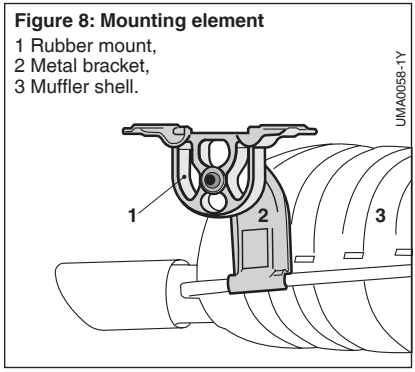
Connecting elements

Pipes are used to connect the catalytic converters and mufflers together. Arrangements where the catalytic converter and muffler are integrated in a single housing may also be used on very small engines and vehicles (Figure 7).

The pipes, the catalytic converter and muffler are connected to form an integrated system by means of plug-in connections and flanges. Many original-equipment systems are fully welded for faster mounting.

The entire exhaust-gas system is connected to the vehicle underbody via elastic mounting elements (Figure 8). The fixing points must be carefully selected, otherwise vibration may be transmitted to the bodywork and generate noise in the passenger compartment. The wrong fixing points may also create strength and therefore durability problems. In some cases, these problems are counteracted by the use of vibration absorbers. These components oscillate at the critical frequency in precisely the opposite direction of the exhaust-gas system, thereby absorbing system vibration.

Figure 8: Mounting element
1 Rubber mount,
2 Metal bracket,
3 Muffler shell.



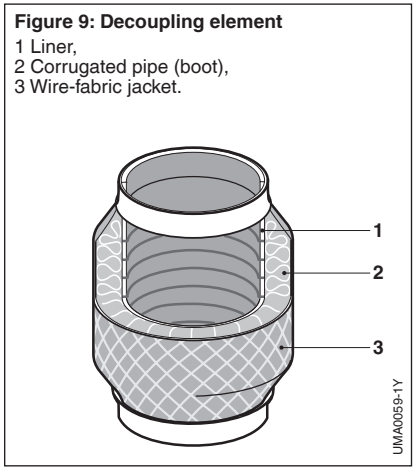


Figure 9: Decoupling element
1 Liner,
2 Corrugated pipe (boot),
3 Wire-fabric jacket.

The exhaust-gas system noise at the exhaust-emission point (tailpipe), as well as sound radiation from the mufflers, can also cause bodywork resonance. Depending on the intensity of the engine vibrations, decoupling elements (Figure 9) are used to isolate the exhaust-gas system from the engine block and to relieve the stress load on the exhaust-gas system. A decoupling element comprises the liner, i.e. an inner pipe with pipe segments that move in each other. The corrugated pipe, also known as the boot, is mounted on top. The liner serves to protect the boot and limit linear expansion. The corrugated pipe exercises the decoupling/isolating effect by way of its soft structure. The corrugated pipe is protected against external influences by a wire-fabric jacket.

Finally, the mounting arrangement of an exhaust-gas system is tuned so that it is rigid enough to withstand vibrations reliably on the one hand, and it exhibits sufficient flexibility and damping properties to reduce the transfer of forces to the bodywork effectively on the other.

Acoustic tuning devices

A number of different components can be used to eliminate disturbing frequencies in the noise emitted from the tailpipe. These components can be used specifically to damp individual frequency ranges very effectively.

Helmholtz resonator
The Helmholtz resonator consists of a pipe arranged along the side of the exhaust-gas train and a defined volume connected to it (Figure 10). The gas volume acts as a spring, while the gas in the pipe section acts as a mass. At its resonant frequency, this spring-mass system provides a very high degree of sound absorption but in a narrow frequency band. The resonant frequency f is dependent on the size of the volume V as well as the length L and the cross-sectional area A of the pipe:

$$f = \frac{c}{2\pi} \sqrt{\frac{A}{L \cdot V}}$$

The value c is the speed of sound.

λ/4 resonators
λ/4 resonators consist of a pipe, sealed at the end, branching off from the exhaust-gas system. The resonant frequency f of these resonators is derived from the length L of the pipe branch. It is expressed as:

$$f = \frac{c}{4L} .$$

These resonators also feature a very narrowband damping range about their resonant frequency.

Exhaust-gas flaps
Exhaust-gas flaps are most commonly found in rear mufflers. Depending on the engine speed or exhaust-gas throughput, they close off a bypass pipe in the muffler or a second tailpipe (Figure 11). As a result, exhaust-gas noise can be substantially damped at lower engine speeds without the need to trade off power losses at high engine speeds.

Exhaust-gas flaps can be either self-controlling based on pressure and flow, or they can be controlled externally. An interface to the engine management system must be provided for externally controlled flaps. This makes them more complex than self-controlled flaps. However, their application range is also more flexible.

Figure 10: Helmholtz resonator

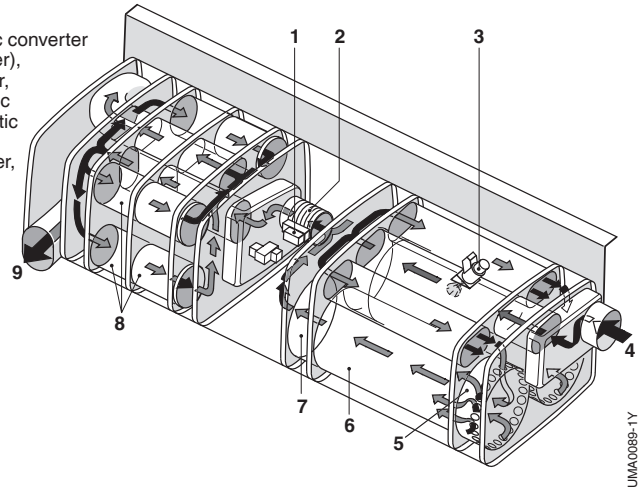
Commercial-vehicle exhaust-gas systems

In commercial-vehicle exhaust-gas systems most of the previously described components are integrated in a housing which is mounted to the vehicle frame. The number of catalytic converters and particulate filters depends on which emissions-control legislation the exhaust-gas system is designed for.

Figure 12: Commercial-vehicle exhaust-gas system for Euro IV
1 SCR catalytic converters, 2 Inlet pipe,
3 Outlet pipe, 4 Tailpipe, 5 Exhaust-gas inlet.



Exhaust-gas systems for Euro IV and Euro V

Generally speaking, a particulate filter is not required for Euro IV and Euro V. Only oxidation and SCR catalytic converters are used (see Exhaust-gas treatment for diesel engines). Alternatively, the diesel engine can also be tuned in such a way that the untreated NO_x emissions comply with the limit values for Euro IV and Euro V. But then a particulate filter is required in the exhaust-gas system.

Figure 12 shows a Euro IV exhaust-gas system with SCR catalytic converters. In contrast to passenger-car exhaust-gas systems, several catalytic converters are frequently arranged in parallel in order to accommodate the required catalytic surface in the space available. Bypass pipes and holes in the bases serve to route the gases and muffle the sound. Depending on the engine size, these systems attain a volume of 150 to 200 *l* and a weight of 150 kg.

Figure 13: Commercial-vehicle exhaust-gas system for Euro VI and EPA 10

2 Decoupling element,
3 HC injector,
4 Inlet pipe,
5 Pre-oxidation catalytic converter (pre catalytic converter),
6 Diesel particulate filter,
7 Post-oxidation catalytic converter (post catalytic converter),
8 SCR catalytic converter,
9 Outlet pipe.

Exhaust-gas systems for EuroVI and EPA10

Exhaust-gas systems for the latest legislation (Euro IV in Europe and EPA 10 in the USA) require all the components, i.e. oxidation catalytic converters, particulate filters and SCR catalytic converters (Figure 13). They are thus even bigger in terms of volume and weight.

Two concepts are currently used. Either all the components are accommodated in a single housing or the SCR catalytic converters and the particulate filters are divided between two housings. The following components are additionally required to ensure correct functioning of exhaust-gas treatment: The SCR function requires a urea metering system (see SCR system), whose nozzle (injector) is located at a suitable location in the exhaust-gas system. Furthermore, to ensure reliable regeneration of the particulate filter, an HC metering unit is frequently needed to inject fuel (see HCI system). In both cases a position must be chosen which ensures that the liquid urea solution and the fuel are adequately vaporized and distributed. If necessary, mixers are used here to prepare the liquids better (see section on Exhaust-gas treatment).

A variety of sensors must also be accommodated in the housings. In addition to pressure sensors for monitoring the filter load, temperature sensors and NO_x sensors for monitoring NO_x conversion are required. The position of the sensors in the exhaust-gas system must, depending on the system design, be optimized to guarantee an adequate signal quality in all operating states.

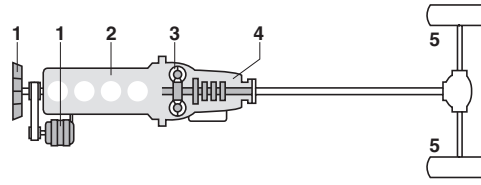
Management for spark-ignition engines

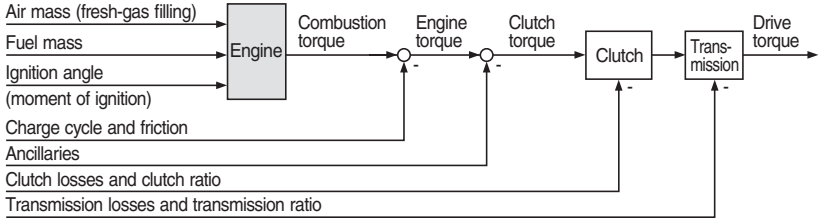
Description of the engine management system

The engine management system ensures that the driver command is implemented. The driver can request acceleration, deceleration or driving at a constant speed – the engine management system ensures that the spark-ignition engine's drive output required to achieve this is set. The system controls all engine functions in such a way that the engine delivers the required level of torque, but fuel consumption and exhaust emissions are kept low.

The power output from a spark-ignition (SI) engine is determined by the available clutch torque and the engine speed. The clutch torque is the torque developed by the combustion process less friction torque (friction losses in the engine), pumping losses, and the torque needed to drive the auxiliary equipment (Figure 1). The drive torque is available at the wheels. This is developed from the clutch torque reduced by the losses in the clutch and in the transmission. This resulting torque is offset by the tractive resistances such as rolling resistance and aerodynamic drag. Depending on the driver command, a state of equilibrium or imbalance exists between these resistances and the drive torque. When the resistances and the drive torque are equal, a constant driving speed is adopted, otherwise the vehicle is subject to acceleration or deceleration.



Combustion torque is generated in the engine's power cycle and is mainly determined by the following variables:
– The air mass which is available for combustion when the intake valves close,
– The fuel mass available in the cylinder,
– The point at which the combustion takes place.



Furthermore, there are also minor influences, for example, due to mixture composition (amount of residual exhaust gas) or combustion processes.

The primary function of engine management is to coordinate the various subsystems (air, fuel and ignition systems) in order to adjust the torque requested by the engine and at the same time meet the exacting standards placed on exhaust-gas emissions, fuel consumption, power output, comfort, and safety. The engine-management system also performs diagnoses on the subsystems.

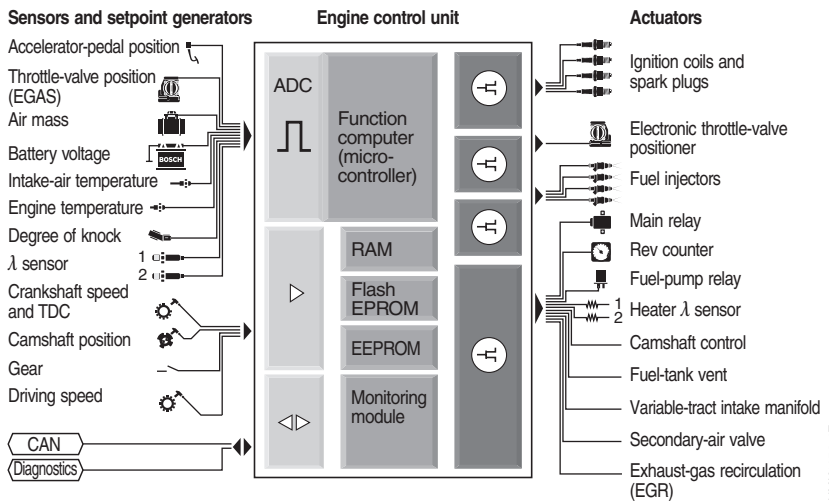
System overview

Electrical system overview



Motronic is the name given to Bosch systems for the open- and closed-loop control of spark-ignition (SI) engines. The Motronic system (Figure 2) comprises all the sensors for detecting ongoing operating data from the engine and vehicle, and all the actuators that perform the required adjustments to the SI engine. The control unit uses data from the sensors to scan the status of the vehicle and engine at very short intervals (every few milliseconds to meet the system's real-time requirements). Input circuits suppress sensor-signal interference and convert the signals to a single uniform voltage scale. An analog/digital converter then transforms the conditioned analog signals into digital values. Other signals are received via digital interfaces (e.g. CAN bus, FlexRay) or via pulse-width-modulated (PWM) interfaces.

The nerve center of the engine control unit is a microcontroller with a program memory (e.g. flash EPROM), which stores all the process control algorithms – i.e. arithmetical processes performed according to a specific pattern – and data (parameters, characteristics, program maps). The input variables derived from the sensor signals influence the calculations in the algorithms, and thus the triggering signals for the actuators. From these input signals, the microcontroller detects the sort of vehicle response the driver wants and calculates, for example, the required torque, the resulting cylinder charge with the associated injected fuel quantity, the correct ignition timing, and the triggering signals for the actuators (e.g. the evaporative-emissions control system, the exhaust-gas turbocharger, and the secondary-air system).

The low-level signal data from the microcontroller outputs are adapted by the driver stages to the levels required by the various actuators.

Another important function of Motronic is the monitoring of the operational ability of the entire system, using On-Board Diagnostics (OBD). Legal requirements (diagnosis legislation) have placed extra demands on Motronic, with the result that about half of Motronic system capacity (in terms of computing power and memory requirements) is dedicated to diagnostics-related tasks.

Figure 2: Components used for electronic control of a spark-ignition engine

Functional system overview
An engine management system has many other secondary functions in addition to its primary functions of cylinder-charge control, fuel supply, mixture formation, and ignition. The entire system is broken down into subsystems so that they can be described more clearly and in greater detail. The full description is shown in the system structure (Figure 3).

Torque Demand (TD) subsystem
The driver issues a concrete driver command through the accelerator-pedal position. The accelerator-pedal position is converted into a setpoint value for the drive torque.

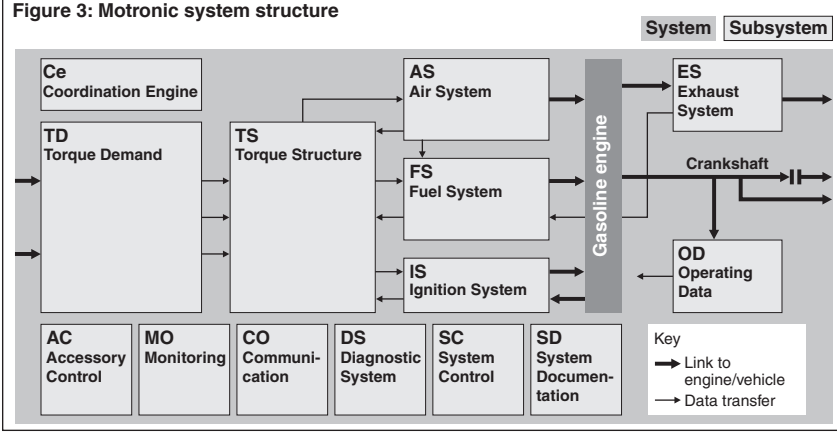
As well as a direct torque input, the driver can also input an indirect driver command via the cruise-control system. A setpoint drive torque is calculated, depending on the current driving condition.

When the accelerator pedal is not pressed, that amount of engine torque which is needed to maintain idle speed is calculated.

Drivability filters, the surge-damping function, the electrical system (starter, alternator, battery) and other electrical consumers such as the air-conditioning system issue further torque demands.

Torque Structure (TS) subsystem
The varied torque demands from the Torque Demand subsystem, demands from the transmission system, driving-dynamics demands, and other engine-specific torque demands (e.g. catalytic-converter heating) are coordinated in the Torque Structure subsystem. The result is the generation of a torque demand made of the internal-combustion engine.

Setpoint values for charge, injection and ignition are generated from the resulting torque demand of the engine.



The charge is input as a relative air mass. The relative air mass (standardization for all engine-performance classes) is the ratio between the real air mass in the cylinder and the maximum possible air mass in the cylinder at the current engine speed.

The setpoint value for ignition is described by an ignition angle.

Torque reductions can be represented with injection blank-outs (e.g. traction control system demand). The number of blank-outs is determined for this purpose.

In systems with gasoline direct injection, it is possible to set lean-burn operating modes (e.g. stratified fresh charge in the combustion chamber). In these operating modes, it is also possible to set the engine torque by inputting a λ setpoint value.

Figure 3: Motronic system structure

Physical models calculate the actual engine torque at the clutch from various sensor signals. The actual torque is used to monitor the Motronic system and is required by other systems such as transmission control.

Air System (AS) subsystem
The input of the relative setpoint air mass from the Torque Structure subsystem is converted into concrete quantities for the actuators which are used for cylinder-charge control.

The throttle valve is the main actuator for charge. Models are used to calculate the throttle-valve opening angle from the setpoint air mass and from this opening angle, a pulse-width-modulated activation of the actuator.

There are systems in which the main setting path is represented by the activation of intake and exhaust valves. The throttle valve usually remains constantly open in such systems. Only in special situations (e.g. in limp-home mode) is the throttle valve used in these systems as the setting path for charge.

In turbocharged engines, wastegate activation for the exhaust-gas turbocharger or control of mechanical superchargers are also taken into consideration.

The camshaft adjustment systems and exhaust-gas recirculation valves are further setting devices.

In addition, the current actual charge of the internal-combustion engine is determined. Sensor signals such as pressure and temperature in the intake manifold are used as basic variables for this purpose.

Fuel System (FS) subsystem
The function of the fuel system is to supply the fuel rail with fuel from the fuel tank in the requested quantity and at the prespecified pressure.

By using the current actual charge, the fuel pressure in the rail and the pressure in the intake manifold, the opening duration of the fuel injectors is calculated from the λ setpoint value.

The fuel injectors are activated synchronously with the crank angle in order to optimize the air/fuel mixture.

Longer-term adaptations of the actual value for λ ensure greater pilot-control accuracy of fuel metering.

Ignition System (IS) subsystem
The resulting ignition angle is calculated from the setpoint input for ignition, from the engine operating conditions and on the basis of interventions (e.g. knock control), and an ignition spark is generated at the spark plug at the desired moment of ignition.

The ignition angle is set in such a way that the engine runs with optimal consumption. The subsystem only deviates from this in a few special situations (e.g. catalytic-converter heating or fast torque reduction when changing gear).

The knock-control system permanently monitors combustion in all the cylinders. It ensures that the engine runs with optimal consumption close to the knock limit. At the same time, damage caused by combustion knock is safely avoided. Failures in the knock-detection path are subject to continuous monitoring so that ignition can be effected in the event of a fault at sufficient distance from the knock limit.

Exhaust System (ES) subsystem
The open- and closed-loop control interventions for optimum operation of the three-way catalytic converter are calculated in this subsystem. The combustion mixture must be regulated within narrow limits around the stoichiometric mixture ratio.

The operational capability of the catalytic converter is also monitored. The signals from exhaust-gas sensors (e.g. λ oxygen sensor) serve as the basis for this monitoring.

Component protection functions ensure that the exhaust system is not subject to thermal overloads. The actual temperatures in the exhaust system required for this purpose are usually modeled.

In lean-burn operating modes with stratified fresh charge (in the case of gasoline direct injection), the combustion mixture is also controlled to ensure optimum operation of the NO_x storage catalytic converter.

Coordination Engine (CE) subsystem
In the case of gasoline direct injection, the operating modes (e.g. operation with homogeneous or stratified mixture distribution in the combustion chamber) are coordinated and switched over. In order to determine the required operating mode, the demands of various functionalities must be coordinated on the basis of defined priorities.

Operating Data (OD) subsystem
The Operating Data subsystem evaluates engine operating-condition variables (e.g. engine speed, temperatures), ensures digital conditioning and plausibilization, and makes the result available to the other subsystems.

Adaptation of tolerances in speed sensing helps to control injection and ignition more accurately.

Engine misfires – as a precondition for catalytic-converter protective functions – are detected.

Accessory Control (AC) subsystem
Additional functionalities such as A/C-compressor control, fan control or engine-temperature regulation are frequently integrated into the engine management system. They are coordinated in the Accessory Control subsystem.

Communication (CO) subsystem
The vehicle network contains many other systems (e.g. transmission control, Electronic Stability Program), as well as the Motronic system. The systems exchange information via standardized interfaces (e.g. CAN communication).

In addition, workshop testers can read out signals from the engine management system and perform defined actuator adjustments (actuator diagnosis).

Diagnostic System (DS) subsystem
The operational capability of the Motronic system is subject to continuous monitoring by diagnostic functions. These include both electrical and plausibility checks though comparisons of sensor signals with models. Faults are stored and managed (e.g. faults are assigned "time stamps"). The faults can be called up at a later stage on workshop testers.

Some diagnostic functions are only operational under certain boundary conditions (e.g. in specific temperature or load ranges). There are also diagnostic function which must occur in a prespecified sequence. Coordination of this sequence control is performed by the Diagnostic System.

Monitoring (MO) subsystem
"Drive by wire" systems are relevant to monitoring. The core function is torque comparison. This compares the permissible torque calculated on the basis of driver command with the actual torque calculated from the engine data.

On further levels, the computer core and its peripherals are monitored.

System Control (SC) subsystem
The run-up of the Motronic system is regulated. Computing frameworks must be provided before individual functionalities are calculated. Different computing frameworks (e.g. frameworks with angle or time synchronism) are required for the resource optimization of the computing time.

Defined functionalities (e.g. function diagnosis of output stages) occur before the engine starts. Sequence control also handles resets and ECU run-on.

System Document (SD) subsystem
In addition to the extensive open- and closed-loop control functions of the Motronic system, numerous documents are required in order to describe a concrete project in detail. These documents include system descriptions of the ECU hardware and software, the wiring harness, the engine data, components, and connection-pin assignments.

Motronic versions for passenger cars

History
Originally, Motronic's function essentially combined electronic fuel injection and electronic ignition in a single control unit. Gradually, more and more functions were added in response to legislative requirements to reduce exhaust-gas emissions, reduce fuel consumption, and meet increased demands in terms of performance, driving comfort, and driving safety. Examples of these additional functions are:
– Idle-speed control,
– λ control,
– Control of the evaporative-emissions control system,
– Exhaust-gas recirculation to reduce NO_x emissions and fuel consumption,
– Control of the secondary-air system to reduce HC emissions in the starting and warm-up phases,
– Control of the exhaust-gas turbocharger and variable-tract intake manifold to increase engine performance,
– Camshaft control to reduce exhaust-gas emissions and fuel consumption and to increase performance,
– Component protection (e.g. knock control, engine-speed limitation, exhaust-gas temperature control).

The basis for the first Motronic, which was introduced from 1979 onwards in production vehicles, was the L-Jetronic fuel-injection system with air-flow sensing and electronic ignition with rotating distributor system for a manifold-injection engine with individual-cylinder injection and a conventional, mechanical throttle valve. This M-Motronic was further developed like the injection and ignition systems further used in parallel for this purpose. For load sensing the air-flow sensor was replaced by the air-mass meter, which enables the engine load to be sensed more accurately. Electronic ignition with rotating ignition distributor system was replaced by fully electronic ignition with static distributor system, in which a separate ignition coil generates the high voltage for each cylinder.

In addition to systems with electronic multipoint fuel injection, the following simpler and, at that time, cost-effective systems were also developed to allow Motronic to be used in mid-range and compact vehicles:
– KE-Motronic, based on KE-Jetronic continuous gasoline injection,
– Mono-Motronic, based on Mono-Jetronic intermittent single point injection.

State of the art
Now, only multipoint fuel-injection systems and fully electronic ignition are used for new vehicles. The following Motronic versions are used:
– ME-Motronic with electronic throttle control (ETC) for controlling injection, ignition, and fresh-air charge on intake-manifold injection systems (Figure 4).
– DI-Motronic (Direct Injection), with additional open- and closed-loop control functions for the high-pressure fuel circuit on gasoline direct-injection systems and to implement the various operating modes of this engine type (Figure 5 for homogeneous operation, Figure 6 for lean-burn concept).
– Bifuel-Motronic for controlling components for running the spark-ignition engine on natural gas or gasoline (see Engines fueled by natural gas).

Motronic versions for motorcycles

The huge diversity of motorcycles available on the market internationally is reflected in the wide range of requirements imposed on engine management. Engine management has not by a long shot arrived on the scene in all segments and markets of the motorcycle sector. The Asian market in particular – India and China – is dominated by single-cylinder vehicles with low engine displacement under 150 cm^3 which are still entirely reliant on carburetor technology. Today, the persistent widespread use of air-cooled engines (see Engine cooling) is a particular characteristic of the motorcycle market.

Because of stricter, applicable legislation for example in Europe (see Emission-control and diagnosis legislation) motorcycles under 150 cm^3 already have electronic engine-management systems.

Motronic for multiple-cylinder engines
Adapted engine-management systems from the passenger-car sector are used for large-capacity multiple-cylinder engines in motorcycles.

Motronic for single-cylinder engines
For single-cylinder engines there are standalone solutions for engine management. A distinction is made between the following systems:
– MSE-M Motronic (SE, Small Engines) for controlling ignition and fuel injection on intake-manifold injection systems with mechanical throttle valves.
– MSE-E Motronic for controlling ignition, fuel injection and fresh-air charge on intake-manifold injection systems with electronic throttle valves (ETC).

Two particular features of these single-cylinder engines for motorcycles are the high rotational non-uniformities of the crankshaft (Figure 7) and the high intake manifold-pressure dynamics over a working cycle (see Cylinder charge). This behavior characteristic of single-cylinder engines can be used to implement the assignment of the engine position to the compression cycle or to the exhaust cycle without a camshaft speed sensor.

System simplifications in the small-engine segment play a key role in equipping the huge number of motorcycles in Asia with efficient engine management.

Requirements
A further requirement that sets apart engine management for motorcycles – both single- and multiple-cylinder motorcycles – from that for passenger cars is the higher rpm range to be covered between idle and maximum speeds. This imposes high demands on the computing capacity of Motronic.

The increasing requirements with regard to exhaust-gas quality and requirements from on-board diagnosis (see Emission-control and diagnosis legislation) will result in system-engineering changes in the future. Thus, a second, heated λ sensor downstream of the catalytic converter is used for example to diagnose catalytic-converter aging. The catalytic converter itself must be adapted in terms of its dimensions to the more stringent limits. The catalytic-converter heating strategy performed by the engine management makes an important contribution to heating the catalytic converter quickly.

Cylinder charge

Component parts

The gas mixture located in the cylinder after the intake valves have closed is termed the cylinder charge. It consists of the supplied fresh A/F mixture and the residual exhaust gas. The major components that influence the cylinder charge are shown in Figure 1. The throttle valve is the most important component on modern systems.

Fresh A/F mixture
The component parts of the fresh A/F mixture drawn in are fresh air and – on systems with external mixture formation – the fuel suspended in it (Figure 1). Most of the fresh air flows through the throttle valve; additional fresh A/F mixture can be drawn in through the evaporative-emissions control system. The air mass present in the cylinder after the intake valves have closed is the decisive factor in the work performed above the piston during combustion, and ultimately in the torque delivered by the engine. Therefore, measures for increasing maximum torque and maximum engine power almost always require an increase in the maximum possible cylinder charge. The theoretical maximum charge is predetermined by the piston displacement and, in the case of turbocharged engines, by the achievable charge-air pressure, as well.

9 Residual exhaust-gas charge (combustion-chamber pressure),
10 Exhaust gas (exhaust-gas backpressure),
11 Intake valve,
12 Exhaust valve,
13 Throttle valve (butterfly valve).
α Throttle-valve angle.

Residual exhaust gas
The residual exhaust gas in the charge is formed by:
– the mass of exhaust gas that remains in the cylinder or is stored briefly during the charge cycle in the intake or exhaust port and then drawn back again, and is not ejected on completion of the charge cycle via the exhaust valve, and
– in the case of systems with exhaust-gas recirculation by the mass of the returned exhaust gas.

The amount of residual exhaust gas is determined by the charge cycle. It does not contribute directly to the combustion process, but does influence ignition and the combustion process as a whole. At wide-open throttle, the amount of residual exhaust gas generally needs to be as small as possible in order to maximize the fresh-air mass and also the power output of the engine.

At part load, however, the amount of residual exhaust gas is desirable in order to reduce fuel consumption. This is achieved by a more favorable cycle, resulting from a change in mixture composition, and also by a reduction in pump losses during the charge cycle, as a higher intake-manifold pressure is required for the same air charge. A specifically introduced amount of residual exhaust gas can likewise reduce the emission of nitrogen oxides (NO_x) and unburned hydrocarbons (HC).

Control of cylinder charge

On spark-ignition (SI) engines with external mixture formation (intake-manifold injection) and on systems with internal mixture formation (gasoline direct injection) and homogeneous cylinder charge, the torque delivered by the engine is determined by the air charge. In contrast to this, in the case of internal mixture formation with an air surplus, the engine torque can also be controlled directly by varying the injected fuel mass (stratified-charge operation).

Throttle valve

The critical adjustment mechanism for controlling air-mass flow supplied to the cylinders is the throttle valve. When the throttle valve is not fully open, the air flow drawn in by the engine is throttled, thus reducing maximum engine torque. This throttling effect is dependent on the position, and thus the opening cross-section of the throttle valve, as well as on engine speed (Figure 2). Maximum torque is developed with the throttle valve wide open.

By the end of the 1990s the mechanical throttle valve was state of the art. The driver directly controls the opening of the throttle valve via a Bowden cable by pressing the accelerator pedal.

On systems with electronic throttle control (ETC), the required air charge is calculated from the desired engine torque, which is obtained from the accelerator-pedal position, and the throttle valve is activated accordingly.

Electronic throttle control (ETC) components

The electronic throttle control system (Figure 3) consists of the accelerator-pedal module, the engine control unit, and the throttle device. The throttle device mainly consists of the throttle valve, the electric throttle-valve drive element, and the throttle-valve position sensor. The drive element is a DC motor, which acts on the throttle-valve shaft via a gear unit. The throttle-valve position sensor, designed as a redundant unit, detects the position of the throttle valve.

The driver command is detected by the redundant sensor system in the accelerator-pedal module, and the signal is sent to the engine control unit. This calculates the required cylinder charge, based on the current engine operating point, and regulates the opening angle of the throttle

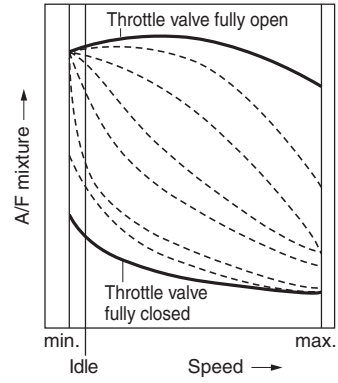

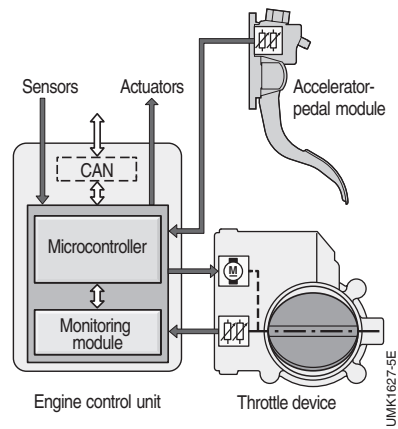

Figure 3: ETC system

valve by means of the throttle-valve drive element and the throttle-valve position sensor.

The redundancies incorporated in the accelerator-pedal module and the throttle device are part of the ETC monitoring concept for avoiding malfunctions.

Charge cycle

The charge cycle of fresh A/F mixture and residual exhaust gas is controlled by the opening and closing of the intake and exhaust valves. The opening and closing times of the valves (timing) and the valve lift curve are critical factors.

Valve timing

Valve overlap, i.e. the overlap of the opened times of the intake and exhaust valves, has a decisive influence on the mass of residual outlet gas remaining in the cylinder. The quantities of fresh A/F mixture and residual exhaust gas in the cylinder can be controlled by changing the valve-lift time curves.

In the overlap phase exhaust gas flows through the intake valve into the intake system due to the pressure differential between the exhaust system and the intake manifold. In the induction stroke it then returns to the combustion chamber (internal exhaust-gas recirculation). The longer the valve overlap lasts (early opening of the intake valve), the more mass of exhaust gas remains in the cylinder. This results in shortened combustion temperatures and thus a reduction in NO_x emissions.

However, since recirculated exhaust gas displaces fresh A/F mixture, opening the intake valve early also leads to a reduction in the maximum torque. In addition, excessively high exhaust-gas recirculation, particularly at idle, can lead to combustion misses which, in turn, cause an increase in HC emissions. With variable valve timing, varying the timing dependent on the operating point can optimize emissions.

By varying the valve timing accordingly (e.g. continuous adjustment of the phase position and valve lift), it is possible to control the air-mass flow, and thus engine performance, without having to use the throttle valve. The amount of residual exhaust gas can also be adjusted by means of valve timing.

On today's systems, the valves are actuated mechanically via the camshaft. Additional measures can be used to vary this activation to a certain degree (e.g. camshaft adjustment or camshaft shifting). However, these mechanical systems cannot dispense with the throttle valve completely.

Scavenging

In modern turbocharged engines valve-gear variabilities are additionally used to increase significantly the torque in the low-rpm range. This timing strategy is called scavenging. For this purpose the phase position of the intake valves and if necessary the exhaust valves are adjusted in the full-load range in such a way as to produce a valve overlap. During the valve overlap a partial flow of air passes directly again through the exhaust valve to the exhaust side, improving the scavenging of residual gas and with it enhancing anti-knock performance. At the same time the additional scavenging air improves process control at the turbocharger so that higher charge-air pressures can be achieved.

Exhaust-gas recirculation (EGR)

The mass of residual exhaust gas in the cylinder can also be increased by "external exhaust-gas recirculation" (EGR). In this case, an exhaust-gas recirculation valve connects the intake manifold and exhaust manifold (Figure 1). When the valve is open and with a pressure differential between the exhaust-gas system and the intake manifold, the engine draws in a combination of fresh A/F mixture and exhaust gas. The engine ECU calculates the level of exhaust-gas recirculation for a specific operating state, and activates the exhaust-gas recirculation valve accordingly.

Fuel reduction

Exhaust-gas recirculation increases intake-manifold pressure. The higher intake-manifold pressure leads to a reduction in the charge cycle work and this lowers fuel consumption.

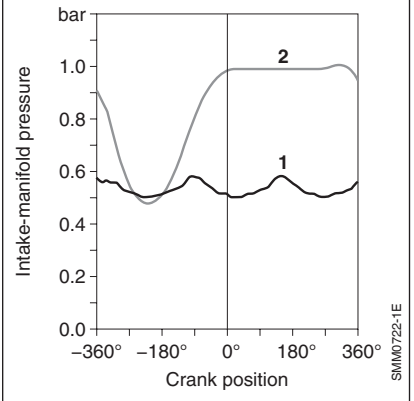
NO_x reduction
Exhaust-gas recirculation is used on engines with gasoline direct injection which operate in lean-burn mode (stratified-charge operation) to reduce NO_x emissions. Exhaust-gas recirculation is the main way to minimize untreated NO_x emissions, and thus prolong the duration of lean-burn operation, which is limited by the NO_x storage catalytic converter.

Exhaust gas can be conducted back to the combustion chamber to reduce peak combustion temperatures. The reduction in temperature is based on the fact that the returned exhaust gas does not participate in the combustion and thus delivers no combustion energy. It is also an additional thermal mass, which means that the combustion energy distributes itself to a higher overall mass.

Higher combustion temperatures induce an over-proportional increase in NO_x formation, and as exhaust-gas recirculation (EGR) reduces combustion temperatures, it represents a particularly effective means of controlling NO_x emissions.

Supercharging
The torque obtainable is proportional to the charge of fresh A/F mixture. This enables an increase in the maximum torque in that the air in the cylinder is compressed by means of dynamic charging, mechanical charging or exhaust turbocharging (see Supercharging).

Recording of air charge



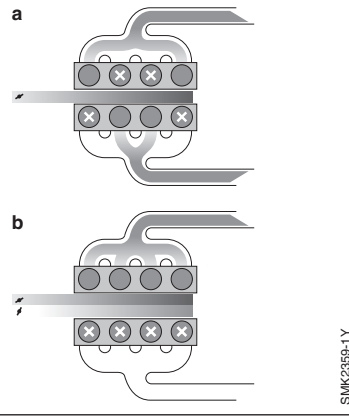
The cylinder charge crucially influences the power output, fuel consumption, and emissions. The composition of the air/fuel mixture plays a decisive role here (see Mixture formation, see Catalytic exhaust-gas treatment). To be able to adjust this correctly, it is necessary among others things to record the cylinder charge in the engine-management system with great precision. The throttle valve, as the central adjustment mechanism, determines the pressure in the intake manifold and uses this to influence the air-mass flow. Therefore the intake-manifold pressure is one of the central input variables which the engine management draws on to calculate the cylinder charge. The fresh-air mass however still depends on many additional factors, such as the ambient pressure, the throttle-valve leakage, the position of the gas-exchange valves, the operating status of the exhaust-gas turbocharger, the position of the swirl control valves, and the exhaust-gas recirculation. To take these influences into account, the engine-management system has in part further sensor technology, such as a hot-film air-mass meter to determine the cylinder charge.

Particularities for motorcycles
Motorcycles generally have less variability in the air system. Turbocharging, exhaust-gas recirculation and variable valve timing have barely featured up to now. Variable intake-manifold geometries have hitherto been the preserve of vehicles of higher performance classes. Particularly in small single-cylinder engines, therefore, the air charge is recorded purely by way of the throttle-valve position and intake-manifold pressure.

Compared with typical passenger-car applications, there are systematic differences in the intake manifold-pressure behavior. These are primarily attributable to different, geometric conditions. While in passenger-car applications a common throttle valve is for the most part used for a number of cylinders, motorcycles frequently rely on individual throttle valves (see Motorcycle intake manifolds). These are installed close to the cylinder head to guarantee good response. The absence of a classic manifold means that the volumes between the throttle valve and the intake valves are comparatively small. This results in small ratios of intake-manifold volume to displacement of the individual cylinder. This factor influences the intake manifold-pressure behavior (see Figure 4). While for a car a virtually constant vacuum is obtained in the intake manifold with a comparable load point and comparable engine speed, for a motorcycle the vacuum is achieved only briefly during the intake phase. As soon as the intake valves are closed, fresh air flows through the throttle valve and the intake-manifold pressure increases to ambient pressure. This behavior must be taken into account in the recording of charge by the engine management since the mean intake-manifold vacuum can only be used to a limited extent to determine the fresh-air mass.

Figure 4: Pressure characteristic in the intake manifold of car and motorcycle at part load

1 Three-cylinder car engine,
2 Single-cylinder motorcycle engine.



Cylinder shutoff

On engines with cylinder shutoff individual cylinders can be shut off at part load. The cylinders that continue to fire then generate the entire demanded torque. The air charge required for this is roughly doubled when every second cylinder is shut off referred to the corresponding full-engine operating point. The lower gas-exchange losses as a result of the de-throttling of the fired cylinders give rise to reduced fuel consumption. The gas-exchange losses can be further reduced by shutting off the gas-exchange valves of the non-fired cylinders. This shutoff necessitates accordingly designed valve gear (see Valve gear).

The most important motivation behind an engine design with cylinder shutoff is the reduction of fuel consumption. Since diesel engines are as a rule operated under de-throttled conditions to a large extent, the advantage is confined to the shutoff of the charge cycle. The reduced consumption that can be achieved by cylinder shutoff is dependent, aside from the operating-point profile, on the individual engine and drivetrain design. In gasoline engines with charge-cycle shutoff, it is realistic to achieve improvements in the higher single-digit percentage range in the conventional driving cycles and in the double-digit percentage range at individual operating points at low load.

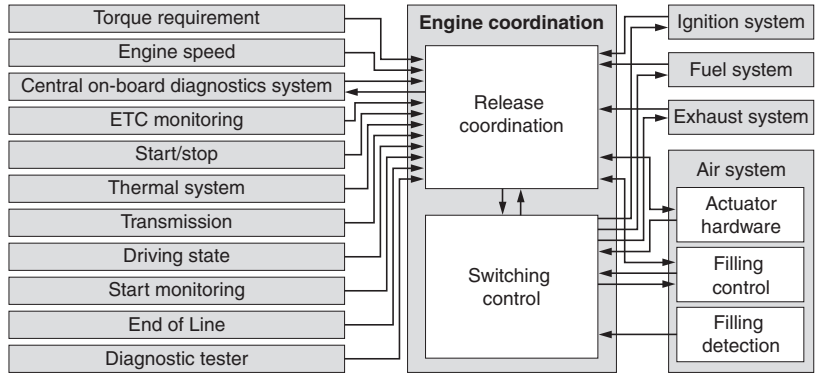
Figure 5: Configuration of cylinder shutoff
a) Half-engine operation,
b) Cylinder-bank shutoff.

Configuration of cylinder shutoff
A cylinder shutoff can be implemented both in an engine with multiple cylinders and in an engine with only two cylinders. Different cylinder-shutoff configurations are possible here. The possible configurations are derived from the engine's design features. The most important criteria are the firing order and the respective layout of the intake and exhaust tracts. In most series applications every second cylinder in firing order and consequently half the cylinders is shut off. In half-engine operation (Figure 5a) shuttable-off and permanently fired cylinders are operated in the same bank. Here it is necessary to shut off the charge cycle, since λ control and the conversion capability of the catalytic converter would not be guaranteed with the oxygen that otherwise enters the exhaust tract.

When all the cylinders in an exhaust bank are shut off (cylinder-bank shutoff, Figure 5b), charge-cycle shutoff can also be dispensed with. This reduces the design complexity and the costs, but does not exploit the full CO_2 savings potential of cylinder shutoff.

Adaptation of vehicle components
With regard to NVH aspects (Noise Vibration Harshness), it may, aside from the valve gear, also be necessary to adapt the design of the dual-mass flywheel, the engine bearings, and the exhaust-gas system. An intake-manifold pressure sensor may also be needed to diagnose the valve actuators.

Engine management
Engine management is particularly important when it comes to operating an engine with cylinder shutoff. Partial-engine operation necessitates the adaptation of numerous software functions (Figure 6). Furthermore, additional functions for requirement and changeover coordination and diagnosis of the valve actuators for zero stroke are required.



Control of the changeover between full- and partial-engine operation is particularly complex because all the changeovers must take place imperceptibly to the driver and the response must not be delayed compared with full-engine operation. As well as charge adaption, exactly timed fading-out and -in of fuel injection for the shuttable-off cylinders and interventions via the moment of ignition are required for this purpose. Therefore, as well as engine coordination, torque structure, air, fuel, ignition and exhaust systems, and ETC monitoring are also adapted.

Cylinder-shutoff requirement
Operating-mode control by engine management constantly monitors numerous conditions for cylinder shutoff. Among the most important input variables is the setpoint torque to be developed by the engine, since the maximum settable torque is limited with cylinder shutoff. Another important input variable is the engine speed, since reliable switching of the gas-exchange valves is not possible above a limit speed. Further input variables are the engine temperature and the driving speed. Conditions are assigned to each input variable. On this basis either partial- or full-engine operation is requested.

Changeover between partial- and full-engine operation
The changeover to partial-engine operation begins with the increase of the air charge so that the still-fired cylinder can generate the entire demanded engine torque. In an engine with one intake manifold the increase is effected jointly for all the cylinders. In an engine with separate intake manifolds the air change can be changed for the still-fired cylinder bank regardless of the bank to be shut off. To deliver the required setpoint torque, the moment of ignition must be retarded accordingly. As soon as a sufficient torque reserve has been created by way of the air-charge buildup, the gas-exchange valves can be deactivated for the cylinders to be shut off and fuel injection faded out. The moment of ignition is then advanced again.

The changeover to full-engine operation begins with the activation of charge cycle and fuel injection and ignition-angle adjustment. The moment of ignition is advanced in parallel with the charge adaptation.

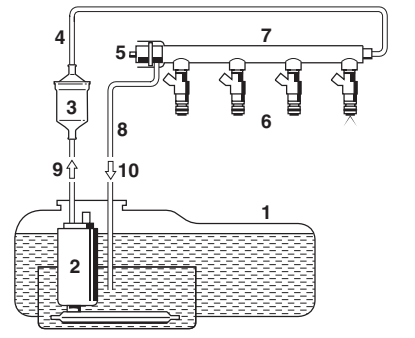
Figure 6: Overview of the coordination of engine management for cylinder shutoff

Fuel supply

Fuel supply and delivery with intake-manifold injection

Different system configurations operating with intake-manifold injection typically at fuel pressures of approx. 300 to 400 kPa (3 to 4 bar) are used to supply fuel.

System with fuel return
The electric fuel pump delivers the fuel and generates the injection pressure (Figure 1). The fuel is drawn from the fuel tank and passes through the fuel filter into the high-pressure line, from where it flows to the engine-mounted fuel rail (fuel distributor). The rail supplies the fuel to the fuel injectors.



The mechanical fuel-pressure regulator mounted on the rail is a differential-pressure regulator with pneumatic connection to the intake manifold. It keeps the difference between fuel pressure in the rail and the intake-manifold pressure constant. The amount of fuel metered by the fuel injectors depends on this pressure differential because fuel is injected against the pressure in the intake manifold. Because the pressure regulator regulates to a constant pressure differential irrespective of the absolute intake-manifold pressure – i.e., irrespective of the engine load – the amount of fuel injected is only dependent on the duration of the fuel-injector activation time (injection time).

The fuel not needed by the engine flows through the rail via the return line connected to the fuel-pressure regulator back to the fuel tank. This excess fuel heated in the engine compartment causes the fuel temperature in the fuel tank to rise. Fuel vapor is generated as a function of fuel temperature. Ensuring adherence to environmental-protection regulations, the vapors are routed through a tank-ventilation system for intermediate storage in a carbon canister until they can be returned through the intake manifold for combustion in the engine (see Evaporative-emissions control system).

Returnless system
In a returnless fuel-supply system the fuel-pressure regulator is located in the fuel-supply module installed in the fuel tank, which means that the return line from the engine to the fuel tank is no longer required (Figure 2). Since the fuel-pressure regulator on account of its installation location has no reference to the intake-manifold pressure, the relative injection pressure compared with the intake-manifold pressure is not dependent on the engine load. This is taken into account in the calculation of the injection time in the engine control unit.

Only the amount of fuel which is to be injected is delivered to the rail. The excess flow volume delivered by the elec-

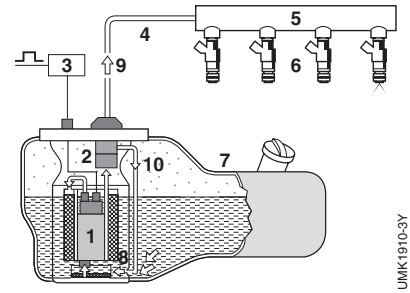
tric fuel pump returns directly to the fuel tank without taking the circuitous route through the engine compartment. In this way, fuel heating in the fuel tank and thus also evaporative emissions are significantly lower than in systems with fuel return. Because of these advantages, it is mainly only returnless systems which are now used.

Demand-regulated returnless system

In a demand-regulated system, the fuel-supply pump delivers only that amount of fuel that is currently used by the engine and that is required to set up the desired pressure. Pressure control is effected by means of a closed control loop in the engine control unit, whereby the current fuel pressure is recorded by a pressure sensor (Figure 2). This dispenses with the mechanical fuel-pressure regulator. To vary the delivery quantity the triggering power of the electric fuel pump is altered by means of a clock module that is triggered by the engine control unit; the triggering is performed with pulse-width modulation (PWM).

The system is equipped with a pressure-relief valve to prevent the buildup of excessive pressure even during overrun fuel cutoff or after the engine has been switched off.



As a result of demand control, no excess fuel is compressed and thus the capacity of the electric fuel pump is minimized. This results in reduced fuel consumption compared with system with non-controlled electric fuel pumps. The in-tank fuel temperature can also be further reduced.

Further advantages of a demand-regulated system are derived from the variably adjustable fuel pressure. On the one hand, the pressure can be increased during hot starting to prevent the formation of vapor bubbles. On the other hand, it is possible above all in turbocharging applications to meter better the very large injected quantities required at high loads and the very small quantities at idle (injected-fuel-quantity spread) by effecting a pressure increase at full load and a pressure decrease at very low loads. This resolves the problem of metering small quantities in the fuel-injector configuration.

Furthermore, the measured fuel pressure provides for improved diagnostic options for the fuel system compared with previous systems. More precise fuel metering is achieved by taking into account the current fuel pressure when calculating the injection time.

Fuel supply and delivery with gasoline direct injection

Compared with injecting fuel into the intake manifold, there is only a limited time window available for injecting fuel directly into the combustion chamber. Mixture formation is therefore more important and fuel must be injected in the case of direct injection at a pressure approximately 50 times greater than is the case with intake-manifold injection.

The fuel system is divided into a low-pressure circuit and a high-pressure circuit.

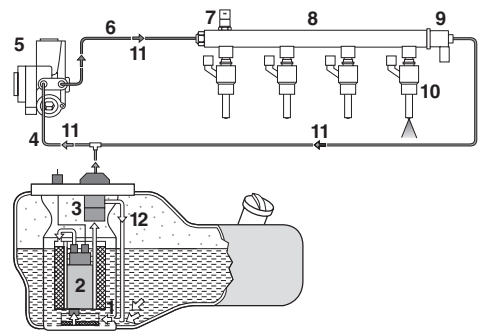
Low-pressure system

With gasoline direct injection the low-pressure system serves to supply the high-pressure system, involving the use of the same fuel systems and components as intake-manifold injection. Because of the high temperatures at the high-pressure pump in hot-start and hot-running conditions, a higher predelivery pressure (admission pressure) is required to prevent the formation of vapor bubbles. It is therefore an advantage to use systems with variable low pressure. Demand-regulated low-pressure systems are therefore particularly suitable here, because they allow the optimum admission pressure to be set for every engine operating state; this admission pressure usually varies in a range of 300 to 600 kPa (3 to 6 bar) relative to the ambient pressure.

Demand-controlled systems are increasingly being used as a further variant. In contrast to demand-regulated systems, in which the pressure is adjusted via a closed control loop by the pressure sensor, the pressure sensor is omitted here and the system costs are thus reduced. The electric fuel pump is activated 100 % by pilot control as a function of the engine operating point.

High-pressure system

High-pressure fuel circuits use predominantly demand-regulated high-pressure pumps as well as continuous-delivery high-pressure pumps. However, continuous-delivery high-pressure pumps can still be found in first-generation gasoline direct-injection systems.



The high-pressure system comprises the fuel rail (high-pressure rail) with high-pressure injectors and a high-pressure sensor (Figures 3 and 4). The continuous-delivery system also requires a separate pressure-control valve.

Depending on the engine's operating point, the pressure varies typically in a continuous-supply system in a range of 5 to max. 11 MPa (50 to 110 bar), and in a demand-regulated system up to max. 35 MPa (350 bar). The high-pressure sensor provides the information on the currently prevailing pressure.

The signal from the high-pressure sensor is also used for injection calculation and for fuel-system diagnostics.

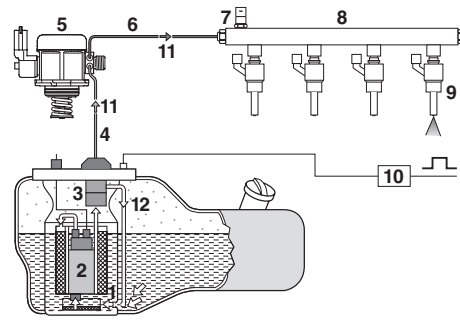
11, 12 Flow direction of fuel.

Continuous-delivery system
The high-pressure pump driven by the engine camshaft – normally a three-barrel radial-piston pump (see High-pressure pumps for gasoline direct injection) – forces fuel into the rail against the system pressure (Figure 3). The pump delivery quantity cannot be adjusted. The excess fuel not required for fuel injection and to maintain the pressure is depressurized by the pressure-control valve and returned to the low-pressure circuit. For this purpose, the pressure-control valve is actuated by the engine control unit in such a way as to obtain the injection pressure required at a given operating point. The pressure-control valve also serves as a mechanical pressure-relief valve.



In continuous-delivery systems, most of the operating points cause significantly more fuel to be compressed to high system pressure than is needed by the engine. This results in unnecessary energy consumption and thus higher fuel consumption than demand-regulated systems. The excess fuel released via the pressure-control valve also contributes to increasing the temperature in the fuel system. For these reasons, only demand-regulated high-pressure systems are used in modern direct-injection engines.

Demand-regulated system
In a demand-regulated system (Figure 4), the high-pressure pump – usually a single-barrel radial-piston pump (see High-pressure pumps for gasoline direct injection) – delivers to the fuel rail only the precise amount of fuel which is actually needed for injection and to set the desired pressure. The pump is usually driven by the engine camshaft, single-barrel pumps being driven via special cams which drive the pump plunger. The delivery quantity is varied by a fuel-supply control valve which is integrated in the high-pressure pump. The engine control unit actuates this valve with each pump lift with such precision as to provide the required delivery quantity in order to set the system pressure needed in the rail for the given operating point (see Fuel-supply control valve).

For safety reasons the high-pressure circuit incorporates a mechanical pressure-relief valve, which is usually integrated directly in the high-pressure pump. Should the pressure exceed the permissible level, fuel is returned via the pressure-relief valve to the low-pressure circuit.

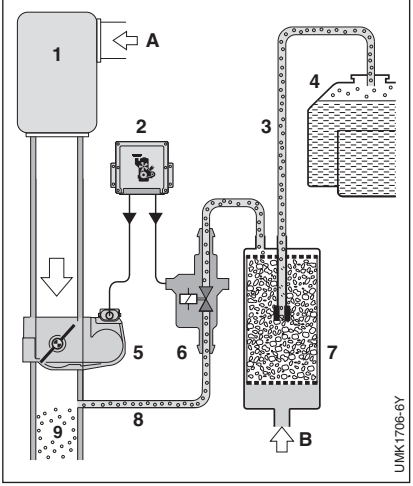
Evaporative-emissions control system

Function



An evaporative-emissions control system (tank ventilation) is required for vehicles equipped with a gasoline engine. Its purpose is to intercept and collect fuel degassing from the fuel tank and to comply with the legal stipulations governing emission limits for evaporative loss. In addition, the line from the fuel tank via the carbon canister to atmosphere provides for pressure equalization of the fuel tank which is required on account of temperature-induced expansion of the fuel or the tank system itself or while the vehicle is being refueled. Degassing increases when the fuel in the fuel tank is heated. This may be caused by the higher ambient temperatures, the power loss of the fuel pump integrated in the fuel tank or – depending on the fuel supply system – the return of fuel heated in the engine and no longer required for the combustion process. Degassing also occurs when the ambient pressure drops, for example due to weather influences or when driving uphill.

Design and operating principle

The evaporative-emissions control system consists of a carbon canister, into which the vent line from the fuel tank projects, as well as a canister-purge valve that is connected both to the carbon canister as well as to the intake manifold (Figure 5). The activated carbon absorbs the fuel vapor. Due to the vacuum prevailing in the intake manifold, fresh air is drawn through the activated carbon when the canister-purge valve frees up the line between the carbon canister and the intake manifold when driving. The fresh air picks up the absorbed fuel and feeds it to the combustion process. This is know as purging the carbon canister.

The engine control unit controls the purge-gas volume depending on the engine operating point. In order to ensure that the carbon canister is always able to absorb fuel vapor, the activated carbon must be regenerated at regular intervals. Since current gasoline engines are operated to increase efficiency in such a way that a high intake-manifold vacuum is avoided (e.g., with downsizing, exhaust-gas turbocharging, lean-burn concepts), adequate regeneration is often not feasible. In this case an additional regenerating line is used which utilizes the pressure drop after the air filter for additional vacuum generation (Figure 6). In turbocharged engines a venturi tube can also be used for this purpose. This utilizes a small part of the charge-air pressure to generate a suction flow to the carbon canister using the loss of pressure at its constriction. A non-return valve is integrated in each ventilation path so that there are no circular flows.

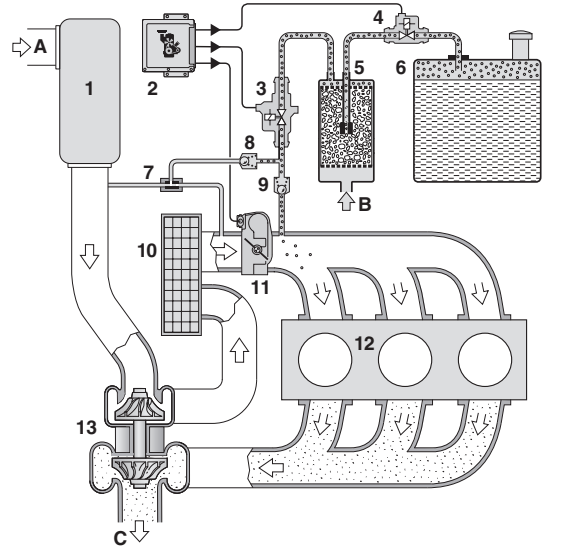
Pressure tank
With hybrid vehicles, which can be run on purely electric power for longer distances, there is in some cases no further opportunity for regeneration. In this case, the usual fuel tank made of plastic is replaced by a pressure-resistant steel tank which is connected via a further shutoff valve mounted on the tank to the carbon canister (Figure 6). In the event of increased degassing the pressure in such a tank rises, which counteracts further degassing of the fuel. If the pressure in the tank reaches critical values, the tank pressure is regulated by the engine ECU, whereby the additional shutoff valve opens and the fuel vapors are channeled into the carbon canister. The tank pressure must also be reduced to refuel the vehicle. For regeneration, operation of the internal-combustion engine is then explicitly requested by the engine ECU.



Gasoline filter

Function
The function of the fuel filter is to filter the fuel that flows into the fuel system. Contaminants in the fuel must be filtered out in order to protect the system and in particular the fuel injectors.

Design
Fuel filters for gasoline engines (gasoline filters) are located on the pressure side after the fuel-supply pump. In-tank filters are the preferred choice in newer vehicles, i.e., the filter is integrated in the fuel-supply module in the fuel tank. In this case, it must always be designed as a lifetime filter, which does not need to be changed over the full service life of the vehicle. Furthermore, in-line filters, which are installed in the fuel line, continue to be used. These can be designed as replacement parts or lifetime parts.

The filter housing is manufactured from steel, aluminum or plastic. It is connected to the fuel feed line by a thread, tube or quick-action connection. The housing contains the filter element, which filters

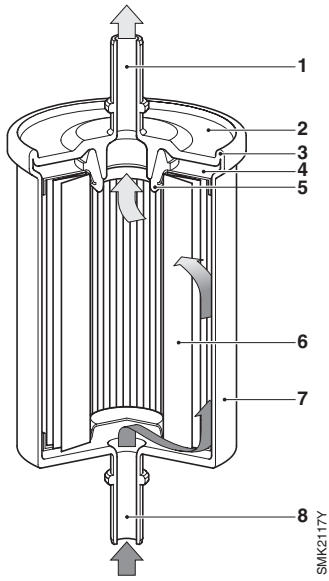
the dirt particles out of the fuel (Figure 7). The filter element is integrated in the fuel circuit in such a way that fuel passes through the entire surface of the filter medium as much as possible at the same flow velocity.



Filter medium

Special resin-impregnated cellulose-fiber papers which are also bonded for heavier-duty applications to a synthetic-fiber (meltblown) layer are used as the filter medium. This bond must ensure high mechanical, thermal and chemical stability. The paper porosity and the pore distribution of the filter paper determine the filtration efficiency and throughflow resistance of the filter.

Fuel filters for gasoline engines are either spiral vee-form or radial vee-form in design. In a spiral vee-form filter, an embossed filter paper is wrapped round a support tube. The fuel flows through the filter in the longitudinal direction.

Figure 7: In-line gasoline filter

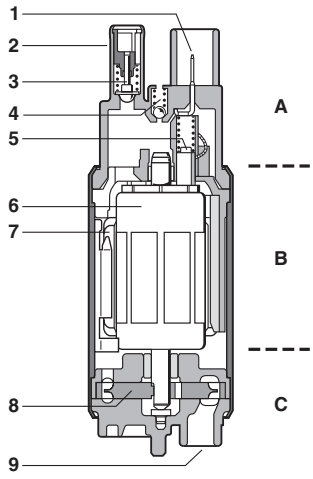
1 Fuel outlet, 2 Filter cover,
3 Laser-welded edge, 4 Support ring,
5 Seal, 6 Radial vee-form filter medium,
7 Pressure-stable filter housing,
8 Fuel inlet.

In a radial vee-form filter, the filter paper is folded and inserted into the housing in the shape of a star (Figure 7). End rings made of plastic, resin or metal and, if necessary, an inner protective jacket provide stability. The fuel flows through the filter from the outside inwards, during which the dirt particles are separated from the filter medium.

Requirements

The required filter fineness is dependent on the fuel-injection system. For systems with intake-manifold injection, the filter element has a mean pore width of approx. 10 µm. Finer filtering is required for gasoline direct injection. The mean pore width here is in the range of 5 µm. Particles larger than 5 µm must be separated off by up to 85 %. In addition, a filter for gasoline direct injection, when new, must satisfy the following residual-dirt requirement: Metal, mineral and plastic particles and glass fibers with diameters of more than 400 µm must not be flushed by the fuel out of the filter.

Filter efficiency depends on the throughflow direction. When replacing in-line filters, it is imperative that the flow direction specified by the arrow be observed.



The interval for changing conventional in-line filters is, depending on filter volume and fuel contamination, normally between 30,000 km and 120,000 km. In-tank filters can generally be used for at least 250,000 km before they have to be replaced. This corresponds to today's design lifetime for a gasoline engine. There are in-tank and in-line filters available for use with gasoline direct-injection systems which feature service lives in excess of 250,000 km. If the in-tank filter has to be exchanged, this is only possible by completely changing the fuel-supply module.

Electric fuel pump

The electric fuel pump must deliver sufficient quantities of fuel to the engine and maintain the pressure required for efficient fuel injection in all operating states. Essential requirements include:
– Delivery quantity between 40 and 300 *l*/h at nominal voltage
– Pressure in the fuel system between 300 and 650 kPa (3.0 to 6.5 bar)
– Buildup of system pressure from 50 to 60 % of nominal voltage; the decisive factor here is operation during cold starting.

Apart from this, the electric fuel pump is increasingly being used as the pre-supply pump for the modern direct-injection systems used on diesel and gasoline engines. In the case of gasoline direct injection, sometimes pressures of up to 650 kPa must be provided during hot-delivery operation.

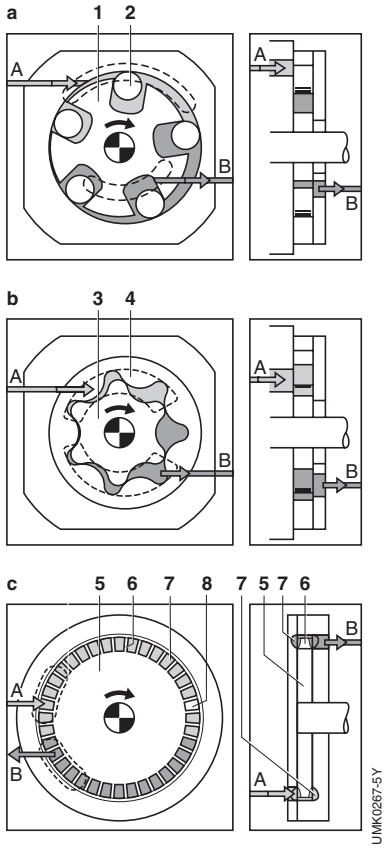
5 Commutator with carbon brushes,
6 Motor armature with windings which are energized by the commutator,
7 Magnet,
8 Impeller ring of flow-type pump,
9 Hydraulic connection (fuel inlet).

Electric motor
The plunger-and-barrel assembly (pump element) of the electric fuel pump (Figure 8) is driven by an electric motor. An armature with copper or carbon commutator is used as standard in this engine. Electronic commutating systems without commutators and carbon brushes are increasingly being used in new vehicles that appear on the market. The design of the electric motor depends on the desired delivery quantity for a given system pressure. It is continuously surrounded by flowing fuel and thereby cooled.

End cover
The end cover contains the electrical connection and the pressure-side hydraulic connection. The non-return valve prevents the fuel lines from draining after the electric fuel pump is switched off; this ensures that the system pressure is maintained for a certain period of time after switch-off.

A pressure-relief valve is integrated as required. Most end covers also include the carbon brushes for the commutation system and interference-suppression elements (inductance coils, with capacitors in some applications).

Plunger-and-barrel assembly
The plunger-and-barrel assembly is designed as a positive-displacement or flow-type pump.



Positive-displacement pump
In a positive-displacement pump, volumes of liquid are basically drawn in and transported in a closed chamber (apart from leaks) by rotation of the pump element to the high-pressure side. A roller-cell pump (Figure 9a), an internal-gear pump (Figure 9b) or a screw-spindle pump may be used for the electric fuel pump.

Roller-cell pump
The slotted rotor arranged eccentrically in the pump housing has metal rollers around its circumferences which are

loosely guided in the slot-shaped openings. The centrifugal force generated by the rotation of the slotted rotor and the fuel pressure press the rollers against the pump housing and the driving flanks of the slots. The rollers operate here as circulating seals. The fuel is delivered in the chamber created between in each case two rollers of the slotted rotor and the pump housing. The pumping effect is created by the fact that, after the inlet opening is sealed, the chamber volume is continuously reduced until the fuel leaves the pump through the outlet opening.

Figure 9: Electric fuel-pump principles
a) Roller-cell pump,
b) Internal-gear pump,
c) Flow-type pump.

A Fuel inlet (suction opening),

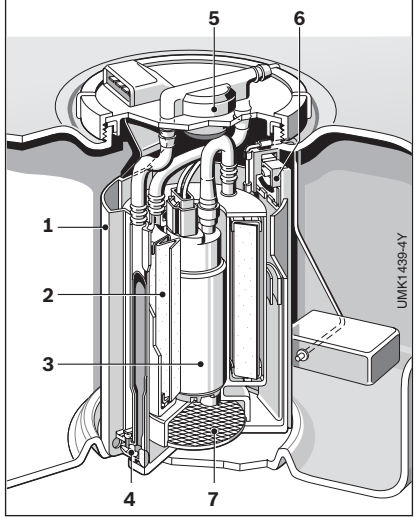
1 Slotted rotor (eccentric),
2 Roller,
3 Internal drive wheel,
4 Rotor (eccentric),
5 Impeller,
6 Impeller blades,
7 Passage (peripheral),
8 Gas-discharge orifice.

Internal-gear pump
The internal-gear pump consists of an internal drive wheel which engages an eccentrically arranged outer rotor. This outer rotor has one tooth more than the drive wheel. The tooth flanks that are sealed against each other create during the rotation process in their spaces variable chambers which provide the pumping effect.

Positive-displacement pumps are advantageous when used with high-viscosity media, e.g. cold diesel fuel. They have a good low-voltage characteristic, i.e. they have a relatively "flat" delivery-rate characteristic over the operating voltage. Efficiency can be as high as 40 %. The unavoidable pressure pulses may cause noise; the extent of this problem varies according to the pump's design configuration and mounting location.

Whereas in electronic gasoline-injection systems the positive-displacement pump has to a large extent been superseded by the flow-type pump for the classical electric-fuel-pump requirements, it has gained a new field of application as the pre-supply pump on diesel common-rail systems with their significantly greater pressure requirements and viscosity range.



Flow-type pump
The flow-type pump has become the accepted solution for gasoline applications. An impeller ring equipped with numerous peripheral vanes rotates within a chamber consisting of two fixed housing sections (Figure 9c). Each of these sections features a passage along the path of the impeller blades, with openings at one end of the passage starting at the suction openings. From there, they extend to the point where the fuel exits

the plunger-and-barrel assembly at system pressure. A small gas-discharge orifice, located at a specified angular distance from the suction opening, improves performance when pumping hot fuel; this orifice facilitates the discharge of any gas bubbles that may have formed (with minimal leakage).

Pressure builds up along the passage as a result of the exchange of pulses between the impeller blades and the liquid particles. This leads to spiral-shaped rotation of the liquid volume trapped in the impeller and in the passages.

Flow-type pumps feature a low noise level since pressure buildup takes place continuously and is practically pulsation-free. Pump design is also much less complex than the positive-displacement unit. System pressures of up to 650 kPa can be achieved. The efficiency of these pumps can, depending on the operating point, exceed 30 %.

Figure 10: Fuel-supply module
1 Swirl pot,
2 Fuel filter,
3 Electric fuel pump,
4 Suction jet pump,
5 Fuel-pressure regulator,
6 Fuel-level sensor,
7 Prefilter.

Fuel-supply module

Whereas in the early stages of electronic gasoline injection the electric fuel pump was mounted exclusively outside the fuel tank (in-line), it is common practice today to install the pump inside the tank itself. The electric fuel pump forms an integral part of a fuel-supply module (in-tank unit, Figure 10) which may comprise further elements:

– a swirl pot,
– a fuel-level sensor (see Sensors),
– a fuel-pressure regulator for returnless fuel supply systems,
– a prefilter for protecting the pump,
– a pressure-side fine-mesh fuel filter, which will not need replacing for the entire life of the vehicle,
– and electrical and hydraulic connections.
– Tank pressure sensors (for diagnosing tank leaks), fuel-pressure sensors (for demand-regulated systems) and valves for tank ventilation may also be incorporated.

The swirl pot is situated centrally in the fuel tank. The suction side of the electric fuel pump is inserted in this beaker-shaped container. When the tank level is high, fuel flows over the beaker edge, when the level is low, fuel passes through a small opening in the beaker base or through the return line of the electric fuel pump into the swirl pot. When the vehicle is cornering, accelerating and braking, the fuel in the fuel tank flows to one side, which, when the tank level is low, could cause the fuel supply to be interrupted. The fuel can only escape slowly from the swirl pot through the small opening such that the fuel supply is safeguarded for a certain period of time.

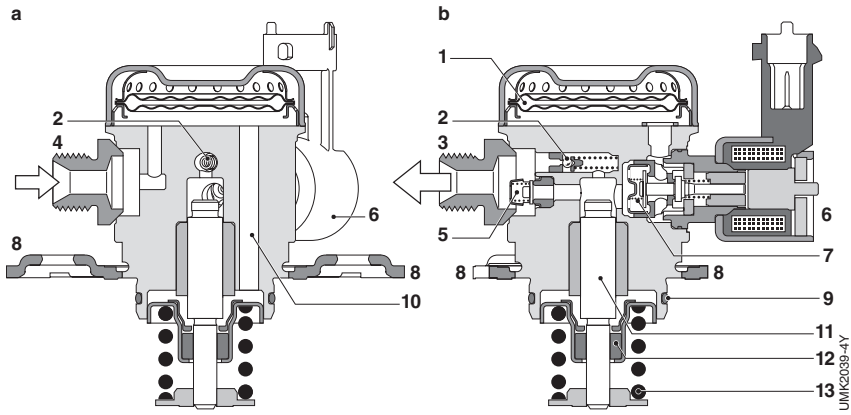
The swirl pot can be filled passively, for example by a flap system or a change-over valve, or actively by a suction jet pump. This pump is designed as a venturi nozzle and does not contain any moving parts. The returning fuel flows as a driving medium into this pump and is accelerated after being discharged through the nozzle. In accordance with Bernoulli's law this produces a pressure drop. In this way, fuel from the fuel tank is drawn in through a second inlet and delivered under pressure with the returning fuel to the pump outlet.

High-pressure pumps for gasoline direct injection

The function of the high-pressure pump is to compress the fuel supplied in sufficient quantity by the electric fuel pump at an rpm- and temperature-dependent admission pressure (program-map value) to the level required for high-pressure injection.

Demand-regulated high-pressure pump

Design and operating principle



The Bosch demand-regulated high-pressure pump is used in systems for gasoline direct injection for injection pressures up to 20 MPa (2nd-generation gasoline direct injection). Subsequent further development of the second generation increases the pressure range to 25 MPa and improves the acoustics of the fuel-supply control valve. The third generation increases the pressure range to 35 MPa, facilitates a greater delivery quantity, and once again improves the acoustics.

The high-pressure pump is a cam-driven single-barrel pump running in oil (Figure 11) with an integrated fuel-supply control valve (also called the metering unit), an integrated pressure-relief valve on the high-pressure side and an integrated fuel-ressure attenuator on the low-pressure side. To comply with future stringent fuel standards and in response to emission-control legislation, the pump is made of stainless steel and is welded at all the emission-relevant connection points.

The high-pressure pump is mounted as a plug-in pump on the cylinder head. The interface between the engine camshaft and the delivery barrel is a bucket tappet for a double cam (Figure 12a), and a roller tappet for triple and quadruple cams (Figure 12b). This ensures that the cam lift curve is transferred to the delivery plunger (pump plunger) of the high-pressure pump with the requirements with regard to lubrication, Hertzian stress and mass inertia. During the cam lift the tappet follows the contour of the cam. This results in the vertical motion, or stroke, of the delivery plunger. In the delivery stroke the push

Figure 11: Demand-regulated single-cylinder high-pressure pump for 2nd-generation gasoline direct-injection systems

rod absorbs the applied pressure, mass, spring and contact forces. It is rotationally secured in the process.

With a quadruple cam, time synchronization of delivery and injection is possible in a four-cylinder engine, i.e., each injection is also accompanied by a delivery. In this way, it is possible – due to the pressure dip in the rail – on the one hand to reduce excitation of the high-pressure circuit and on the other hand to reduce the rail volume.

In order to ensure that the system pressure can still be sufficiently quickly achieved or varied with the engine at maximum fuel demand, the maximum delivery quantity of the high-pressure pump is configured for maximum demand plus necessary factors which affect delivery behavior (e.g., high-pressure starting, hot gasoline, pump aging, dynamic response).

The volumetric efficiency is derived from the ratio of actually delivered fuel quantity to theoretically possible quantity. This is dependent on the delivery-plunger diameter and stroke. The volumetric efficiency is not constant across all engine speeds. It is dependent on the following factors:

– In the lower speed range: plunger and other leakages,
– In the upper engine speed range: dynamics (inertia and opening pressure) of the inlet and outlet valves,
– In the total speed range: dead volume of the delivery chamber and temperature dependence of fuel compressibility.

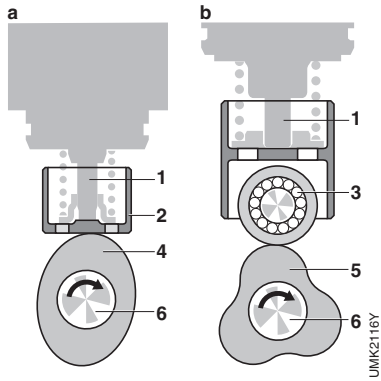

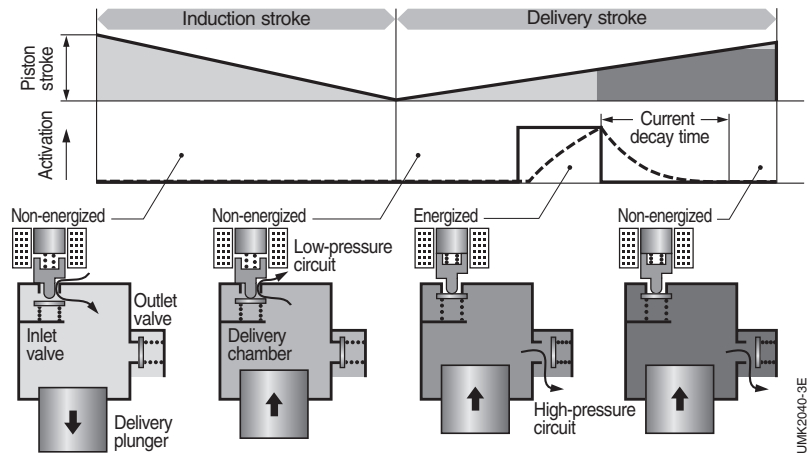

Figure 13: Activation concept of fuel-supply control valve

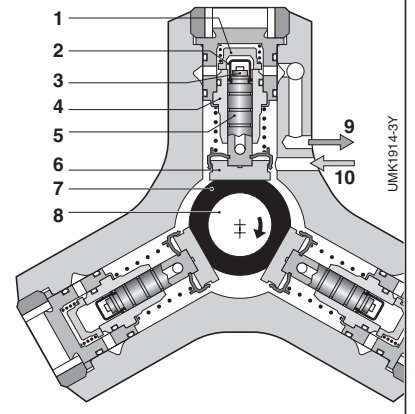

Fuel-supply control valve
Demand control of the high-pressure pump is effected with the fuel-supply control valve (Figure 13). The fuel delivered by the electric fuel pump is drawn into the delivery chamber via the inlet valve of the open fuel-supply control valve. In the subsequent delivery stroke, the fuel-supply control valve remains open after bottom dead center so that fuel that is not needed at the relevant load point is returned at admission pressure to the low-pressure circuit. After the fuel-supply control valve is actuated, the inlet valve closes, the fuel is compressed by the delivery plunger and delivered to the high-pressure circuit. The inlet valve then remains closed during the delivery stroke on account of the pressure in the delivery chamber even when the fuel-supply control valve is non-energized. The engine-management system calculates the time from which the fuel-supply control valve is actuated as a function of delivery quantity and rail pressure. The start of delivery is varied here for demand control.

Fuel-pressure attenuator
The variable fuel-pressure attenuator (Figure 11) integrated in the high-pressure pump, together with the delivery plunger designed as a stepped plunger (backpumping in the induction stroke due to the smaller diameter in the lower area causes a repumping effect), attenuate the pressure pulsations stimulated by the high-pressure pump in the low-pressure circuit and at high rotational speeds ensure a good delivery-chamber charge. The fuel-pressure attenuator takes up the fuel quantity diverted at the relevant operating point via the deformation of its gas-filled metal diaphragms and releases it again in the induction stroke to fill the delivery chamber. Operation with variable admission pressure – i.e., the use of demand-regulated low-pressure systems – is possible here.

Continuous-delivery high-pressure pump
Design and operating principle
The Bosch continuous-delivery high-pressure pump is used in systems for gasoline direct injection for injection pressures up to 12 MPa (1st-generation gasoline direct injection). It is a radial-piston pump with three delivery barrels situated at circumferential offsets of 120° (triple-barrel radial-piston pump, Figure 14).

The delivery quantity of the continuous-delivery high-pressure pump is proportional to the rotational speed. The three barrels deliver fuel at circumferential offsets of 120° in order to ensure overlapping and therefore continuous delivery. This gives rise to minimal pressure pulsations only. This means that, when compared with demand-regulated systems with single-plunger pumps, less demands

Figure 14: Continuous-delivery high-pressure pump for 1st-generation gasoline direct-injection systems (cross-section, schematic)

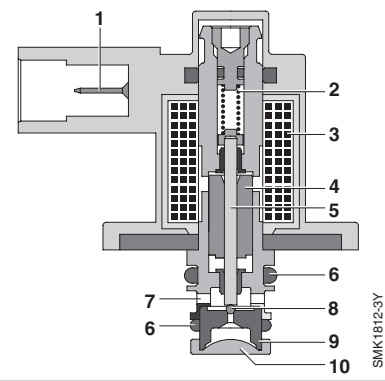
10 Fuel supply (low-pressure).

have to be placed on the pump connections and piping. Furthermore, there is no need for a low-pressure attenuator. On the downside, continuous delivery at high pressure means that it has a higher power loss than a demand-regulated pump.

When the pump operates at constant rail pressure or at part load, the pressure of the excess fuel is reduced to admission pressure level by the pressure-control valve mounted on the rail and returned to the intake side of the high-pressure pump. The pressure level in the high-pressure circuit is regulated and adjusted by means of the engine control unit, which specifically actuates the pressure-control valve.

Pressure-control valve
The pressure-control valve (Figure 15) is a proportional control valve which is closed at zero current and actuated by means of a pulse-width-modulated signal. During operation, the energizing of the solenoid coil sets a magnetic force which relieves the load on the spring, lifts the valve ball off the valve seat, and thereby alters the flow cross-section. The pressure-control valve sets the desired rail pressure as a function of the pulse duty factor. The excess fuel delivered by the high-pressure pump is diverted via the drain hole into the low-pressure circuit.

A pressure-limiting function is integrated by way of the valve spring to protect the components against unacceptably high rail pressures, for example, in the event of actuation failure. If one or more of the pump barrels should fail, emergency operation is possible with the intact barrels or by means of the electric fuel pump with admission pressure.



Fuel rail

Intake-manifold injection
The function of the fuel rail is to store the fuel required for injection, to attenuate pulsations and to ensure uniform distribution to all the fuel injectors. The fuel injectors are mounted directly on the rail. Next to the fuel injectors it is possible in systems with fuel return to integrate a fuel-pressure regulator and if necessary a fuel-pressure attenuator in the rail.

Local pressure fluctuations caused by resonance when the fuel injectors open and close is prevented by careful selection of the fuel-rail dimensions. As a result, irregularities in injected fuel quantity which can arise as a function of load and engine speed are avoided.

Gasoline direct injection
The fuel rail (Rail, Figure 16) has the task of storing and distributing the volume of fuel required for each operating point. The fuel is stored by way of its volume and compressibility. In this way, the volume or the inside diameter is engine-power-dependent and must be adapted to the relevant engine demand (injected fuel quantity) and pressure range. Full design of the rail is provided by the dimensioning of the outside diameter or the wall thick-

Figure 15: Pressure-control valve

ness of the rail to guarantee strength. The rail is designed to be operationally stable, which is checked by way of special pressure load profiles which have been derived from real operating loads. The volume also ensures hydraulic attenuation in the high-pressure range, i.e., pressure fluctuations in the rail are compensated.

The rail consists of different add-on components which act either as interfaces or as functional groups. Specifically, these are:

– a stainless-steel pipe for accommodating the volume and mounting further attachments (copper-brazed or screwed),
– retainer for securing the rail to the engine block,
– cup for accommodating the fuel injectors,
– high-pressure line connection with integrated restrictor,
– pressure-sensor connection,
– end cap,
– hold-down element for securing the injector position during operation with combustion-chamber pressure and vibration acceleration,
– wiring harness with clipped-on plastic duct (around the pipe).

In part these solid, constructed or deep-drawn attachments are also designed as function modules (e.g., retainer and cup). The fuel injectors are sealed by O-rings, the pressure sensor and the high-pressure connection by a screwed ball-taper geometry.

Figure 16: Rail for gasoline direct injection
1 High-pressure sensor, 2 Fuel injectors, 3 Retainer, 4 Rail.

A particular feature is the “suspended design” of the injector mounting, which ensures a low load thanks to its pressure-compensated construction. The drawback of this variant is the increased amount of space required.

The biggest challenge in the development of rails is the large number of necessary solutions in that it must always be integrated in the engine in an already specified installation space.

The rail for 1st-generation fuel-injection systems is designed for a pressure range up to 12 MPa (plus 0.5 MPa pressure-relief valve opening pressure). For the 2nd generation the pressure range extends up to 25 MPa (plus 5.0 MPa pressure-relief valve opening pressure), for the 3rd generation according to the high-pressure pump up to 35 MPa. The acoustics of the rail in the overall system are also improved as part of the further development.

Fuel-pressure regulator

Function
With intake-manifold injection the amount of fuel injected by the fuel injector depends on the injection period and the pressure differential between the fuel pressure in the fuel rail and the back pressure in the intake manifold. On fuel systems with fuel return, the influence of pressure is compensated for by a fuel-pressure regulator which maintains the differential between fuel pressure and intake-manifold pressure at a constant level. This pressure regulator permits just enough fuel to return to the fuel tank so that the pressure drop across the fuel injectors remains constant. In order to ensure that the fuel rail is efficiently flushed, the fuel-pressure regulator is normally located at the end of the rail.

On returnless fuel systems, the fuel-pressure regulator is part of the fuel-supply module in the fuel tank. The fuel-rail pressure is maintained at a constant level with reference to the ambient pressure. This means that the pressure differential between fuel-rail pressure and intake-manifold pressure is not constant and must be taken into account when the injection duration is calculated.

Mounting on the rail
The fuel-pressure regulator (Figure 17) is of the diaphragm-controlled overflow type. A rubber-fabric diaphragm divides the pressure regulator into a fuel chamber and a spring chamber. Through a valve holder integrated in the diaphragm, the compression spring forces a movable valve plate against the valve seat. As soon as the pressure applied to the diaphragm by the fuel exceeds the spring force, the valve opens again and permits just enough fuel to flow back to the fuel tank that equilibrium of forces is achieved again at the diaphragm.

The spring chamber is pneumatically connected with the intake manifold behind the throttle valve. As a result, the intake-manifold vacuum also has an effect in the spring chamber. There is therefore the same pressure ratio at the diaphragm as at the fuel injectors. This means that the pressure drop across the fuel injectors is solely a function of spring force and diaphragm surface area, and therefore remains constant.

Installation in the fuel-supply module
For applications in the fuel-supply module the fuel-pressure regulator can have a simpler design that the pressure regulator mounted on the rail. These simple pressure regulators (Figure 18) have therefore become the accepted choice. The fuel flows through a coarse prefilter (protecting the pressure regulator against fouling) against the valve plate. An annular gap opens when the fuel pressure exceeds the spring force that presses the valve plate against the seal seat. The fuel flows through this annular gap and returns through the pressure regulator housing directly to the swirl pot.

Fuel-pressure attenuator

Function, design and operating principle
The repeated opening and closing of the fuel injectors, high-pressure pump pulsations (the principal cause today) and the periodic supply of fuel when electric positive-displacement fuel pumps are used lead to fuel-pressure oscillations. These can cause pressure resonances which adversely affect fuel-metering accuracy. It is even possible that under certain circumstances noise can be caused by these vibrations being transferred to the fuel tank and the vehicle bodywork through the mounting elements of the electric fuel pump, fuel lines, and fuel rail. These problems are alleviated by the use of special-design mounting elements and fuel-pressure attenuators.

The fuel-pressure attenuator has a similar design to the fuel-pressure regulator. Here too, a spring-loaded diaphragm separates the fuel chamber from the air chamber. The spring force is set in such a way that the membrane rises from its seat as soon as the fuel delivery pressure reaches its working range. This means that the fuel chamber is variable and not only absorbs fuel when pressure peaks occur, but also releases fuel when the pressure drops. In order to always operate in the most favorable range when the absolute fuel pressure fluctuates due to conditions at the manifold, the spring chamber can be provided with an intake-manifold connection.

Similar to the fuel-pressure regulator, the fuel-pressure attenuator can also be attached to the rail or installed in the fuel line. In the case of gasoline direct injection, it can also be attached to the high-pressure pump.

Mixture formation

Basic principles

A/F (Air/fuel) mixture
To be able to operate, a spark-ignition engine requires an air-fuel mixture. The mixture for ideal, theoretically complete combustion requires a mass ratio of 14.7:1 (stoichiometric ratio), i.e. 14.7 kg of air are required to burn 1 kg of fuel. Or: 1 *l* of fuel burns completely in roughly 9,500 *l* of air.

The specific fuel consumption is essentially dependent on the air-fuel ratio. Excess air is required in order to ensure genuine complete combustion, and thus as low a fuel consumption as possible. However, limits are imposed due to the flammability of the mixture and the available combustion time.

The A/F mixture also has a decisive impact on the efficiency of exhaust-gas treatment systems. State-of-the-art technology is represented by the three-way catalytic converter. However, it needs a specific stoichiometric A/F ratio in order to operate at maximum efficiency. This can reduce damaging exhaust gas components by higher than 99 %. The homogeneous engines available today are therefore operated with a stoichiometric mixture as soon as their operating status allows this. By way of departure, individual direct-injection engines are also operated with a lean mixture (stratified-charge operation) in the interest of fuel economy.

Certain engine operating statuses require mixture adaptation. Selective modifications to the mixture composition are required e.g. in the case of a cold engine.

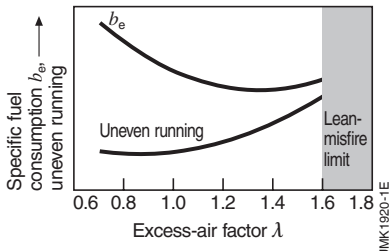
Excess-air factor λ
The excess-air factor or air ratio λ (lambda) has been chosen to designate the extent to which the actual air/fuel mixture differs from the theoretically necessary mass ratio (stoichiometric ratio 14.7:1). λ denotes the ratio of air mass in the cylinder to the air requirement in the case of stoichiometric combustion.

Stoichiometric ratio
$\lambda = 1$: The inducted air mass corresponds to the theoretically required air mass.

Air deficiency
$\lambda < 1$: This indicates air deficiency and therefore a rich A/F mixture. The maximum engine output results at $\lambda = 0.85$ to 0.95.

Enriching the air-fuel mixture may be necessary to protect components against thermal overload (component protection). This reduces the exhaust-gas temperature, since the fuel is converted not completely to CO_2, but to CO. The enthalpy for the reaction to CO is lower than for complete conversion to CO_2. A lower thermal load e.g. for exhaust-gas turbocharger, λ sensor and catalytic converter results from the lower exhaust-gas temperature.

Figure 1: Effects of excess-air factor λ on specific fuel consumption b_e and uneven running at constant power output



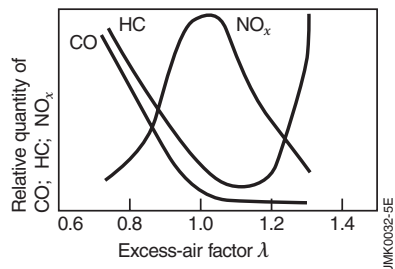


Figure 2: Effect of excess-air factor λ on pollutant composition

However, this also entails increased consumption. Enrichment is therefore only performed for high-load points for which an exhaust-gas temperature of over 900 °C would be reached.

Air surplus
$\lambda > 1$: In this range, there is an air surplus and thus a lean mixture.

This excess-air factor is characterized by reduced fuel consumption (Figure 1), but also by reduced power output. The maximum value for λ – the "lean-misfire limit" – that can be achieved is very strongly dependent on the construction of the engine and the mixture-formation system used. The mixture is no longer ignitable at the lean-misfire limit because of the lower number of HC molecules. Combustion misses occur, and this is accompanied by a marked increase in uneven running.

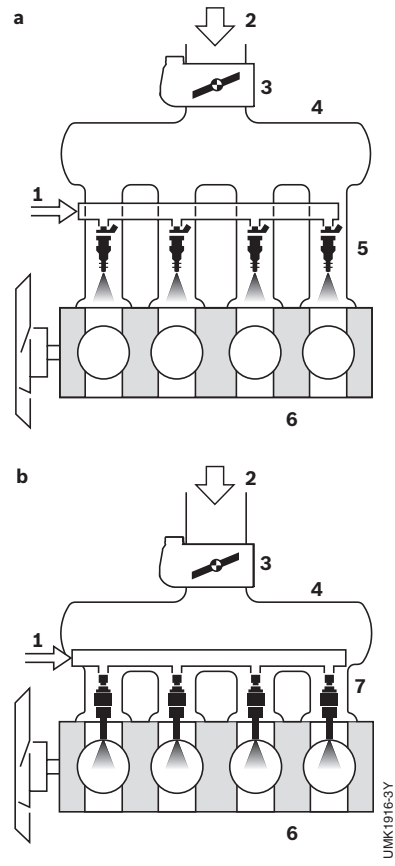
Influence of λ on fuel consumption and exhaust-gas composition
Spark-ignition engines achieve the lowest fuel consumption at constant engine output dependent on the engine at 20 to 50 % air surplus (λ = 1.2 to 1.5). This potential can however only be achieved with lean-burn concepts (homogeneous-lean or stratified-charge operation).

For a typical engine with intake-manifold injection, Figures 1 and 2 show the dependency of the specific fuel consumption and uneven running, as well as development of pollutants, on the excess-air factor at constant engine output. It can be deduced from these graphs that there is no ideal excess-air factor at which all the factors assume the most favorable value. In order to implement "optimal" consumption at "optimal" power output, excess-air factors of λ = 0.95 to 1.05 have proven conducive to the achievement of objectives for engines with intake-manifold injection and for homogeneous direct-injection engines – above all in view of exhaust-gas treatment with the three-way catalytic converter, which can optimally convert all three pollutant components only in a narrow range around λ = 1.

To achieve this, the inducted air mass is recorded precisely and an exactly metered fuel mass is apportioned by means of λ regulation in the engine-management system.

Intake-manifold injection
For optimum combustion in engines with intake-manifold injection, not only is a precise injected fuel quantity necessary, but also a homogeneous A/F mixture. This requires efficient fuel atomization. If this precondition is not satisfied, large fuel droplets will precipitate on the intake manifold or on the combustion-chamber walls. These large droplets cannot fully combust and will result in increased hydrocarbon emissions (HC).

Gasoline direct injection
Direct-injection engines with charge stratification involve different combustion conditions so that the lean-misfire limit occurs at significantly higher global λ values. In the part-load range, these engines can therefore be operated with considerably higher excess-air factors (up to λ = 4). Here too the area around the spark plug requires locally a stoichiometric mixture for good flammability.



Unfortunately, in this case of a globally lean mixture, only two of the three ways of the three-way catalytic converter function. CO emissions and unburnt hydrocarbons can still be oxidized since sufficient oxygen is available. However, the third chief reaction, reducing the NO_x emissions, cannot be carried out sufficiently in lean-operation mode, since insufficient reduction partners are available. For this reason, in addition to catalytic exhaust-gas treatment with a three-way catalytic converter, a further exhaust-gas treatment facility must be installed for NO_x reduction (e.g. an NO_x storage catalytic converter).

Mixture-formation systems

It is the job of fuel-injection systems, or carburetors, to provide an A/F mixture which is adapted as well as possible to the relevant engine operating status. Without fuel-injection systems, particularly electronic systems, it would not be possible to maintain the increasingly narrowly defined limits for mixture composition and thus to adhere to the stipulations of the emission-control legislation. These requirements and the significant improvements in fuel metering and mixture formation together with the benefits in terms of fuel consumption, driving performance and power output have meant that, in the automotive sector, gasoline injection has completely superseded the carburetor in moder engines.

Until the beginning of this century, the automotive industry almost exclusively used systems in which A/F mixture formation takes place outside the combustion chamber (intake-manifold injection, Figure 3a). Systems with internal A/F mixture formation, i.e. where the fuel is injected directly into the combustion chamber (gasoline direct injection, Figure 3b), are designed to reduce fuel consumption even further and to increase power output, and have therefore become increasingly more important.

Figure 3: Schematic representation of fuel-injection systems

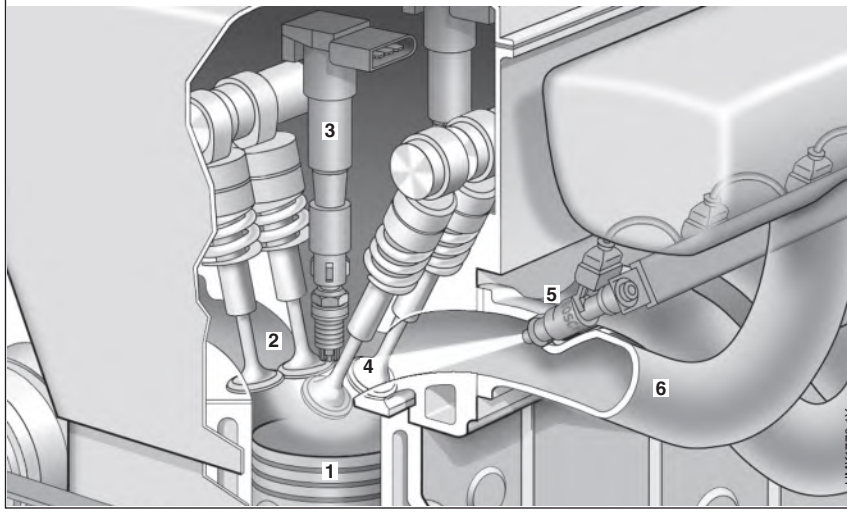
Intake-manifold injection

Gasoline injection systems for external mixture formation are characterized by the fact that the A/F mixture is created outside of the combustion chamber (in the intake manifold). The state of the art is represented by electronic intake-manifold injection systems where the fuel is injected cyclically for each individual cylinder directly ahead of the intake valves (Figure 4).

Systems that are based on mechanical-continuous fuel injection (K-Jetronic) or a central fuel injection arranged upstream of the throttle valve (Mono-Jetronic) are no longer of any significance for new developments.



Requirements

The high requirements for engine smooth-running and exhaust emissions make high demands on the A/F mixture composition in each power cycle. Precise injection timing is vital, as well as precise metering of the injected fuel mass as a factor of the engine intake air. In electronic multipoint fuel-injection systems, therefore, not only is each engine cylinder assigned an electromagnetic fuel injector, but this fuel injector is also activated individually for each cylinder. The engine control unit has the task of calculating both the required fuel mass for each cylinder and the correct start of injection for the fuel mass drawn in and the current engine operating status. The injection time required to inject the calculated fuel mass is a function of the opening cross-section of the fuel injector and the pressure differential between the intake manifold and the fuel supply system.

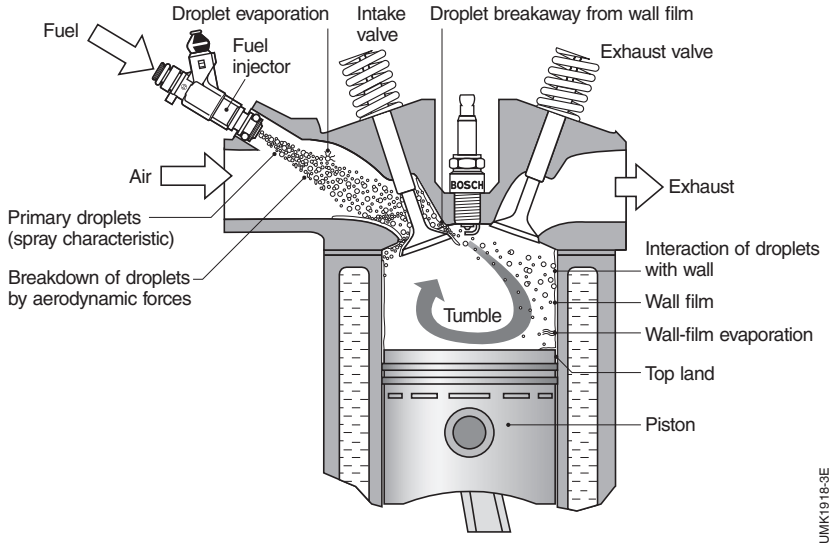
Fuel system

In intake-manifold injection systems, fuel is sent via the electric fuel pump (see Fuel supply), the fuel supply lines, and the fuel filter at typical system pressures of 3 to 7 bar to the fuel rail, which ensures that the fuel is evenly distributed to the fuel injectors. How the fuel is prepared by the fuel injectors is extremely important for the quality of the A/F mixture. It is essential that the fuel is atomized into very fine droplets. The spray shape and spray dispersal angle of the fuel injectors are adapted to the geometric shape of the intake manifold and cylinder head (see Intake-manifold fuel injector).

Figure 4: Principle of intake-manifold injection
1 Cylinder with piston, 2 Exhaust valves, 3 Ignition coil with spark plug, 4 Inlet valves, 5 Fuel injector, 6 Intake manifold.

Fuel injection

The exactly metered fuel mass is injected directly upstream of the cylinder intake valve(s). As the air enters through the throttle valve there is a pulse exchange with the finely atomized fuel, and the droplets on the surface mix increasingly with the air and therefore evaporate to a large extent (Figure 5). The required air-fuel mixture can therefore be formed at the right time by varying the point of injection.



The amount of time available for mixture formation can be increased by injecting the fuel into the intake valves that are still closed. How much air-fuel mixture is created directly after injection depends on the quality of the fuel injector (primary droplet size). In this case, the primary evaporation occurs only when the intake valves open in response to the high flow velocities with an initially very small valve gap.

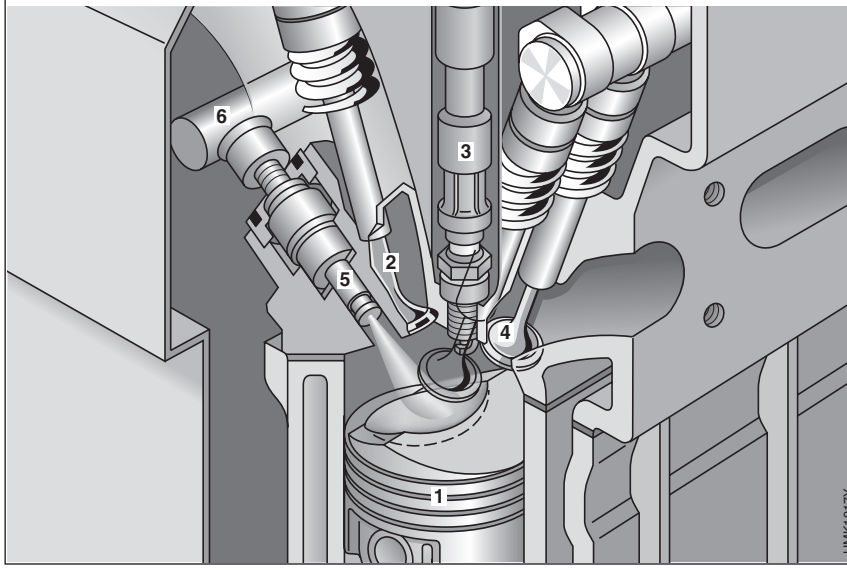
A proportion of the fuel precipitates on the intake duct (part of the intake manifold leading directly to the combustion chamber) and on the lower edge of the intake valves as wall film; the thickness of this film essentially depends on the pressure in the intake manifold, and thus on the engine load condition. In the case of non-stationary (dynamic) engine operation, this precipitation can lead to temporary deviations in the desired λ value ($\lambda = 1$), which means that the fuel mass stored in the wall film is to be kept as low as possible.

Wall-coating effects in the intake duct, particularly in cold-start conditions, cannot be neglected either. As fuel does not evaporate sufficiently, more fuel is required initially in the starting phase in order to create an ignitable A/F mixture. When the intake-manifold pressure then drops, parts of the previously formed wall film will vaporize. This may result in increased HC emissions if the catalytic converter is not running at operating temperature.

Irregular fuel injection may also result in the formation of wall films in the combustion chamber, and may in turn become critical emission sources. Defining the geometric alignment of fuel sprays ("spray targeting") will allow the selection of suit-

Figure 5: Mechanisms and factors influencing mixture formation in intake-manifold injection

able fuel injectors which will control and minimize manifold-wall fuel condensation in the area of the intake duct and the intake valves.



The intake manifolds used can be optimally adapted to the combustion air flow and the dynamic gas requirements of the engine.

Gasoline direct injection

In gasoline direct injection (GDI), unlike intake-manifold injection, pure air flows through the intake valves into the combustion chamber. Only then is the fuel injected into the air via an injector (see high-pressure fuel injector) located directly in the cylinder head (internal mixture formation, Figure 6). There are basically two main operating modes. Fuel injection in the intake stroke is called homogeneous operation, while fuel injection during compression is called stratified-charge operation. There are also various special modes, which are either a mixture of the two main operating modes or a slight variation of them.

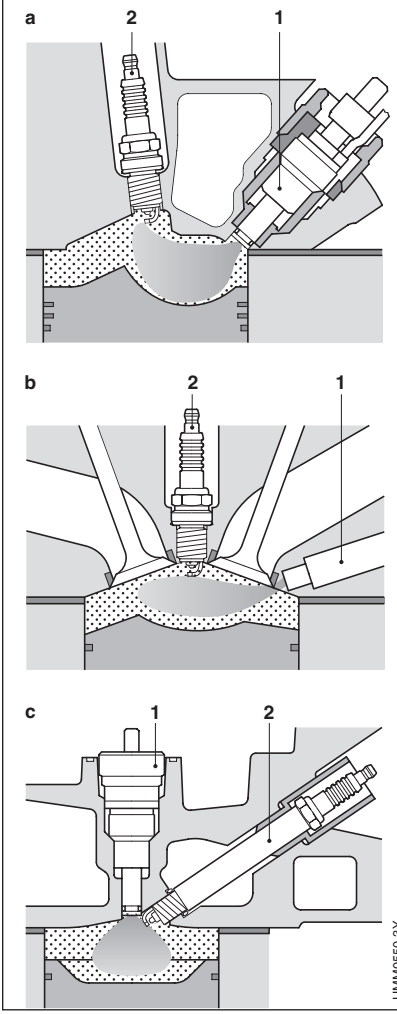
In stratified-charge operation, the air is not restricted; the A/F mixture is lean. The excess air in the exhaust gas prevents conversion of the nitrogen oxides by means of a three-way catalytic converter. These direct-injection systems therefore require exhaust-gas treatment with an additional NO_x storage catalytic converter. For this reason, mostly direct-

Figure 6: Principle of gasoline direct injection
1 Cylinder with piston, 2 Intake valves, 3 Ignition coil with spark plug, 4 Exhaust valves, 5 High-pressure fuel injector, 6 Rail.

injection systems that work exclusively in the homogeneous mode are currently being placed on the market.

Homogeneous operation

In homogeneous operation, mixture formation is similar to intake-manifold injection. The mixture is formed in a stoichiometric ratio (λ = 1). However, from a mixture formation point of view, there are some differences. For instance, there is no flow process around the intake valve to promote mixture formation, and there is much less time available for the mixture formation process itself. Whereas injection can take place across the overall 720° crankshaft (stored and synchronous with induction) of the four operating cycles in the case of intake-manifold injection, only an injection window of 180° crankshaft remains in the case of gasoline direct injection.



Fuel injection is only permitted in the induction stroke. This is because, prior to this, the exhaust valves are open and unburned fuel would otherwise escape into the exhaust-gas train. This would cause high HC emissions and catalytic converter problems. In order to deliver a sufficient quantity of fuel in this shortened period, the fuel flow through the injector must be increased for gasoline direct injection. This is achieved mainly by increasing fuel pressure. The increase in pressure brings with it an additional advantage as it increases turbulence in the combustion chamber, which in turn promotes mixture formation. The fuel and air can therefore be completely mixed, even though the air/fuel interaction time is shorter compared with intake-manifold injection.

Stratified-charge operation

In stratified-charge operation, a distinction is made between several combustion strategies. All strategies have one thing in common, namely they all attempt to achieve charge stratification. This means that, instead of supplying the corresponding stoichiometric air flow rate to the fuel quantity required for a specific load point by adjusting the throttle valve, the full air flow rate is supplied. Only a portion of the air interacts with the fuel, while the rest of the fresh air surrounds this stratified-charge cloud. This dethrottling action facilitates, together with the cooling effects of the directly injected fuel (evaporative emis-

b) Air-directed combustion,
c) Spray-directed combustion.
1 High-pressure fuel injector,
2 Spark plug.

sion), an increase in compression and thus considerable fuel-saving potential.

Wall-directed combustion process
In a wall-directed combustion process, fuel is injected into the combustion chamber from the side (Figure 7a). A recess in the piston crown deflects the fuel spray in the direction of the spark plug. Mixture formation takes place on the path from the injector tip to the spark plug. As the mixture-formation time is very short during injection in the compression stroke (stratified-charge operation), the fuel pressure for this system must often be even higher than for homogeneous operation. The increased fuel pressure shortens the injection time and increases interaction with the air because pulse reflection is greater.

The disadvantage of the wall-directed combustion process is that fuel condenses on the piston wall, which increases HC emissions. As mixture-formation time is short, the stratified-charge cloud usually contains rich mixture zones at higher loads, and this increases the risk of soot production. At low loads, the pulse of the fuel droplets, which is used as a means of transporting the stratified-charge cloud to the spark plug, is low due to the small fuel mass. As a result, the flow must usually be restricted here so that the fuel meets with a lower density of air and thus a lower air resistance.

Air-directed combustion process
In principle, an air-directed combustion process works in exactly the same way as a wall-directed process. The main difference is that the stratified-charge cloud does not interact directly with the piston recess. Instead, it moves on a cushion of air (Figure 7b). The cushion of air is generated by the air present in the cylinder. In contrast to the wall-directed combustion process, with air-directed combustion the fuel-spray injection angle is much flatter such that the fuel spray cannot penetrate the full amount of air up to the piston. This solves the problem of fuel condensing on the piston recess.

Compared with wall-directed combustion processes, the air flows in air-directed combustion processes cannot be fully reproduced. This gives rise to large variations from injection to injection and thus frequently to poor combustion stability right through to individual misfires.

Often, the actual combustion processes are a mixture of wall-directed and air-directed processes, depending on the operating point in each case.

Spray-directed combustion process
The spray-directed combustion process is visually different from the other two processes in that the injector is installed at a different location. It is located top center and injects vertically down into the combustion chamber (Figure 7c). The fuel spray is not deflected. As a result of the high injection pressure (200 bar), an air-fuel mixture forms around the fuel spray already during the injection process. Located directly next to the injector is the spark plug, which ignites the air-fuel mixture.

As a result, with the spray-directed combustion process the mixture-formation time is very short. This requires an even higher fuel pressure for the spray-directed combustion process. This combustion process can eliminate the disadvantages of fuel condensing on the manifold walls, air-flow dependency, and flow restriction at low loads. It therefore has the greatest potential for fuel saving. Nevertheless, the short mixture formation time is a huge challenge for the fuel-injection and ignition systems.

Other operating modes
In addition to homogeneous and stratified-charge operation, there are also special operating modes. They include “changeover between operating modes” (homogeneous-stratified mode), “catalytic-converter heating”, and “knock protection” (homogeneous-split mode), and “homogeneous-lean mode”. These operating modes are sometimes very complex and only ever represent short, temporary states. Therefore they are frequently not operating modes for longer operation.

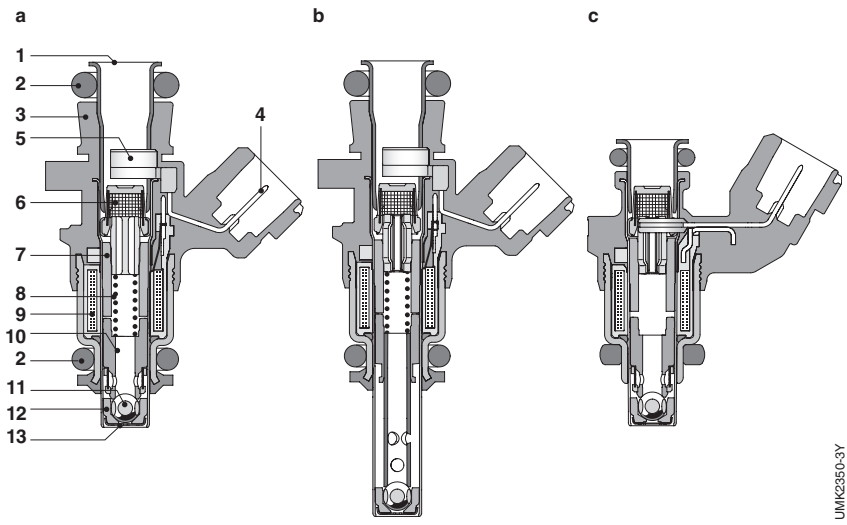
Fuel injectors

Essentially, the mixture-formation components must ensure that the air-fuel mixture is formed in the most optimal way possible to facilitate combustion. In intake-manifold injection, this is mainly the task of the fuel injector, while in gasoline direct injection, the high-pressure fuel injector can be assisted by a turbulence flap.

Essentially, there are two different ways of actuating the fuel injectors. If one injector is operated by means of a conventional electromagnet, the other has a piezoelectric stack serving as the actuator.

Intake-manifold fuel injector

Design and function



Essentially, electromagnetic fuel injectors are comprised of the following components: the valve housing with electrical connection and hydraulic port, the solenoid coil, the moving valve needle with solenoid armature and valve ball, the valve seat with injection-orifice plate, and the valve spring.

Figure 8a and Figure 8b show the EV14 fuel injector, as is used in intake-manifold injection. The new reduced-size fuel-injector variant EV-SE (Figure 8c) has been developed for small installation spaces and small engines (e.g. for two-wheeled vehicles). Both injector variants are also available with an extended injection point.

To adapt the installation position optimally to the intake-manifold and intake-port geometries, different EV14 design variants are available to choose from: Three overall lengths are available with different electrical connector variants and optionally with an extended injection point (Figure 9.)

A filter strainer in the fuel inlet protects the fuel injector against contamination. The sealing ring (O-ring) on the hydraulic port seals off the injector at the fuel rail. The lower sealing ring provides the seal between the injector and the intake manifold.

Figure 8: Fuel injectors (Bosch) for intake-manifold injection
a) Fuel injector, standard version EV-14fT (flat tip),
b) Fuel injector EV14-xT (extended tip) with extended injection point,
c) Fuel injector EV-SE of reduced size for use e.g. in motorcycles.
1 Hydraulic port, 2 Sealing ring (O-ring), 3 Valve housing, 4 Electrical connection, 5 Connector clip, 6 Filter strainer, 7 Internal pole (stop for solenoid armature), 8 Valve spring, 9 Solenoid coil, 10 Valve needle with solenoid armature, 11 Valve ball, 12 Valve seat, 13 Injection-orifice plate.

When the solenoid coil is de-energized, the valve needle and valve ball are pressed against the cone-shaped valve seat by the valve spring and the force exerted by the fuel pressure. The fuel-supply system is thus sealed off from the intake manifold.

When the solenoid coil is energized, this generates a magnetic field which attracts valve-needle solenoid armature. The valve ball lifts off the valve seat and the fuel is injected. When the excitation current is switched off, the valve needle closes again due to spring force.

The fuel is atomized by an injection-orifice plate. The orifices are stamped out of the plate and ensure that the injected fuel quantity remains highly reproducible. The spray pattern and the atomization quality of the fuel leaving the injector is produced by the number of orifices and their configuration (maximum twelve).

The injected fuel quantity per unit of time is determined mainly by the system pressure in the fuel-supply system (typically 3 to 4 bar, corresponding to 300 to 400 kPa), the back pressure in the intake manifold, and the geometry of the fuel-exit area.

Spray formation and spray targeting

An injector's spray formation, i.e. its spray shape, spray angle, and fuel-droplet size, influences the formation of the air/fuel mixture. Individual geometries of intake manifold and cylinder head make it necessary to have different types of spray formation. Different spray-formation variants are available in order to satisfy with these requirements.

Tapered spray

Individual fuel sprays emerge through the openings in the injection-orifice plate (Figure 10a). These fuel sprays combine to form a spray taper.

Tapered-spray injectors are typically used in engines which feature only one intake valve per cylinder.

Dual spray

Dual-spray formation (Figure 10b) is as a rule used in engines which feature two intake valves per cylinder. The holes in the injection-orifice plate are arranged in such a way that two fuel sprays – which are each formed from a number of individual sprays that produce a homogeneous spray shortly after leaving the injection or-

ifices – impact ahead of the intake valves or against the web between the intake valves.

Gamma angle
Compared to the injector's principle axis, the fuel spray in this case (single spray and dual spray) is at an angle: the offset spray angle (Figure 10c).

Injectors with this spray shape are mostly used when installation conditions are difficult, for example when the injectors are installed so steeply in the intake manifold that the required spray targeting can only be achieved by the use of a gamma-angle spray.

Figure 11: Activation of fuel injector
a) Activation signal,
b) Current curve,
c) Valve-needle lift,
d) Injected fuel quantity.
t_{on} Pickup time,
t_{off} Dropout time.

Electrical activation
The output module in the engine ECU actuates the injector with a switching signal (Figure 11a). The current in the solenoid coil rises (Figure 11b) and causes the valve needle to lift (Figure 11c). After the pickup time has elapsed, the maximum valve-needle lift is achieved at the solenoid-armature stop at the internal pole. Depending on the solenoid-valve design, the current continues to rise after the armature stop because the magnetic circuit at this point is not yet at 100 % saturation. The kink in the current curve is triggered by the armature stop.

Fuel is sprayed as soon as the valve ball lifts off its seat. The quantity of fuel injected during an injection pulse is shown in Figure 11d.

Because the magnetic field is not decreased abruptly after activation is shut down, the valve closes with a delay. The valve is fully closed again after the dropout time has elapsed.

The non-linearity during the valve pickup and dropout phases must be compensated for throughout the period that the injector is activated (injection duration). The speed at which the valve needle lifts off its seat is also dependent on the battery voltage. Battery-voltage-dependent injection-duration extension corrects these influences.

Electromagnetic high-pressure fuel injector

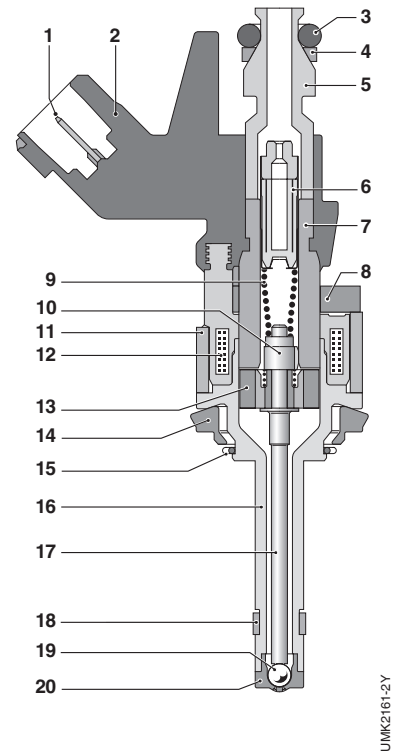
The high fuel pressure required for gasoline direct injection (nominal pressure up to approximately 35 MPa) and the installation location give rise to extended requirements for the fuel-injector component when compared with intake-manifold fuel injectors.

Design and function
The function of the high-pressure fuel injector is to meter and atomize the fuel. Atomization ensures that the fuel is quickly mixed with the air in the combustion chamber. In the process, the A/F mixture is formed within a physically restricted area.

The high-pressure fuel injector (Figure 12) consists of the individual components:

– housing with hydraulic port and electrical connection, tolerance compensation and acoustic decoupling element, and a locking element,
– valve seat with injection orifices and pre-stages,
– valve needle with mechanically isolated solenoid armature and spring,
– return spring with setting sleeve,
– coil with conductor bar.

Depending on the installation position in the cylinder head – lateral or central – either short or long valves are used. The long valve is typically based on a short valve which is adapted to the required length with an extension tube for the hydraulic port and an extended conductor bar for the electrical connector. The current generation has an valve-tip diameter reduced to 6 mm to satisfy the requirements with regard to installation space in downsizing engines.



When current flows through the coil, it generates a magnetic field in conjunction with the other components of the magnetic circuit. This magnetic field accelerates the solenoid armature when the valve needle is still at rest. When the solenoid armature contacts the upper stop, the latter lifts the valve needle against spring force and the hydraulic load off the valve seat and opens the valve outlet opening. As the fuel pressure is considerably higher than the combustion-chamber pressure, the fuel is injected into the combustion chamber.

When the current is switched off, the valve needle and the hydraulic load on the valve needle are pushed back into the seat by the return spring, and this stops the injection process. The solenoid armature is returned by the spring to its rest position on the lower stop.

Reproducible fuel quantities can be metered by defining the opening and keeping the opening cross-section constant with the needle fully raised. Here, the fuel quantity is dependent on the pressure in the fuel rail, the backpressure reaction in the combustion chamber, and the valve opening time.

Spray formation
Predominantly multi-hole valves are used to prepare the fuel. By suitable spray configuration the injection-orifice alignment is adapted to match the installation position to the respective combustion chamber. Here the sprays must be configured in such a way that fuel and fresh air mix thoroughly in the combustion chamber and in the process valves, pistons and combustion-chamber walls are moistened with fuel as little as possible. The fuel injectors are typically configured with five to seven sprays, depending on the desired throughflow, which is configured to match the output per cylinder and thereby determines the mean orifice diameter. The penetration depth of the sprays can be reduced for individual injection orifices by a diameter that is smaller than the mean diameter of all the injection orifices. This makes it possible to reduce the moistening of the piston and the combustion-chamber walls with liquid fuel. Other sprays with a larger orifice diameter are provided to achieve the required throughflow. The injection orifice is for the most part supplemented by a pre-stage. The purpose of this pre-stage is to keep the injection orifice free from deposits which are produced depending on the boundary operating and environmental conditions and on the fuel used.

Electrical activation
To ensure a defined and reproducible injection process, the high-pressure fuel injector is activated by a complex current curve. The engine control unit delivers a digital signal for this purpose. An output module uses this signal (Figure 13a) to generate the actuating signal (Figure 13b) for the high-pressure fuel injector.

A DC/DC converter in the engine ECU generates the booster voltage of 65 V. This voltage creates in conjunction with the booster capacitor a high current at the beginning of the activation process, thus ensuring that the solenoid armature and the valve needle are raised quickly. In the pickup phase, the valve needle then achieves the maximum opening lift (Figure 13c). When the fuel injector is open (maximum valve-needle lift), a lower control current (holding current) is sufficient to keep the valve open. With a constant injector-needle lift, the injected fuel quantity is proportional to the injection duration (Figure 13d).

The CVO process (Controlled Valve Operation) has been specially developed to reduce the quantity scatter from valve to valve. The opening and closing times of the fuel injector can be determined from the electrical variables with this mechatronic approach. The current actual open duration is formed from these measured variables; this is delivered to a controller, where it is compared with a setpoint open duration. In this way, it is possible particularly for very small quantities to achieve high metering precision and maintain this level of precision with a downstream adaptation over the entire service life.

During multiple fuel injection the high-pressure fuel injector is actuated more than once during an engine cycle, reducing the level to which the internal en-

gine walls are moistened with liquid fuel. For the fuel injector this means achieving short idle times and more numbers of load cycles to be withstood over the operating time compared with single injection.

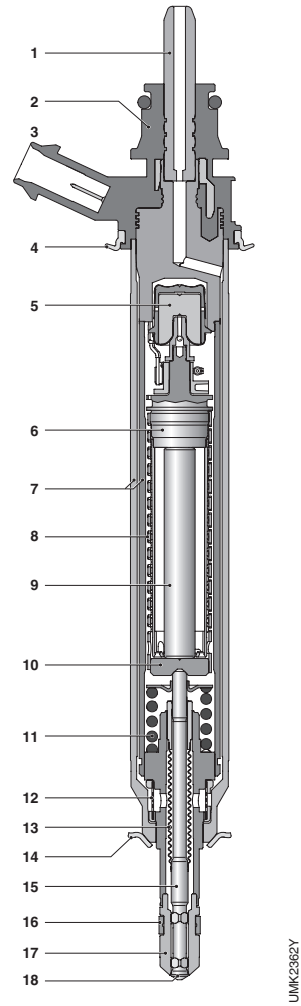
Piezo high-pressure fuel injector

Area of application

The piezo high-pressure fuel injector has been used since 2005 in complex combustion processes which impose specific requirements on the quality of the fuel spray and its stability over the engine's service life. Moreover, it combines outstanding very-small-quantity metering precision with high maximum injected fuel quantities and thus makes possible high specific power output without having to make compromises at low-load operating points. An example of highly-developed combustion processes is the spray-guided stratified-lean combustion process, which is achieved exclusively with the piezo high-pressure fuel injector in production vehicles.

Design and function

The piezo high-pressure fuel injector is operated at 20 MPa (200 bar) fuel pressure and comprises the function elements of valve assembly, actuator module, compensation element (“coupler”), and housing and connecting parts (Figure 14).



The valve assembly admits injected fuel into the combustion chamber and defines the shape of the spray. It essentially consists of the outward-opening valve needle which is pretensioned by a closing spring against a housing body. The nominal valve-needle lift (full lift) is 33 µm and is achieved after 180 µs. The closing operation also takes 180 µs from full lift.

Further important components of the valve assembly are a fine filter in the inlet to protect the nozzle against particulates and bellows to isolate the fuel from the dry actuator chamber.

Installed in the actuator chamber is the piezo actuator, which through its change of length under voltage opens and closes the valve needle and thus substantially determines fuel-quantity metering. It consists of over 400 active layers and is pretensioned by a tube spring. Aside from the actuator and tube spring, the electrical

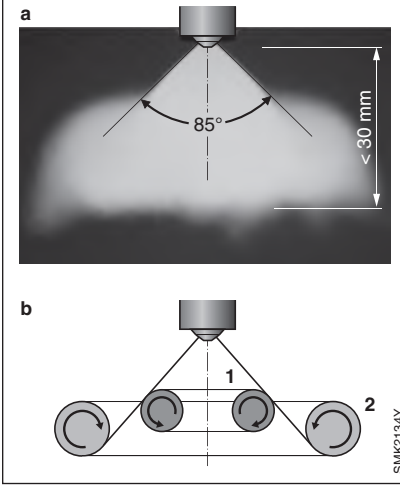
contacting and insulation of the actuator against the electrical components are the essential elements of the actuator module. The direct non-positive connection between actuator module and valve needle provides for very short activation times from 75 µs. In the event of such very short activations the valve needle does not achieve its full lift.

The coupler exerts in the switching chain (comprising the valve needle, the actuator module, and the coupler itself) a defined force which counteracts the closing-spring force. In the coupler two steel diaphragms hold a hydraulic fluid which moves a working piston by means of a slow movement between two cavities. This brings about a compensation of the different thermal expansions of the metallic and ceramic components with the result that the coupler force within the switching chain remains to a large extent constant over all the thermal operating conditions of the high-pressure fuel injector. In this way, a reproducible valve-needle lift and thus a reproducible injected fuel quantity in the different engine operating states are made possible. Fast, short changes of switching-chain length by activation of the piezo actuator are not compensated by the coupler in contrast to changes of switching-chain length as a result of slow thermal effects. It works in this respect like a high-pass filter.

The above-mentioned modules are mounted together with the housing components including the fuel supply. A coding process integrated in the production sequence determines the individual charge demand of each piezo high-pressure fuel injector in order to compensate production tolerances. Compensating the production tolerances improves the precision of the fuel-quantity metering. The charge demand is written in the form of a data matrix code to the fuel injector and read later into the engine ECU.

Spray formation and spray targeting



The spray of an outward-opening nozzle differs by virtue of the principle involved fundamentally from that of a multi-hole nozzle: The annular orifice created when the valve needle opens causes a tapered discharge of spray with droplet sizes in the region of 8 to 13 µm. A rotationally symmetric hollow taper with a nominal spray angle of 86 ° is created. Spatially permanently assigned boundary vortices, which can be used in the course of a combustion process, form both outside and inside along the taper surfaces (Figure 15). The spray shape is stable over a large combustion-chamber-pressure and charge-movement range such that even injections that shortly follow each other are possible in the compression stroke up to shortly before ignition (thus at high combustion-chamber pressures). The spray is, thanks to the design of the nozzle, very robust against disturbance, deposit, and aging influences. The is advantageous particularly for the stratified combustion process mentioned at the start, but also for example in catalyst-heating mode.

Electrical activation

The piezo high-pressure fuel injector is operated with up to 200 V. Activation is performed by an output stage integrated in the ECU, with the voltage generated by a

1 Inner boundary vortex,
2 Outer boundary vortex.

DC/DC converter (Figure 16). Activation is charge-controlled: The injector is opened by a specifically targeted charging operation (nominal value for full lift 0.69 mC) and closed by an analogous discharging operation. The activation duration (75 to 5000 µs) serves as the primary activation variable, the charge value to be achieved and the charging and discharging speeds are parameterizable. Varying the pressure to obtain an injected-fuel-quantity spread between minimum and maximum quantity is, due to the possible extremely short activation duration and on account of the high hydraulic cross-section at full lift, not necessary: Injected fuel quantities between 0.5 mg and 150 mg can be covered by a fuel injector per working cycle. The injection characteristic is linear right through to the smallest injected fuel quantities (Figure 17). Idle times between two opening operations right down to 50 µs can be achieved; this is considerably shorter than with a fuel injector with a solenoid-operated mechanism.

Finally, a number of adaptation functions which measure the fuel injector in the installed state are used in engine operation to guarantee very-small-quantity metering precision of the injector's service life. As well as model-based compensations of the temperature-dependent reactions of the actuator to an electric charge, it is also possible to compensate on a cylinder-specific basis very small quantity deviations over the injector's service life which if uncompensated would generate torque differences. The compensations act on the basis of the causative principle either on the valve-needle lift or on the activation duration.

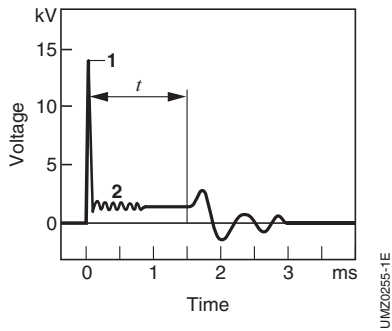
Ignition

Basic principles

Function

On a spark-ignition (SI) engine, the combustion process is initiated by an externally supplied ignition. The ignition is responsible for igniting the compressed A/F mixture at the right time. This is done by producing an electric spark between the electrodes of a spark plug in the combustion chamber.

Consistent, reliable ignition under all conditions is essential to ensure fault-free engine operation. Misfiring leads to combustion misfires and damage or destruction of the catalytic converter, poor exhaust emission figures, higher consumption and lower engine performance.



Ignition spark

An electric spark can only occur at the spark plug if the necessary ignition voltage is exceeded (Figure 1). The ignition voltage is dependent on the spark-plug electrode gap and the density of the A/F mixture at the moment of ignition. It can be up to several 10 kV. After flashover, the voltage at the spark plug drops to the firing voltage. The firing voltage depends on the length of the spark plasma (electrode gap and excursion by the A/F mixture flow) and can rise from several 100 V to a few kV.

During the ignition-spark combustion time (spark duration), the ignition-system energy is converted into the ignition spark. After the spark has broken away, the voltage is damped and drops to zero.

Figure 1: Spark-plug voltage characteristic with static or semi-static A/F mixture

1 Ignition voltage,
2 Firing voltage,
t Spark duration.

Mixture ignition and ignition energy

The electrical spark between the spark-plug electrodes generates a high-temperature plasma. If mixture conditions at the spark plug are suitable and sufficient energy has been supplied by the ignition system, the resulting arc develops into a flame front that propagates independently.

The ignition must guarantee this process under all engine operating conditions. Under ideal conditions (e.g. in a simulation of a combustion chamber, a “combustion bomb”), provided that the A/F mixture is stationary, homogeneous and stoichiometric, an energy of approx. 0.2 mJ is required to ignite the mixture by means of electric spark for each individual ignition process. In real engine operation, however, much higher energy levels are required. Some of the spark energy is converted at flashover, and the rest in the spark combustion phase.

Larger electrode gaps generate a larger arc, but require higher ignition voltages. Lean A/F mixtures or turbocharged engines have a higher ignition-voltage demand. At a given level of energy, the spark duration shortens as the ignition voltage increases. A longer spark duration generally stabilizes the combustion; lack of mixture homogeneity at the moment of ignition in the area of the spark plug can be compensated for by means of a longer spark duration. A/F-mixture turbulences such as those which occur in the stratified-charge mode with gasoline direct injection can divert the ignition spark to such an extent that it extinguishes. Follow-up sparks are then required to ignite the A/F mixture again.

The need for higher ignition voltages, longer spark durations, and the provision

of follow-up sparks have resulted in the design of ignition systems with higher ignition energy. If not enough ignition energy is produced, inflammation will not occur, resulting in engine misfire. The system must therefore deliver enough ignition energy to ensure reliable ignition of the A/F mixture under all operating conditions.

Efficient fuel atomization and good access of the A/F mixture to the ignition sparks enhance ignitability, extend spark duration and spark length, and lengthen the electrode gap. The dimensions of the spark plug determine the position (see Spark position, spark plug) and length of the spark; spark duration depends on the type and design of the ignition system, as well as on the instantaneous ignition conditions in the combustion chamber. Dependent on the engine requirements (intake-manifold injection, gasoline direct injection or exhaust-gas turbocharging), the spark energy of ignition systems lies in a range of approx. 30 to 100 mJ.

Moment of ignition

The start of combustion in a spark-ignition (SI) engine can be controlled by selecting the moment of ignition. The moment of ignition always refers to the top dead center of the spark-ignition (SI) engine power cycle. The earliest possible moment of ignition is determined by the knock limit, and the latest possible moment of ignition by the combustion limit or the maximum permissible exhaust-gas temperature. The moment of ignition affects the torque output, exhaust-gas emissions and fuel consumption.

Basic ignition point

Maximum combustion, and thus maximum combustion pressure, should occur shortly after top dead center (Figure 2) to deliver maximum engine torque. Since a certain amount of time passes from the moment of ignition to complete combustion of the A/F mixture, ignition must occur before top dead center. The moment of ignition must be advanced as rotational speed increases and charge decreases.

Likewise, the moment of ignition must be advanced in the case of lean A/F mixtures ($\lambda > 1$) because the flame front propagates more slowly. Recirculated or retained exhaust gas (external or internal exhaust-gas recirculation) has a compa-

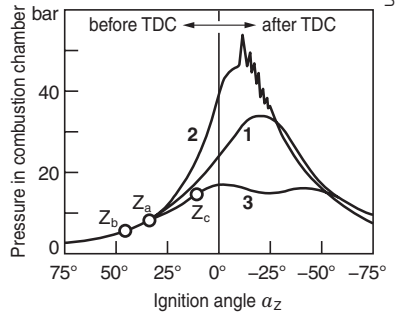
2 Ignition (Z_b) too advanced,
3 Ignition (Z_c) too retarded.



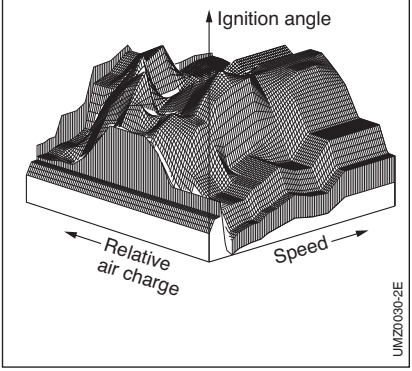


Figure 3: Ignition map as a function of engine speed and relative air charge

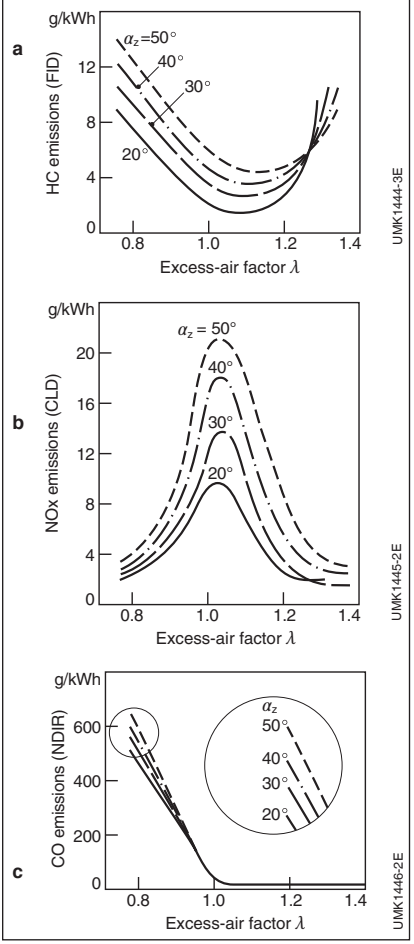
rable effect. Ignition-timing adjustment, therefore, essentially depends on rotational speed, charge, and the air/fuel ratio (excess-air factor λ) or in today's customary stoichiometric homogeneous engines the amount of residual exhaust gas in the cylinder. The moments of ignition are determined on the engine test bench and, in the case of electronic engine management systems, are stored in program maps (Figure 3).

Ignition-timing corrections and operating-point-dependent moments of ignition

Electronic engine-management systems can take other effects on the moment of ignition into consideration in addition to rotational speed and charge. The basic moment of ignition can either be modified by means of additive corrections or replaced for certain operating points or ranges by special ignition angles or ignition maps. Examples of ignition-timing corrections are knock control, the correction angle for the gasoline direct injection homogeneous-lean operation, and warm-up. Examples of special ignition angles or ignition maps are gasoline direct injection stratified-charge operation, and starting operation. Final implementation depends on the prevailing application.

Exhaust gas and fuel consumption

The moment of ignition has a considerable impact on exhaust gas because it can be used to control the various untreated exhaust-gas constituents directly. However, the various optimization criteria, such as exhaust gas, fuel economy, drivability, etc., may not always be compatible, so it is not always possible to derive the ideal moment of ignition from them.



Shifts in the moment of ignition induce mutually inverse response patterns in fuel consumption and exhaust-gas emissions (Figure 4 and Figure 5). Whereas more spark advance increases torque and therefore power and reduces fuel consumption, it also raises HC and, in particular, nitrogen-oxide emissions. Excessive spark advance can cause engine knock that may damage the engine. Retarded ignition results in higher exhaust-gas temperatures, which can also harm the engine.

Electronic engine-management systems featuring programmed ignition curves are designed to adapt the moment of ignition in response to variations in factors such as rotational speed, load, temperature,

Flame Ionization Detector (FID)
Chemiluminescence Detector (CLD)
Non-Dispersive Infrared Detector (NDIR)

etc. They can thus be employed to achieve the optimum compromise between these mutually antagonistic objectives.

Knock control

Basic principles

Electronic control of the moment of ignition offers the possibility of accurate control of the ignition angle as a function of rotational speed, load, temperature, etc. Nevertheless, if there is no knock control, there must still be some means to define a clear safety margin to the knock limit.

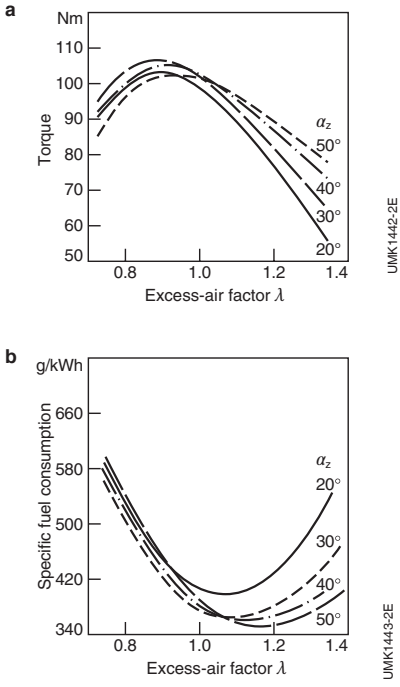
This margin is necessary to ensure that, even in the most knock-sensitive case with regard to engine tolerances, engine aging, environmental conditions, and fuel quality, no cylinder can reach or exceed the knock limit. The resulting engine design leads to lower compression, retarded moments of ignition, and thus worsening fuel consumption and torque.

These disadvantages can be avoided through the use of knock control. Experience shows that knock control increases engine compression. This results in lower fuel consumption and higher torque. Now, however, the pilot control ignition angle no longer has to be determined for the conditions most sensitive to knocking but rather for the conditions least sensitive to knocking (e.g. compression of the engine at lowest tolerance limit, best possible fuel quality, cylinder least sensitive to knocking). Each individual engine cylinder can now be operated throughout its service life in virtually all operating ranges at its knock limit, and thus at optimum efficiency. For this type of ignition angle adjustment, a reliable method of knock detection is essential. It should detect knock for each cylinder throughout the engine's operating range starting from a specified knock intensity.

Knock-control system

A knock-control system consists of knock sensor, signal evaluation, knock detection, and ignition-angle control system with adaptation facility (Figure 6).

Figure 5: Influence of excess-air factor λ and moment of ignition α_z on fuel consumption and torque
a) Torque,
b) Specific fuel consumption.



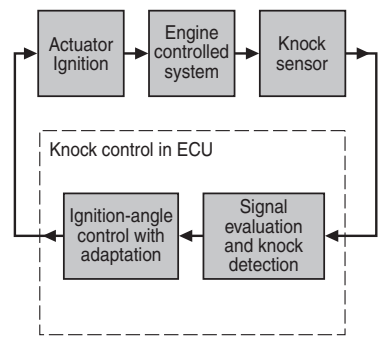


Figure 6: Schematic of a knock-control system

Knock sensor
A typical symptom of combustion knock is high-frequency vibrations which are superimposed on the high-pressure curve in the combustion chamber (Figure 2). These vibrations are best detected directly in the combustion chamber by means of pressure sensors. As fitting these pressure sensors in the cylinder head for each cylinder is still relatively costly, these vibrations are usually picked up using knock sensors fitted to the exterior of the engine. These piezo-electric acceleration sensors (Figure 7) pick up the characteristic vibrations of knocking combustion and convert them into electrical signals.

There are two types of knock sensor. A wide-band sensor, with a typical frequency band of 5 to 20 kHz, and a resonance sensor, which preferably transmits only one knock-signal resonant frequency. When combined with the flexible signal-evaluation system in the control unit, it is possible to evaluate different or several resonant frequencies from one wide-band knock sensor. This improves knock detection performance, which is why the wide-band knock sensor is increasingly replacing the resonance sensor.

To ensure sufficient knock detection in all cylinders and across all operating ranges, the number and location of the required knock sensors must be carefully determined for each engine type. Four-cylinder in-line engines are usually fitted with one or two knock sensors, while 5- and 6-cylinder engines are fitted with two, and 8- and 12-cylinder engines with four knock sensors.

Signal evaluation
For the duration of a timing range in which knock can occur, a special signal evaluation circuit in the control unit evaluates from the wide-band signal the frequency band(s) with the best knock information and generates a representative variable for each combustion process. This very flexible signal evaluation of the wide-band sensor enables high detection quality. When using a resonance knock sensor that transmits just one resonant frequency for analysis of all cylinders assigned to it across the entire engine map, knock detection is normally no longer possible at higher engine speeds.

Knock detection
The variable produced by the signal-evaluation circuit is classified in a knock-de-

d Ignition advance step.

tection algorithm as “knock” or “no knock” for each cylinder and for each combustion process. This is done by comparing the variable for the current combustion process with a variable which represents combustion without knock.

Ignition-angle control system with adaptation facility

If combustion knock is detected in a cylinder, the moment of ignition for that cylinder is retarded (Figure 8). When knock stops, the moment of ignition is advanced again in stages up to the precontrol value. The knock-detection and knock-control algorithms are matched in such a way as to eliminate any knock that is audible and damaging to the engine, even though each cylinder is operated at knock limit within the optimum efficiency range.

Real engine operation produces different knock limits, and thus different moments of ignition for individual cylinders. In order to adapt precontrol values for the moment of ignition to a particular knock limit, the ignition retard values are stored for each cylinder dependent on the operating point. They are stored in non-volatile program maps in the permanently powered RAM for load and engine speed. In this way, the engine can be operated at optimum efficiency for each operating point and without audible combustion knocks, even if there are rapid load and engine-speed changes.

This adaptation even enables the use of fuels with lower antiknock properties (e.g. premium instead of Super Plus gasoline).

Phenomenon of pre-ignition

Basic principles

There is currently a clear trend in the development of modern gasoline engines towards downsizing (displacement reduction at same engine performance) and downspeeding (speed reduction by means of longer transmission ratio) in combination with direct injection and supercharging. Supercharging allows for a reduction in displacement without lowering performance level. The engine can therefore be operated in part load at higher loads with higher part-load efficiency, and fuel consumption can be reduced. The charge-air pressure increase to improve efficiency is however limited by the phenomenon of pre-ignition.

A few years ago the terms “extreme knocker” or “superknocker” were used, but they described the symptom and not the cause of the phenomenon of pre-ignition. However, the term “pre-ignition” has become the established term for some time now. In the name there is therefore also a clear distinction from normal combustion knock.

Pre-ignition

Pre-ignitions are uncontrolled auto-ignitions of the air-fuel mixture, which occur before the ignition that is triggered by the spark plug. Compared to normal combustion, this premature initiation of combustion leads to a considerable increase in pressure and temperature, which then leads to severe combustion knock in the subsequent combustion process. In doing so, individual events can pre-damage the engine.

Detection of pre-ignitions

Reliably detecting pre-ignitions is absolutely necessary in order to prevent engine damage. Knocking events as a result of pre-ignitions can be clearly evaluated and detected based on knock sensors by means of position and frequency ranges. This process allows for a high level of detection quality with a clear distinction from normal combustion knock.

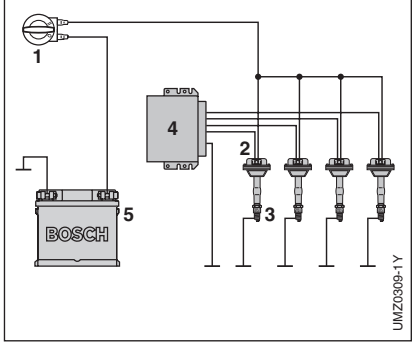
Measures to prevent pre-ignitions
If pre-ignitions are detected, countermeasures are necessary in order to prevent further pre-ignitions. However, since pre-ignition is an uncontrolled auto-ignition, there is no direct manipulated variable – e.g. the ignition angle at combustion knock – that can be used to reliably prevent further pre-ignitions. For this reason, the pre-ignition functionality involves initiating multiple countermeasures after detected pre-ignitions in order to quickly reduce the temperature level in the combustion chamber and thus prevent further pre-ignitions. The various measures, such as mixture enrichment or charge lowering, can be activated in the combination that is ideal for the respective engine type.

Pre-ignitions are heavily dependent on fuel and on oil emissions. This functionality is therefore absolutely necessary to protect the engine, especially for turbocharged gasoline engines. This enables vehicle manufacturers to develop efficiency-optimized, supercharged gasoline engines and to market them worldwide despite different fuel and oil grades.

Risk of accidents
All electronic ignition systems are high-voltage systems. To avoid any risks, always switch off the ignition, or disconnect the power supply when working on the ignition system. Such work includes, for example:
– Replacing parts such as spark plugs, ignition coils, or ignition transformers, high-tension ignition cables, etc.
– Connecting engine analyzers, such as stroboscopic lamps, dwell angle/rotational speed testers, ignition oscilloscopes, etc.

When checking the ignition system, remember that dangerously high levels of voltage are present within the system whenever the ignition is on. All tests and inspections should therefore only be carried out by qualified professional personnel.

Ignition systems



On modern vehicles, the ignition systems are almost always incorporated as subsystems of the engine-management system. Autonomous ignition systems are now only used for special applications (e.g. small engines). In the case of ignition systems, coil ignition (inductive ignition) with a separate ignition circuit per cylinder (static high-voltage distribution with single-spark coils, Figure 9) has come to the fore.

Alongside this, but to a much lesser extent, high-voltage capacitor ignitions (capacitive ignition) or other special designs such as magnetos are used for small engines. The next section will focus on coil ignition alone.

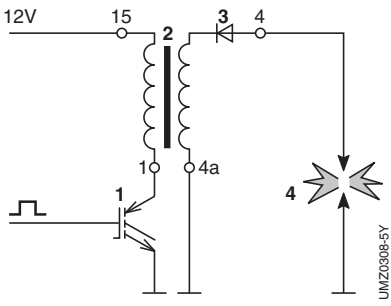
Coil ignition (inductive ignition)

Principle of coil ignition
The ignition circuit of a coil-ignition system (Figure 10) consists of:
– An ignition coil with a primary and a secondary winding
– An ignition output stage to control the current by means of the primary winding, predominantly integrated as an IGBT (Insulated Gate Bipolar Transistor) in the engine control unit or in the ignition coil
– A spark plug connected to the high-voltage connection point of the secondary winding

Figure 9: Ignition system with single spark coils
1 Ignition lock, 2 Ignition coil, 3 Spark plug, 4 Control unit, 5 Battery.

Before the desired moment of ignition, the ignition output stage switches a current from the vehicle electrical system through to the primary winding of the ignition coil. While the primary current circuit is closed (dwell period), a magnetic field builds up in the primary winding.

At the moment of ignition, the current through the primary winding is interrupted again, and the magnetic-field energy is discharged, mainly via the magnetic-coupled secondary winding (induction). In the process, a high voltage is produced in the secondary winding. Flashover occurs if the ignition voltage supply of the ignition system exceeds the ignition-voltage demand of the spark plug. After flashover, the remaining energy is converted at the spark plug while the spark is present.



Functions of an ignition system with coil ignition

Moment-of-ignition determination

The current moment of ignition in each case is determined from program maps dependent upon the operating point and output.

Figure 10: Structure of an ignition circuit with single spark coils

2 Ignition coil with primary and secondary windings,
3 Activation arc diode (Activation Spark Suppression),
4 Spark plug.
15, 1, 4, 4a Terminal designations,
⎍⎍ Triggering signal.

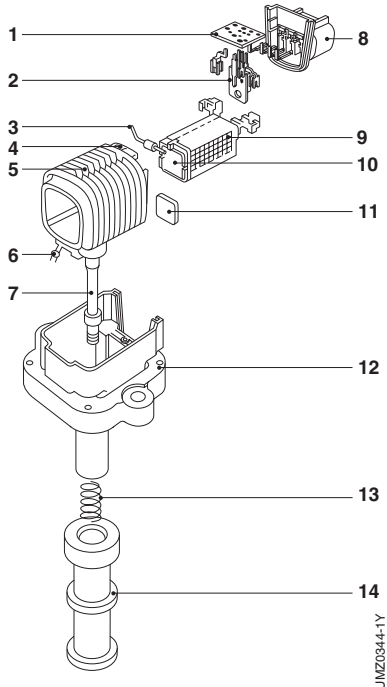
Dwell-period determination

The required ignition energy is made available at the moment of ignition. The amount of ignition energy is dependent upon the amount of primary current at the moment of ignition (cutoff current) and the inductance of the primary winding. The amount of cutoff current is mainly dependent upon the operating time (dwell period) and upon the battery voltage at the ignition coil. The dwell periods required to achieve the desired cutoff current are contained in characteristic curves or program maps as a function of the steady-state voltage. The change in dwell period with temperature can also be compensated for.

Ignition release

The ignition release ensures that the ignition spark occurs at the right cylinder at the right time and with the required level of ignition energy. On electronic-controlled systems, a trigger wheel with a fixed-angle reference mark (typically 60 – 2 teeth, two teeth missing at the reference mark) on the crankshaft is usually scanned (sensor system with hall or inductive sensor). From this, the control unit can calculate the crankshaft angle and the momentary rotational speed. The ignition coil can be switched on and off at any required crankshaft angle. An additional phase signal from the camshaft is required for the unambiguous identification of the cylinder.

For each combustion, the control unit uses the desired moment of ignition, the required dwell period and the current engine speed to calculate the switch-on time and switches on the output stage. The moment of ignition, or the switchoff point for the output stage, can be triggered either when the dwell period expires or when the desired angle is reached.



Ignition coil

Function

The ignition coil is principally an energy-charged high-voltage source similar in structure to a transformer. Energy is supplied by the vehicle electrical system during the dwell period or charging time. At the moment of ignition, which at the same time is the end of the charging time, the energy is then transferred with the required high voltage and sparking energy to the spark plug (inductive ignition system).

Figure 1: Design of the compact ignition coil

8 Connector, 9 Primary winding,
10 I-core, 11 Permanent magnet, 12 O-core,
13 Contact spring (spark-plug contacting),
14 Silicone jacket (high-voltage insulation).

Design

The ignition coil (Figure 1) comprises two windings that are magnetically linked by an iron core (I-core and O-core). This iron core may contain a permanent magnet for energy optimization. Compared with the secondary winding, the primary winding has significantly fewer coils. The turns ratio $\ddot{u}$ is in the range of $\ddot{u}$ = 80 to 150.

The windings must have good electrical insulation to prevent electrical discharge and flashovers either to the inside or to the outside. For this purpose, the windings are usually cast in epoxy resin in the ignition coil housing.

As a rule, the iron core consists of stacked, ferromagnetic steel-plate fins in order to minimize above all eddy-current losses.

Alternatively, the ignition output stage can be incorporated into the ignition coil instead of the engine control unit. Interference-suppression elements may also be incorporated into the ignition coil together with the activation arc diode (activation spark suppression). An interference-suppression resistor is commonly used on the high-voltage output to the spark plug.

Operation

The ignition output stage switches the primary current in the ignition coil. The current rises with a delay, in accordance with the inductance. Energy is stored in the magnetic field created in the process. The operating time (charging time) is calculated in such a way that a specific cutoff current, and thus a specific level of stored energy, will be reached by the end of the operating time.

The current is cut off by the ignition output stage, which causes a swift change in the magnetic flux in the ignition coil's iron core. This change in flux results in a voltage induction in the secondary winding. The design of the secondary winding, the geometric arrangement of the secondary winding to the iron core and the primary winding and the materials used in the insulation system and the iron core give rise to inductive and capacitive properties that lead to a voltage supply in excess of 30,000 V on the secondary side.

When the ignition-coil voltage supply equals the ignition-voltage demand at the spark-plug electrodes, the voltage drops to

a spark voltage of about 1,000 V. A spark current then flows and decreases as spark duration increases, until the spark is finally extinguished.

As the current changes over time when the primary current is cut off, an induction voltage occurs at the ignition coil output, similar to the start of charging time. However, this voltage is much smaller than the voltage at the moment of ignition and has an inverse polarity to that voltage. To prevent this "transient voltage" causing unwanted ignition, it is usually suppressed by means of a high-voltage diode in the secondary circuit (activation arc diode, activation spark suppression).

The design of an ignition coil can determine its electrical characteristics. In this respect, the requirements in terms of installation space (e.g. geometry of cylinder head and cylinder-head cover, position of fuel injector and intake manifold) and the two specified interfaces, the ECU with output stage (e.g. cutoff current) and the spark plug (e.g. ignition voltage, spark data), are decisive.

Design variations

There are several types of ignition coil that are distinguishable by their various features.

Individual coils and modules

In addition to the individual coils, which normally sit directly on the spark plug, several ignition coils can be grouped together in a single housing as a module. They are then mounted directly on the spark plugs, or they may be located a short distance away, in which case the high voltage must be supplied via appropriate cables.

Single-spark and dual-spark ignition coils

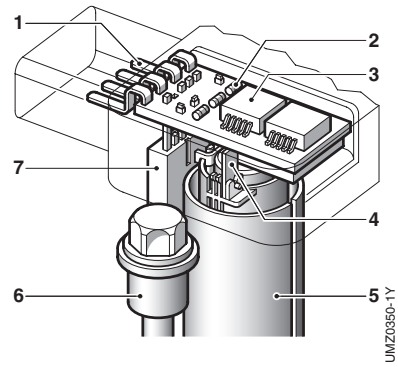
In addition to ignition coils with just one high-voltage output (single-spark ignition coil), there are also coils that use both ends of the secondary winding as an output (dual-spark ignition coil). The electric circuit must always be closed by both spark gaps to prevent discharge on the secondary side. One feasible application for this design is dual ignition, i.e. two spark plugs per cylinder supplied by one ignition coil. Another application involves splitting up the two high-voltage outputs between two spark plugs on different cylinders. In this case, one of the two spark plugs will always be in the ignition stroke. As a result, the voltage and energy requirements of the "passive spark" (backup spark) are reduced substantially. Above all, this variant offers cost advantages; however, it must be matched to the overall system to prevent damage from unwanted ignition events caused by backup sparks.

Compact coil and pencil coil

Ignition coils are also distinguishable by their basic design. For example, there is the conventional compact coil, that features an equal-sided coil body and an O-I core or C-I core magnetic circuit. The coil body sits in the engine above the spark-plug well.

Another type is the pencil coil whose coil body projects into the spark-plug well. Here, too, the windings are located on an I or pencil core, with a plate (yoke plate) arranged concentrically around the windings serving as a magnetic yoke.

Ignition coils with ignition output stage



Ignition coils are available with or without the ignition output stage. The reason for integrating the output stage is to relieve the strain on the engine ECU. Additionally, further electronic circuitry is used in the ignition coil in order to meet the existing requirements (Figure 2).

Requirements
The principal requirements of modern ignition systems are derived indirectly from necessary emission and fuel reductions. Requirements of ignition coils are derived from relevant engine solutions, such as high-pressure supercharging and lean-burn and stratified-charge operation (spray-guided direct injection) in combination with increased exhaust-gas recirculation rates (EGR).

It is necessary to represent an increased ignition-voltage and energy demand with increased temperature requirements. This is effected among others by means of
– High-energy coils with high voltage supply (in excess of 40,000 V)
– Multispark ignition (MSI), i.e. spark-sequence control with integrated electronics (ASIC), controlled by way of primary- and secondary-current evaluation
– Diagnostic functions (e.g. charge-time monitoring, ionic-current measurement for combustion diagnosis)
– Protective functions (e.g. overtemperature cutoff, cutoff-current regulation)

Furthermore, motor vehicles are subject to increased demands with regard to electromagnetic compatibility (EMC). Precisely because of the increased ignition-voltage demand, the increased ignition frequencies necessitated by multispark ignition and the increased cutoff currents, it is now necessary to reduce the interference emitted by the ignition system so as not to disrupt the functioning of other automotive components (ECUs, microcontrollers, sensors, actuators).

Figure 2: Installation of ignition output stage in a pencil ignition-coil housing
1 Connector,
2 SMD components (Surface Mounted Device),
3 Electronic circuitry for ignition functions,
4 Primary-winding contacts,
5 Yoke plate of pencil ignition-coil transformer,
6 Attachment lug,
7 Ignition output stage.

The integration of increasingly more electronic circuitry in ignition coils gives rise to more stringent demands with regard to the interference immunity of these components. In the interests of avoiding impaired functioning and malfunctions, the electronic circuity must be immune to the emissions of the ignition system itself and to the interference emitted by other vehicle components.

Spark plug

Function

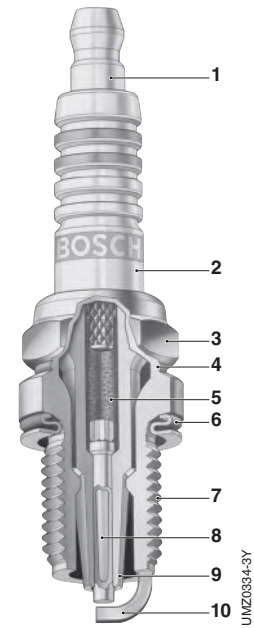
The spark plug transfers the ignition-coil energy into the combustion chamber in a spark-ignition engine. The high voltage applied creates an electric spark between the spark-plug electrodes, which ignites the compressed A/F mixture and thereby initiates combustions.

In combined operation with the other engine components, e.g. the ignition and the mixture-formation systems, the spark plug determines the function of the spark-ignition engine to a decisive extent. It must provide for reliable cold starting, guarantee misfire-free operation over its entire service life (at least 30,000 km), and not exceed the maximum permissible temperature even during extended operation at critical operating points. Furthermore, the spark plug must always reliably insulate the high voltage against the cylinder head and seal the combustion chamber towards the outside.

Requirements

The spark plug must satisfy a variety of challenging performance demands. It is exposed to the varying periodic processes within the combustion chamber, as well as external climatic conditions.

When spark plugs are used with electronic ignition systems, ignition voltages of up to 40 kV can occur; these high voltages must not cause ceramic or insulator-head flashovers. The deposited residues from the combustion process such as soot, carbon and ash from fuel and oil additives are electrically conductive under certain thermal conditions. Nevertheless, no flashovers via the insulator are permitted to occur. The electrical resistance of the insulator must be sufficiently high up to 1000 °C and is only permitted to drop slightly over the spark plug's service life.



Mechanically, the spark plug is subjected to the pressures (up to 150 bar) occurring periodically in the combustion chamber; however, gas tightness may not be impaired. In addition, the spark-plug electrode materials exhibit extreme resistance to thermal loads and continuous vibratory stress. The spark-plug shell must be able to absorb the forces occurring during assembly without any lasting deformation.

At the same time, the section of the spark plug that protrudes into the combustion chamber is exposed to high-temperature chemical processes, making resistance to aggressive combustion deposits essential.

Above all, the spark-plug insulator and the electrodes must be capable of withstanding high thermal loads as they are exposed in rapid succession to high temperatures from the hot combustion gases and low temperatures of the cold air/fuel mixture (thermal shock). The electrodes and the insulator at the cylinder head must have good heat dissipation properties – essential for reliable spark-plug perfor-

mance. The connection end of the spark plug should heat up as little as possible.

As well as these requirements, the spark plug must also be adapted to the geometric specifications of the engine design (e.g. spark-plug position in the cylinder head).

In view of these requirements – resulting from the great variety of engines – a wide range of spark plugs is required.

Design

The spark plug consists of at least two electrodes (center and ground electrodes), between which the ignition spark is generated. The high voltage is transferred to the center electrode via the terminal stud by an electrically conductive glass seal inside the insulator. The insulator prevents a short-circuit to the spark-plug shell, in which the plug (insulator with operationally reliable mounted center electrode and terminal stud) is mounted (Figure 1).

Terminal stud and high-voltage terminal

The steel terminal stud has at the end projecting out of the insulator a thread (M4) into which the spark-plug connector of the ignition cable engages. For the standardized connector either a terminal nut (SAE) is screwed onto the terminal-stud thread or the stud is already provided during manufacture with a solid standardized terminal (e.g. cup). Spark plugs with metal shields are available for watertight systems and for maximum interference suppression.

Conductive glass seal

This electrically conductive glass seal acts as a mechanical support for the components, while providing a gas seal against the high combustion pressure. It can also incorporate resistor elements for interference suppression and burn-off.

Insulator

The insulator consists of a special ceramic. Its function is to insulate the center electrode and the terminal stud electrically against the spark-plug shell. The requirements of good thermal conductivity with simultaneously high insulation resistance are in stark contrast to the properties of most insulating materials. The material used by Bosch consists of aluminum oxide (Al_2O_3), to which other substances are added in small quantities.

At the connection end, the insulator has a lead-free glaze to repel moisture and dirt. This avoid insulator flashovers to a great extent.

Spark-plug shell

The shell is made of steel. The lower part of the shell has a thread so that the spark plug can be secured in the cylinder head and exchanged after a specified change interval. Depending on the spark-plug concept, up to four ground electrodes are welded onto the end face of the shell.

To protect the shell against corrosion, its surface is nickel-plated so as to prevent the thread from seizing in the aluminum cylinder heads. The upper part of the shell features a hexagon or bi-hexagon head for application of a wrench. The bi-hexagon head requires less space in the cylinder head while the insulator-head geometry remains unchanged, allowing the engine design engineer greater freedom in designing the cooling ducts.

The upper part of the shell is flanged after the plug is fitted and locates the latter in its position. The subsequent shrinking process by inductive heating under high pressure creates the gastight connection between the insulator and the shell, and guarantees good heat conduction.

Seal seat
Depending on the engine design, the spark plug has a flat or conical seal seat, which provides the seal against the cylinder head. In the case of the flat seal seat, a "captive" sealing ring is used as the sealing element. It has a special shape and provides a permanently elastic seal when the spark plug is fitted. In the case of the conical seal seat, a conical shell surface provides a direct seal on a corresponding surface of the cylinder head without the use of a sealing ring.

Electrodes
The electrodes subjected to high thermal load are primarily made of a nickel-based multi-alloy. Through the addition by alloying of manganese and silicon the chemical resistance of nickel is improved, above all against the highly aggressive sulfur dioxide (SO_2, sulfur is an ingredient of lube oil and fuel). Additives made of aluminum and yttrium additionally increase the resistance to scaling and oxidation.

Compound electrodes with a jacket material made of a nickel alloy and a copper core are used to improve heat dissipation and consequently wear performance.

Center electrode
The center electrode is anchored with its head in the conductive glass seal. For longlife spark plugs it is sensible to use corrosion- and oxidation-resistant materials like platinum (Pt) and platinum alloys, which also exhibit high burn-off resistance. The center electrode then accommodates a precious-metal pin, which is permanently joined to the base electrode by laser welding.

Ground electrodes
The ground electrodes are welded to the shell and have predominantly a rectangular cross-section. Depending on the arrangement, a distinction is made between front and side electrodes (Figure 3) and special applications (e.g. spark plug without distinct ground electrode for racing engines). As well as thermal conductivity, the length, the profile cross-section and the number of ground electrode determine their temperature and hence their wear performance.

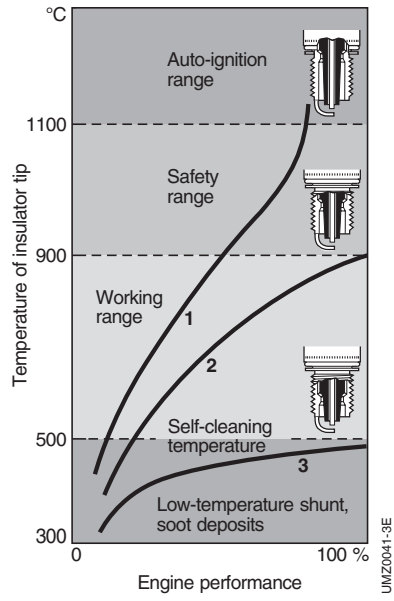
Heat range
Operating temperature of the spark plug
When the engine is operating, the spark plug is heated by combustion heat. Some of the heat absorbed by the spark plug is diverted to the fresh A/F mixture. Most of the heat is transmitted to the spark-plug shell via the center electrode and the insulator, and is diverted to the cylinder head. The operating temperature of the spark plug represents a balance between heat absorption from the engine and heat dissipation to the cylinder head.

The aim is for the insulator nose to reach a self-cleaning temperature of approx. 500 °C even at low engine performance. If the temperature drops below this level, there is the danger that soot and oil residue from incomplete combustion will settle on the cold areas of the spark plugs (particularly when the engine is not at normal operating temperature, at low outside temperatures and during repeated starts) (Figure 2, curve 3). This can create a conductive connection (shunt) between the center electrode and the spark-plug shell. This will cause ignition energy to leak away in the form of short-circuit current (risk of misfiring).

At higher temperatures, the residue containing carbons burn on the insulator nose; the spark plug thus "cleans" itself (Figure 2, curve 2).

An upper temperature limit of approx. 900 °C should be observed since, in this range, spark-plug electrode wear increases drastically (due to oxidation and hot-gas corrosion). If this limit is exceeded by a significant extent, it increases the risk of auto-ignition (ignition of the A/F mixture on hot surfaces) (Figure 2, curve 1). Auto-ignition subjects the engine to extreme loads, and may result in engine destruction within a short period of time. The spark plug must therefore be adapted to the engine type in terms of its heat-absorbing property.

Heat-range code number
The identifying feature of a spark plug's thermal loading capacity is its heat range, which is defined by a heat-range code number and determined in comparison measurements with a reference standard source (calibration spark plug).



A low code number (e.g. 2 to 5) denotes a "cold spark plug" with low heat absorption through a short insulator nose. High heat-range code numbers (e.g. 7 to 10) denote "hot spark plugs" with high heat absorption through long insulator noses.

The heat range matching the respective engine is determined in the course of application measurements during development.

Ionic-current measurement procedure
The Bosch ionic-current measurement procedure employs the combustion process as a factor for determining the heat-range requirement. The ionizing effect of flames is used to assess how combustion develops over time; this is done by measuring conductivity in the spark gap.

Figure 2: Spark-plug temperature response
1 Spark plug with excessively high heat-range code number (hot plug),
2 Spark plug with suitable heat-range code number,
3 Spark plug with excessively low heat-range code number (cold plug).

The working range temperature should be from 500 °C to 900 °C for different engine performance ratings.

Characteristic changes in the combustion process due to increased thermal loading of the spark plugs can be detected using ionic current and used in the assessment of the auto-ignition process.

Thermal ignition
Ignitions of the air/fuel mixture which occur independently of the ignition spark and for the most part on a hot surface (e.g. on the excessively hot insulator-nose surface of a spark plug with excessively high heat range) are called auto-ignitions. These can be subdivided into two categories on the basis of their position in time relative to the moment of ignition.

Post-ignition
Post-ignitions occur after the electrical moment of ignition, but are not critical for practical engine operation since electrical ignition occurs at an increasingly earlier stage. To find out whether thermal ignitions are initiated by the spark plug, individual ignitions are cyclically suppressed during the ionic-current measurement. When a post-ignition occurs, the ionic current increases significantly only after the moment of ignition. But since a combustion is initiated, a pressure increase and hence a torque output are also to be observed.

Pre-ignitions
Pre-ignitions occur before the electrical moment of ignition and can, on account of their uncontrolled progression (see Irregular operating states), cause serious engine damage. Excessively early combustion initiation shifts not only the position of the pressure maximum to top dead center (TDC), but also the maximum combustion-chamber pressure to higher values. This increases thermal and mechanical load on the components in the combustion chamber.

Spark-plug choice
The aim of an adaptation is to choose a spark plug which can be operated without thermal ignitions before the moment of ignition (pre-ignition) and has a sufficient heat-range reserve. In this way, the variations in engine and spark-plug production are covered and it is also taken into consideration that engines can change in terms of

their thermal properties over the course of their operating life. Thus, for example, oil-ash deposits in the combustion chamber can increase the compression ratio, which in turn causes a higher temperature load on the spark plug.

The correct heat range for the engine is determined when no failures with sooted spark plugs occur in the concluding cold-start tests with this heat-range recommendation.

The use of materials with higher thermal conductivity for the center electrodes (silver or nickel alloys with copper core) provides – with the same heat-range code number – for a significant increase in the insulator-nose length, the upshot of which is that the spark plug is less prone to heavy sooting. This reduces the likelihood of combustion misses and misfiring – with their attendant massive increases in hydrocarbon emissions – and provides benefits in exhaust emissions and fuel consumption in part-throttle operation at low load factors.

Close cooperation between engine and spark-plug manufacturers is customary when it comes to choosing suitable spark plugs.

Electrode gap and ignition voltage

The electrode gap is the shortest distance between the center electrode and the ground electrode (Figure 3). It determines, among other things, the ignition-spark length and should on the one hand be as large as possible to enable the ignition spark to activate a large area of the air/fuel mixture. This gives rise through stable flame-core formation to a reliable ignition of the air/fuel mixture. On the other hand, a lower ignition voltage is needed to produce a spark with a smaller electrode gap. If the electrode gap is too small, however, only a small flame core will be created around the electrode. Since energy will be drawn from the flame core via the contact areas with the electrodes (quenching), the flame core will only be able to propagate very slowly. In extreme cases, so much energy may be drawn off that misfires will occur.

During flashover and operation at higher temperature the electrode material is subjected to such high stress that the electrodes wear and consequently the electrode gap gets bigger. As the electrode gap increases the ignition conditions are in fact improved, but the ignition-voltage demand increases. As the ignition coil's voltage supply is a fixed amount, the ignition-voltage reserve is reduced and the risk of misfiring increases.

The required ignition voltage is influenced not only by the electrode gap, the electrode shape, the temperature, and the electrode material, but also by parameters specific to the combustion chamber, such as mixture composition (λ value), flow velocity, turbulence, and density of the ignitable gas.

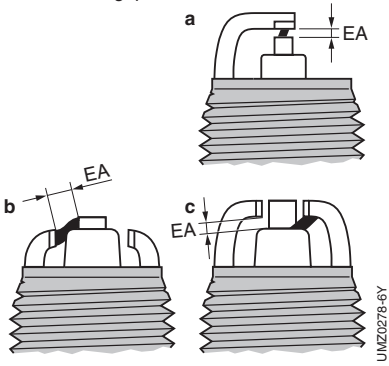
In modern engine concepts with high mixture density, which frequently feature high charge turbulence, electrode gaps must be carefully defined in order to guarantee reliable ignition, and thus misfire-free operation throughout the required service life.

Spark position

The position of the spark gap relative to the combustion chamber wall defines the spark position. On modern engines (and particularly with gasoline direct-injection engines), the spark position has a considerable influence on combustion. A perceptible improvement in ignition response is observed when the spark position projects deeper into the combustion chamber. Combustion can be characterized by smooth-running engine performance, which can be derived directly from engine speed fluctuations.

However, because the ground electrodes are longer, higher temperatures are achieved. This, in turn, has an effect on electrode wear and electrode durability. It is possible to achieve the required service life by implementing design measures (e.g. extending the spark-plug shell beyond the combustion chamber wall), or by using compound electrodes, or high-temperature-resistant materials.

Spark-plug concepts



One or more ground electrodes can be advantageous, depending on the demands placed on the spark plug (wear, ignition response, etc.). The spark-plug type is determined by the relative location of the electrodes to each other and the position of the ground electrodes with respect to the insulator.

Air-gap spark concept
In the air-gap spark concept (Figure 3a) the ignition spark crosses between the center electrode and the ground electrode by the direct route and ignites the air/fuel mixture.

Surface-gap spark concept
The position of the ground electrode relative to the ceramic produces the surface-gap spark concept, in which the spark travels from the center electrode across the surface of the insulator nose before jumping across a gas-filled gap to the ground electrode (Figure 3b). The advantages here are the lower voltage demand with the same electrode gap, improved ignition properties,and the insulator-cleaning effect of the surface-gap spark for better repeat cold-starting performance.

Surface-air-gap spark concept
When both forms of discharged are made possible by the specific geometric arrangement of the ground electrodes, this is called the surface-air-gap spark concept (Figure 3c). Depending on operating conditions, the spark behaves either as an air-gap spark or a surface-gap spark with different ignition-voltage demand values.

Figure 3: Spark-plug concepts
a) Air-gap spark concept with front electrode,
b) Surface-gap spark concept with side electrodes,
c) Surface-air-gap spark concept with side electrodes.
EA Electrode gap.

In view of the trend towards increasing combustion-chamber pressures, air-gap spark concepts are to be preferred since these do not cause spark embedding in the insulator.

Simulation-based development of spark plugs
The Finite-Element Method (see FEM examples) is used for spark plugs to calculate temperature and electric fields and to solve structure-mechanical problems. Changes to the geometry and materials of spark plugs or even different physical boundary conditions and their effects can thus be determined in advance without complicated tests. This is the basis for a targeted production of test specimens, with which the calculation results are verified by way of example.

Spark-plug operating performance
Electrode wear
As spark plugs operate within an aggressive atmosphere, sometimes at extremely high temperatures, electrodes are subject to wear. This material erosion causes the electrode gap to increase noticeably the longer the spark plug is in service, therefore causing the ignition-voltage demand to increase. When this requirement can no longer be met by the supply from the ignition coil, misfiring will occur.

There are essentially two mechanisms that are responsible for electrode wear: spark erosion and corrosion in the combustion chamber. The flashover of electric sparks results in an increase in the temperature of the electrodes up to their melting temperature. The fused microscopically small surface areas react with the oxygen or the other constituents of the combustion gases. The consequence is material erosion.

Materials with a high thermal resistance (special-steel alloys of platinum or iridium) are used to minimize electrode wear. But material wear can also be reduced for the same period of use by the appropriate selection of electrode geometry (e.g. smaller diameters, thin pins) and spark-plug concept (surface-gap spark plugs). In a surface-air-gap spark plug with four ground electrodes, there are eight possible spark gaps. In this way, the wear is evenly distributed across all four electrodes.

The electrical resistance effected in the conductive glass seal also reduces erosion and wear.

Changes in operation
Dirt and changes in the engine caused by aging (e.g. higher oil consumption) can also affect operation of the spark plug. Deposits on the spark plug can result in shunts, and thus in misfiring. This, in turn, may cause a considerable rise in pollutant emissions, and even damage the catalytic converter.

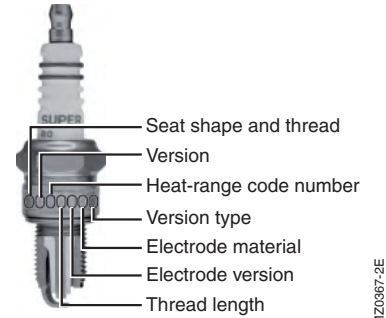
For these reasons, spark plugs have a defined service life after which the spark plugs must be replaced.

Irregular operating states
Irregular operating states may arise and the engine and the spark plugs may sustain damage due to incorrectly set ignition systems, the use of spark plugs whose heat range is unsuitable for the engine, or the use of unsuitable fuels.

Auto-ignition
Auto-ignition (pre-ignition) is an unwanted ignition process. This arises in response to overheated components (e.g. on the tip of the spark-plugs insulator nose, on an exhaust valve, on protruding cylinder-head gaskets) with the result that the air/fuel mixture ignites there under uncontrolled conditions. Severe damage can be caused to the engine and spark plug as a result of auto-ignition.

Combustion knock
Knocking is characteristic of an uncontrolled combustion process with very sharp rises in pressure (see Knocking). The combustion process is considerably faster than normal combustion. The components (cylinder head, valves, piston, and spark plugs) are subject to high temperature load which can result in damage. Knocking can be prevented by retarded ignition angle (see Knock control).

Versions and applications
The different spark-plug types are identified by a type designation. This contains all the essential spark-plug features (Figure 4, [1]). The electrode gap is additionally indicated on the packaging. The spark plug which is suitable for a given engine is specified or recommended by the engine manufacturer and by Bosch.



Standard spark plug for automobiles
The spark plug pictured in Figure 1 can be referred to as the standard plug for older, simply built, naturally aspirated engines.

The demands imposed on the spark plug are constantly increasing as engines are further developed up to higher specific power outputs due to, for example, improved fuel efficiency and emission-control legislation. The most sophisticated engines are direct-injection engines with multi-stage supercharging and valve-timing adjustment.

Spark plugs for direct-injection engines
Direct-injection engines impose particularly high demands on spark plugs. They must therefore be specially adapted to the needs of the respective engine (e.g. power output, mean pressure). This results in different requirements of the spark-plug concept for combustion processes with stratified or homogeneous operation.

Through the combination of direct injection with turbocharging, the emphasis in spark-plug development is on expanding

Figure 4: Designation code
The type designation describes the following features.

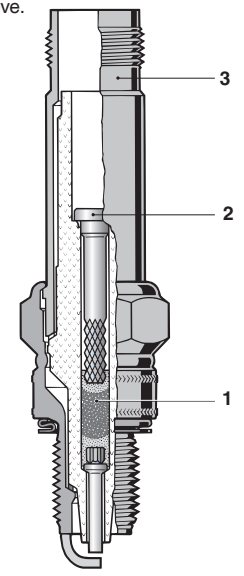
ignition-voltage demand, thermal load capability of the electrodes, mechanical load capability, and service life (wear reduction). For this reason, spark plugs with precious metal electrodes and M12 thread are normally used, and they are also specifically aligned in the combustion chamber when used for spray-guided combustion processes with stratified operation.

Spark plugs for gas and flex-fuel applications
The spark-plug design for natural-gas and flex-fuel use is comparable with that described previously. For each application the appropriate spark-plug version is determined while taking into account the operating conditions within the framework of the application measurements.

As a rule, alternative fuels have higher antiknock properties such that the moment of ignition can be advanced for an optimum combustion. For the most part a lower heat range is recommended for the spark plug in view of the resulting higher thermal load on the spark plug.

Special spark plugs
Special spark plugs are used for particular requirements. These differ in their design, which is dictated by the usage conditions and the installation conditions in the engine.

Spark plugs for motor sport
Engines for sports vehicles are exposed to extreme thermal loads on account of the high proportion of wide-open throttle applications involved. Spark plugs for these operating conditions mostly have precious-metal electrodes (silver, platinum) and a short insulator nose with low heat absorption.



Fully-shielded spark plugs
In the event of very high interference-suppression demands, it may be necessary to shield the spark plugs. On fully-shielded spark plugs the insulator is wrapped in a metal shielding sleeve. The terminal is located inside the insulator (Figure 5). Fully-shielded spark plugs are watertight.

Spark-plug practice
Spark-plug installation
When installed correctly and the right type is chosen, the spark plug is a reliable component of the ignition system. The electrode gap can only be re-adjusted in spark plugs with front electrodes. On surface-gap and surface-air-gap spark plugs the ground electrodes must not be re-adjusted as this will alter the spark-plug concept.

Errors and their consequences
For a particular engine type only the spark plugs approved by the engine manufacturer or recommended by Bosch may be used. Using unsuitable spark-plug types can cause serious engine damage.

Incorrect heat-range code number
The heat-range code number must without fail match the engine manufacturer's spark-plug specification or the recommendation by Bosch. Auto-ignitions may result if spark plugs with a heat-range code number other than that prescribed for the engine are used.

Figure 5: Fully-shielded spark plug
1 Special conductive glass seal (interference-suppression resistor),
2 Ignition-cable terminal,
3 Shielding sleeve.

Incorrect thread length
The thread length of the spark plug must match the thread length in the cylinder head. If the thread is too long, the spark plug will project too far into the combustion chamber. Damage to the piston is a potential consequence. In addition, coked spark-plug threads may make it impossible to unscrew the spark plug or cause the spark plug to overheat.

If the thread is too short, the spark plug will not project far enough into the combustion chamber. This may result in poorer mixture ignition. Furthermore, the spark plug will not reach its self-cleaning temperature and the lower threads in the cylinder head will sustain coking.

Tampering with the seal seat
On spark plugs with conical seal seats neither a plain washer nor a sealing ring may be used. On spark plugs with flat seal seats only the "captive" sealing ring located on the spark plug may be used. It must not be removed or replaced by a plain washer. Without the sealing ring the spark plug projects too far into the combustion chamber, the transfer of heat from the spark-plug shell to the cylinder head is compromised, and the spark-plug seat provides a poor seal. If an additional sealing ring is used, the spark plug does not project far enough into the threaded hole, and the transfer of heat from the spark-plug shell to the cylinder head is likewise compromised.

Assessment of spark-plug faces
The spark-plug face refers to the combustion end of the spark plug with the electrodes and the insulator nose. Their appearance in terms of color and deposits provides indications of the spark plug's operating performance and the engine's mixture composition and combustion process.

Catalytic exhaust-gas treatment

Catalytic converter

Emission-control legislation defines limits governing pollutant emissions from motor vehicles. Engine-design measures alone are not sufficient to comply with these limits. In addition to reducing untreated engine emissions, the emphasis in spark-ignition engines is on catalytic aftertreatment of the exhaust gas in order to convert the pollutants. Catalytic converters convert the pollutants produced during combustion into harmless components.

Three-way catalytic converter

Function

The state-of-the-art technology for engines operating with a stoichiometric A/F mixture is the three-way catalytic converter (TWC). Its task is to convert pollutant components HC (hydrocarbons), CO (carbon monoxide), and NO_x (nitrogen oxides), which arise during the combustion process, into harmless components. The end products are H_2O (water vapor), CO_2 (carbon dioxide), and N_2 (nitrogen).

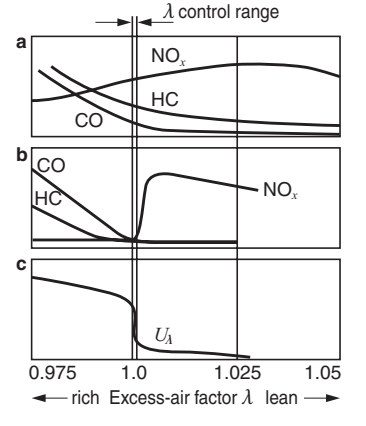
Design and operating principle

The catalytic converter comprises a steel-plate container as housing, the substrate and the substrate coating (washcoat) made of aluminum oxide (Al_2O_3) on which the precious metal is finely spread. The substrate is usually a ceramic monolith, though metallic monoliths are used for special applications (see Ceramic monolith and Metal monolith). On the monolith is a substrate coating, which enlarges the effective area of the catalytic converter by a factor of up to around 10,000. The catalytic layer on top of this contains the precious metals palladium or in the past platinum and rhodium. Platinum and palladium accelerate the oxidation of HC and CO, while rhodium is responsible for reducing NO_x. The amount of precious metal contained in a catalytic converter is approx. 1 to 10 g depending on the engine displacement and the exhaust emissions standard to be met.

For example, oxidation of CO and HC takes place according to the following equations:

$$2\ CO + O_2 \rightarrow 2\ CO_2,$$
$$2\ C_2H_6 + 7\ O_2 \rightarrow 4\ CO_2 + 6\ H_2O.$$

Reduction of nitrogen oxides takes place, for example, according to the following equations:



$$2\ NO + 2\ CO \rightarrow N_2 + 2\ CO_2,$$
$$2\ NO_2 + 2\ CO \rightarrow N_2 + 2\ CO_2 + O_2.$$

The oxygen required for the oxidation process is either present in the exhaust gas as exhaust-gas oxygen (resulting from incomplete combustion), or it is taken from the NO_x, which is reduced at the same time.

The concentrations of pollutants in the untreated exhaust gas (upstream of the catalytic converter) depend on the excess-air factor λ (Figure 1a). In order for the conversion of the three-way catalytic

Figure 1: Catalytic-converter efficiency as a function of the excess-air factor λ

a) Exhaust-gas emission upstream of three-way catalyst,
b) Exhaust-gas emission downstream of three-way catalyst,
c) Electrical signal of two-step λ sensor.
U_λ Sensor voltage.

converter to be as high as possible for all three pollutant components, a mixture composition in the stoichiometric ratio $\lambda = 1$ is required (Figure 1b). At $\lambda = 1$, there is a state of equilibrium between oxidation and reduction reactions which facilitates a full oxidation of HC and CO and, at the same time, reduces the NO_x. In this way, HC and CO act as reducing agents for NO_x. The "window" (λ control range) in which the mean time value of λ must lie is very small. Mixture formation must therefore be corrected in a λ control loop with the aid of the signal of a λ oxygen sensor (Figure 1c) (see λ control).

Oxygen storage
The λ accuracy in the dynamic range is typically 5 %, i.e. fluctuations of $\lambda = 1$ in this scale are inevitable. The catalytic converter can compensate for minor mixture fluctuations itself. It has the ability to store excess oxygen in the lean phase in the catalytic converter in order to release it again in the subsequent rich phase. Its substrate coating contains ceroxide, which can make oxygen available via the following balance reaction:

$$2\ Ce_2O_3 + O_2 \leftrightarrow 4\ CeO_2.$$

The task of the engine-management system is, therefore, clear: The mean time value of the resulting λ upstream of the catalytic converter must be very precise at one (a deviation of only a few thousandths is permitted). The mean value deviations, converted to oxygen input and output, must not overtax the available oxygen retained in the catalytic converter. Typical oxygen-storage values are in the range of 100 mg to 1 g; these values decrease as the catalytic converter ages. All conventional methods of diagnosing catalytic converters are based on the direct or indirect determination of this oxygen storage capacity (osc).

NO_x storage catalytic converter
Function, design and operating principle
During lean-burn operation, it is impossible for the three-way catalytic converter to convert the nitrogen oxides (NO_x) which have been generated during combustion. CO and HCs are oxidized by the high residual-oxygen content in the exhaust gas and are therefore no longer available as reducing agents for the nitrogen oxides.

The catalytic layer of the NO_x storage catalytic converter also contains substances which can store NO_x (e.g. barium oxide). All conventional NO_x storage coatings also have the properties of a three-way catalytic converter, with the result that the NO_x storage catalytic converter operates like a three-way catalytic converter at $\lambda = 1$.

In stratified lean-operation mode (see Gasoline direct injection), NO_x is not converted continuously, but instead in three stages.

NO_x storage
During storage, NO_x is initially oxidized to NO_2, which then reacts with the special oxides of the catalytic-converter surface and oxygen (O_2) to form nitrates (e.g. barium nitrate):

$$2\ NO + O_2 \rightarrow 2\ NO_2,$$
$$2\ BaO + 4\ NO_2 + O_2 \rightarrow 2\ Ba(NO_3)_2.$$

Regeneration
As the quantity of stored NO_x (load) increases, the ability to continue binding NO_x decreases. At a predefined laden state, the NO_x accumulator must be regenerated, i.e. the nitrogen oxides stored in it must be released again and converted. For this purpose, the engine switches briefly to rich homogeneous operation ($\lambda < 0.8$) to reduce NO to N_2, without emitting CO and HC in the process. In a second stage, the rhodium coating reduces the nitrogen oxides with CO:

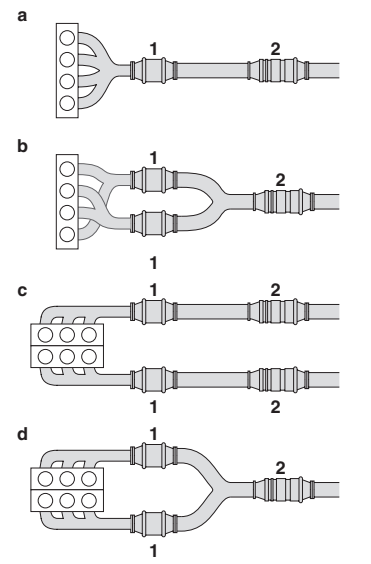
$$Ba(NO_3)_2 + 3\ CO \rightarrow 3\ CO_2 + BaO + 2NO.$$
$$2\ NO + 2\ CO \rightarrow N_2 + 2\ CO_2.$$

The end of the storage and release phase is either calculated using a model-based method or measured with a λ oxygen sensor after the catalytic converter.

Desulfating
The sulfur contained in the fuel also reacts with the accumulator material in the catalytic layer. The result is that, over time, the amount of accumulator material available for NO_x accumulation diminishes. This creates sulfates (e.g. barium sulfate) which are very temperature-resistant and are not reduced during NO_x regeneration. For desulfating, special measures must be used to heat the catalytic converter to 600 to 650 °C before exposing it alternately to rich (λ = 0.95) and lean exhaust gas (λ = 1.05) for a few minutes. This process reduces the sulfates.

The various methods to heat up the NO_x storage catalytic converter located in the underfloor regions must be careful not to overheat the close-coupled catalytic converter.

Catalytic-converter operating temperature
Catalytic converters do not start significant conversion until they have reached a specific operating temperature (light-off temperature). On a three-way catalytic converter, this is approximately 300 °C. Ideal conditions for a high conversion rate are achieved at 400 to 800 °C.



In the case of the NO_x storage catalytic converter, the favorable temperature range is lower; it reaches maximum storage capacity at 300 to 400 °C. The reason for the lower temperature range is that the maximum storage capacity is reduced at higher temperatures. At temperatures higher than 500 to 550 °C the barium compound is no longer stable, which means that nitrogen oxides can no longer be stored.

Operating temperatures of 800 °C to 1,000 °C result in intensified thermal aging of the catalytic converter. This is caused by sintering of the precious metals and the substrate coating, which reduces the active surface. At temperatures above 1,000 °C, thermal aging increases considerably until the catalytic converter has no effect at all.

Catalytic-converter configurations
The required operating temperature of the three-way catalytic converter limits the installation options. Engine-proximate catalytic converters quickly reach operating temperature, but can be exposed to very high thermal loads.

Figure 2: Catalytic-converter configurations
a) Deployment of a close-coupled catalytic converter and an underfloor catalytic converter.
b) 4-into-2 exhaust manifold for power-optimized engine design: The positioning of the underfloor catalytic converter only after the second junction is unfavorable for the heating-up characteristics, which means that preferably two close-coupled catalytic converters are deployed.
c) Engine with more than one cylinder bank (V engine): The exhaust-gas system runs completely as twin-branch with an upstream and an underfloor catalytic converter for each.
d) Engine with more than one cylinder bank (V engine): Y-shaped junction in the underfloor area to form an overall exhaust-gas train with a joint underfloor catalytic converter for both banks.

1 Close-coupled catalytic converter,
2 Underfloor catalytic converter or coated particulate filter.

A widely used configuration of the three-way catalytic converter is the split arrangement with a close-coupled catalytic converter and an underfloor catalytic converter. The close-coupled catalytic converter is optimized with regard to high-temperature stability, the underfloor catalytic converter with regard to "low light off" (low activation temperature). Figure 2 shows different possible arrangements of the primary and underfloor catalytic converters. Owing to their lower maximum permissible operating temperature, NO_x storage catalytic converters are always installed in the underfloor area.

Catalytic-converter heating

Whereas a catalytic converter at operating temperature reaches very high conversion rates of almost 100 %, considerably greater amounts of pollutants are emitted in the cold start phase and in the warm-up phase. The HC and CO emissions are particularly high when the engine is cold because fuel condenses onto the cold cylinder walls, leaves the combustion chamber unburned and cannot be converted by the cold catalytic converter.

It is therefore important to minimize untreated emissions during the warm-up phase before the catalytic converter lights off (operating temperature reached). Measures are also required to bring the catalytic converter up to operating temperature quickly. The required heat is provided by raising the exhaust-gas temperature and increasing the exhaust-gas mass flow. This is made possible by the following measures.

Ignition-angle adjustment

The main measure for increasing the exhaust-gas heat flow is ignition-angle adjustment. Combustion is initiated as late as possible and takes place during the expansion phase. The exhaust gas has a relatively high temperature at the end of the expansion phase. Retarded combustion has an unfavorable effect on engine efficiency.

Idle speed increase

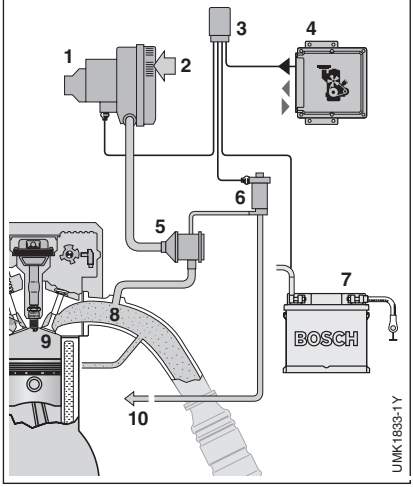
A supporting measure is to raise the idle speed and thereby increase the exhaust-gas mass flow. The increased engine speed permits a greater ignition-angle retardation. However, in order to ensure reliable ignition, the ignition angles are limited to roughly 10 to 15 °KW after TDC. The heat output limited in this way is not always enough to achieve the current emission limits.

Exhaust-camshaft adjustment

A further contribution to increasing the heat flow can be achieved, if necessary, with exhaust-camshaft adjustment. The process of the exhaust valves opening as early as possible interrupts the retarded combustion early and the mechanical work generated is thus reduced further. The quantity of energy not converted into mechanical work is available as a quantity of heat in the exhaust gas.

Homogeneous split

With gasoline direct injection, there is, in principle, the possibility of multiple injection. This enables the catalytic converter to be quickly heated up to operating temperature without the need for additional components. The "homogeneous-split" measure involves initially creating a homogeneous, lean basic mixture by means of injection during the induction stroke. Subsequent injection during the compression stroke generates a stratified charge cloud. This facilitates retarded moments of ignition and results in high exhaust-gas heat flows. The exhaust-gas heat flows that can be achieved are comparable with those of a secondary-air injection.



Secondary-air injection

Thermal afterburning of unburnt fuel constituents increases the temperature in the exhaust system. A rich (λ = 0.9) to very rich (λ = 0.6) air/fuel basic mixture is adjusted for this purpose. A secondary-air pump supplies oxygen to the exhaust system (Figure 3) to produce a leaner exhaust-gas composition. Where the basic mixture is very rich (λ = 0.6), the unburnt fuel constituents oxidize above a specific temperature threshold exothermically before entering the catalytic converter. To

achieve this temperature, it is necessary on the one hand to raise the temperature level with retarded ignition angles and on the other hand to introduce the secondary air as closely as possible to the exhaust valves. The exothermic reaction in the exhaust system increases the heat flow to the catalytic converter and therefore shortens its heating period. The HC and CO emissions are for the most part reduced before entering the catalytic converter.

Where the basic mixture is less rich (λ = 0.9), there is no significant reaction ahead of the catalytic converter. The unburnt fuel constituents oxidize in the catalytic converter and heat it up from the inside. For this purpose, however, the end face of the catalytic converter must first be brought up to a level above the light-off temperature by means of conventional measures (e.g. ignition-angle adjustment).

Figure 3: Secondary-air system
1 Secondary-air pump,
2 Inducted air,
3 Relay,
4 Engine control unit,
5 Secondary-air valve,
6 Control valve,
7 Battery,
8 Point of introduction into exhaust pipe,
9 Exhaust valve,
10 To intake-manifold connection.

As a rule, a less rich basic mixture is adjusted, because, if the basic mixture is very rich, the exothermic reaction ahead of the catalytic converter occurs reliably only under stable boundary conditions.

Secondary-air injection is performed with an electric secondary-air pump, which is switched by means of a relay on account of the high power demand. Since the secondary-air valve prevents backflow of exhaust gases into the pump, it must remain closed when the pump is deactivated. Either it is a passive non-return valve or it is actuated by purely electrical or (as shown in Figure 3) pneumatic means with an electrically actuated control valve. When the control valve is actuated, the secondary-air valve opens in response to the intake-manifold vacuum. The secondary-air system is coordinated by the engine ECU.

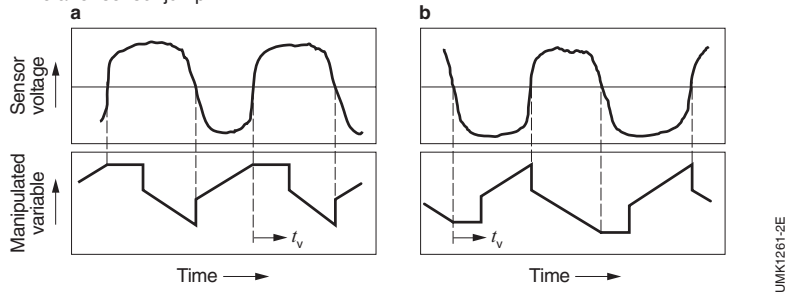
Alternative concepts for active heating
As a supplement in special cases, an electrically heated catalytic converter is used for quick heating up of the catalytic converter. This has been used previously in individual small-series projects.

λ control

To insure that the conversion rates of the three-way catalytic converter are as high as possible for the pollutant components HC, CO and NO_x, the reaction components must be present in the stoichiometric ratio. This requires a mixture composition of $\lambda = 1.0$, i.e. the stoichiometric air/fuel ratio must be adhered to very precisely.

Mixture formation must be followed up in a control loop, because sufficient accuracy cannot be achieved solely by controlling the metering of the fuel. When the λ control loop is used, deviations from a specific air/fuel ratio can be detected and corrected through the quantity of fuel injected. The residual-oxygen content in the exhaust gas, which is measured with λ oxygen sensors (see Two-step λ oxygen sensor and Broad-band λ oxygen sensor), serves as the measure for the composition of the air/fuel mixture.

Two-step λ control



Two-step λ control adjusts the mixture to $\lambda = 1$. A manipulated variable, composed of the voltage jump and the ramp, changes its direction of control for each voltage jump of the two-step λ sensor. This indicates a change from rich to lean or from lean to rich (Figure 4). The typical amplitude of this manipulated variable has been set in the range of 2 to 3 %. The result is a limited controller dynamic, which is predominantly determined by the sum of the response times (pre-storage of fuel in the intake manifold, four-stroke principle of the spark-ignition (SI) engine, and gas travel time).

The typical shift of the oxygen zero transition point (theoretically at $\lambda = 1.0$) and therefore the jump of the λ sensor, caused by the variation in exhaust-gas composition, can be control-compensated by shaping the manipulated variable's characteristic curve asymmetrically (rich or lean shift). Here, the preferred method is to hold the ramp value at the voltage jump for a controlled dwell time t_V after the sensor is subjected to a voltage jump. A rich or lean shift is performed depending on the operating point. When a shift is made towards "rich", the manipulated variable holds at the rich position for a dwell time t_V although the sensor signal has already jumped towards "rich" (Figure 4a). Jump and ramp of the manipulated variable do not also move towards "lean" until the dwell time has elapsed. If the sensor signal then jumps towards "lean", the manipulated variable directly counteracts this (with jump and ramp) without dwelling on the lean position. The dwell time t_V is the result of a pre-control coefficient, which is corrected by a proportion from the two-sensor λ control system (post cat control).

The behavior is reversed in a shift to "lean". If the sensor signal indicates a lean mixture, the manipulated variable holds at the lean position for the dwell time t_V (Figure 4b) and then adjusts towards "rich". A

a) Shift to "rich", b) Shift to "lean".
t_v Dwell time after sensor jump.

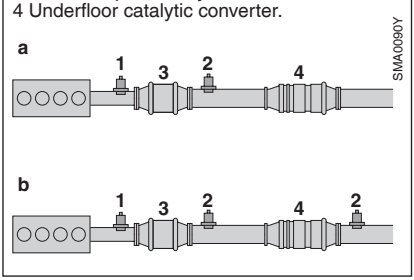
sensor signal jump from "lean" to "rich" is, however, immediately counteracted.

Continuous λ control

The defined dynamic response of a two-step control can only be improved if the deviation from $\lambda = 1$ can actually be measured. The broad-band λ sensor can be used to achieve continuous-action control at $\lambda = 1$ with a stationary, very low amplitude in conjunction with high dynamic response. The control parameters are calculated and adapted as a function of the engine's operating points. Above all, with this type of λ control, compensation for the unavoidable offset of the stationary and non-stationary pilot control is far quicker.

The broad-band λ oxygen sensor also enables adjustment to mixture compositions that deviate from $\lambda = 1$. Thus, controlled enrichment ($\lambda < 1$), e.g. for component protection, can be effected. The broad-band λ sensor also enables controlled leaning ($\lambda > 1$), e.g. for a leaner warm-up during catalytic-converter heating.

Two-sensor λ control



When it is situated upstream of the catalytic converter, the λ sensor is heavily stressed by high temperatures and untreated exhaust gas, and this leads to limitations in λ sensor accuracy. The voltage-jump point of a two-step sensor or the characteristic curve of a broad-band sensor can shift, for example, as a result of changed exhaust-gas compositions. A λ sensor downstream of the catalytic converter is subjected to these influences to a much lesser extent. However, λ control on its own with the sensor downstream of the catalytic converter demonstrates disadvantages in dynamic response on account of the gas travel times, and responds to mixture changes more slowly.

Greater accuracy is achieved with two-sensor control. Here, a slower correction control loop is superimposed on the two-step or continuous-action λ control described by means of an additional two-step λ sensor (Figure 5a). The voltage of the two-step sensor downstream of the catalytic converter is compared with a setpoint value (e.g. 600 mV) for this purpose. On this basis the control evaluates the deviations from the setpoint value and additionally alters over a dwell time t_v additively the controlled rich or lean shift of the first control loop of a two-step control or the setpoint value of a continuous-action control.

Three-sensor λ control

There are SULEV concepts (Super Ultra-Low-Emission Vehicle) with a third sensor downstream of the underfloor catalytic converter. The two-sensor control system (single cascade) has been supplemented here by an extremely slow closed-loop control system using a third sensor located downstream of the underfloor catalytic converter (Figure 5b). The aim of development is, however, the two-sensor concept.

Particulate filter for gasoline engines

Function

The function of the particulate filter in the gasoline engine with gasoline direct injection is to adhere to the limit values for particulate matter and particulate number laid down in the exhaust-emissions standard Euro 6c or Euro 6d(-temp) (see also Particulate filter for diesel engines). An additional catalytic coating of the particulate filter serves to increase the catalytic-converter volume available for the oxidation of CO and HC and the reduction of NO_x. A catalytically coated particulate filter can thus replace a three-way catalytic converter.

Design

The particulate filter for gasoline engines is designed in the same way as the particulate filter in diesel engines (see Particulate filter for diesel engines). For gasoline applications the ceramic is currently made of cordierite.

Regeneration of the particulate filter

Soot is oxidized by oxygen only at temperatures above approximately 550 to 600 °C. In gasoline applications of the particulate filter the temperatures reached in normal operation and the requirement of additional engine measures to increase the exhaust-gas temperature are determined by the filter installation position. Usually the filter is positioned downstream of the three-way catalytic converter. When installed directly downstream of the three-way catalytic converter temperatures of 550 to 600 °C can be achieved in part-load operation without additional measures, while this is only achieved with an installation position in the underfloor area in high-load operation. In terms of regeneration performance an installation position directly downstream of the three-way catalytic converter therefore exhibits clear advantages, but the space required for this must be available near the engine. Integrating the filter function into the three-way catalytic converter for the four-way catalytic converter (FWC) does exhibit clear advantages with regard to the regeneration performance and near-engine installation area, but up to now has only been implemented in individual applications due to the highest thermal load at full load.

The most important engine measure to increase the exhaust-gas temperature is, as with heating the catalytic converter, ignition-angle retardation, which simultaneously brings about de-throttling and an increase in the exhaust-gas mass flow and in the case of gasoline direct injection can be combined with multiple injection ("homogeneous split"). Another measures is the alternate rich/lean adjustment of individual cylinders while adhering to an exhaust-gas λ of 1. Unburned exhaust-gas constituents from the rich-burn cylinders are exothermally converted here with O_2 from the lean-burn cylinders in the three-way catalytic converter.

In contrast a diesel engine, in a gasoline engine operated with exhaust-gas λ of 1 there is no O_2 available for soot oxidation in normal operation. After the required temperature is reached, the soot can therefore be burned off initially in an overrun phase. Alternatively, it is possible to achieve soot burn-off by setting a lean exhaust-gas λ of up to approximately 1.1, which is however to be avoided because of the increased NO_x emissions involved.

Saturation detection

The strategies used to determine the amount of soot stored in the particulate filter are comparable with the method used on diesel engines (see Particulate filter for diesel engines).

Motor sport

Requirements

The basic requirements regarding components in motor-sport vehicles are different from those in production vehicles. A racing car requires maximum performance for a few hours with the lowest possible weight, whereas durability and low costs are the desired attributes in a production car. Furthermore, the components in a racing car are exposed to greater loads from heat, dust, moisture, and vibrations than those in a production car.

The Bosch Motorsport Division develops, produces and sells electronic systems and components for this special field of application. Both modified mass-produced parts and pure motor-sport developments, which often have no equivalent in series production, are offered.

Components

Modified mass-produced parts

Reducing weight

Technicians are constantly on the lookout for ways of reducing the weight of production components for racing applications. The reduced service life generally associated with this is tolerated.

By using ultralight special materials and specific special constructions, it is possible to reduce the weight of many components – and all this with higher power output. As the motto goes: Remove as much material as possible, keep as little material as is necessary. A quotation that goes around in design-engineer circles puts it in a nutshell: "The perfect racing car crosses the finishing line in first place and then falls apart into its component parts".

Increasing performance

There is a huge range of measures to increase the performance of production components. Alternators for instance have additional windings and thereby produce more energy. Their rotors are fine-balanced and are those less sensi-

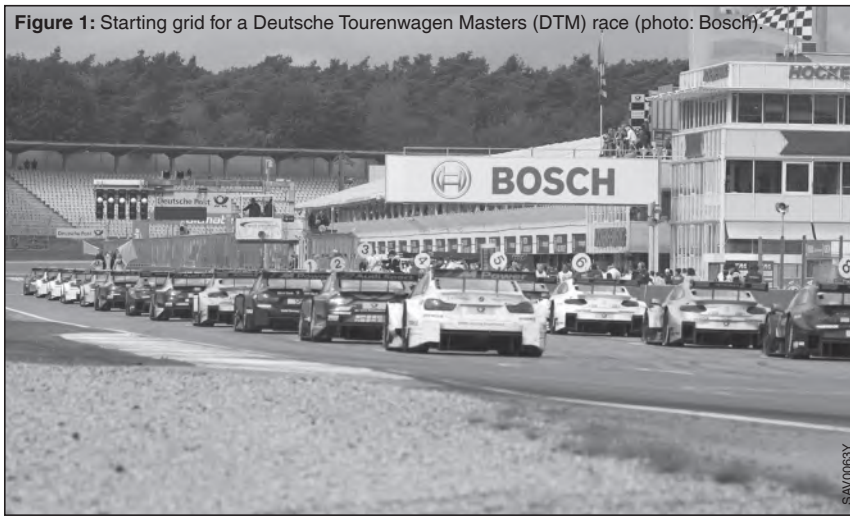

Figure 1: Starting grid for a Deutsche Tourenwagen Masters (DTM) race (photo: Bosch).

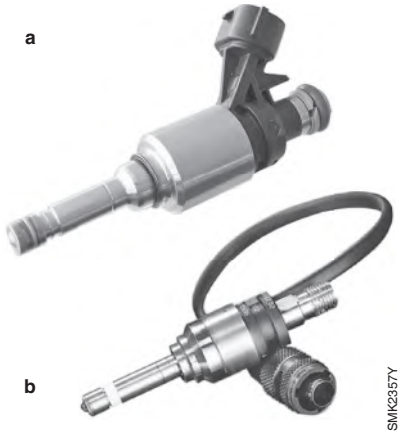


tive to high rotational speeds. Temperature sensors respond much more quickly once the metal that normally encloses the measuring capsule has been removed. Changes to fuel pumps and fuel injectors are frequently made with increased throughflow and increased pressure in mind.

The sometimes significantly higher specific engine performance of racing cars makes these measures absolutely necessary. The use of better ferromagnetic materials generate higher magnetic forces in the coils of the fuel injectors. This makes possible greater needle strokes, which in turn permit a higher fuel flow.

The modifications to ignition coils go even further. Here only the original shell remains the same, the technology inside is all new. The coils are made with fewer windings from thicker wire, the coil cores are made of higher-quality material. The higher spark energy required for direction-injection highly supercharged racing engines can be guaranteed in this way. The shorter dwell periods increase the upper speed limit to 15,000 rpm.

Figure 2: High-pressure fuel injectors in motor sport

a) Component with production connector on the housing.
b) Component with cable and motor-sport connector.

Replacing connectors

Production connectors made of plastic are not designed for frequent opening and closing and have only limited resistance to vibrations and moisture. They are therefore often removed from motor-sport components and replaced by cables with motor-sport connectors (Figure 2). Their metal housings have a bayonet catch for reliable and rapid opening and closing. They are dust-proof and watertight and, because they are no longer rigidly connected to the component, can be installed in locations that are less exposed to vibration. Particularly for sensors, ignition coils and fuel injectors this modification makes installation and removal easier and increases operational reliability by minimizing primarily vibration-induced damage. These connectors are standard in motor racing and are compatible with virtually all wiring harnesses and diagnostic tools.

Dissipating heat

High-performance electronic systems generate a lot of heat which can jeopardize temperature-sensitive components. This heat is dissipated by cooling fins to the housing walls and the use of thermal-conduction paste in the housings. These housings are often black to improve heat dissipation.

Regular maintenance

Unlike in production-vehicle manufacturing, where starters and alternators as a rule go through the entire life of the vehicle without maintenance and repairs, these components are overhauled in motor racing after a certain period of operation. Bosch offers its customers this service for all motor-sport components. The components are dismantled, cleaned and provided with new wearing parts at the factory. They are then restored to the same operational reliability as new parts.

ECUs

The fundamental difference from a production ECU, where the manufacturer must guarantee tuning protection measures, is the free access to the software for all motor-sport systems. In this way, the teams can tune each car individually to racetrack, weather and driver. The computer programs required for tuning on the laptop computer are developed by Bosch itself. Furthermore, programs for analyzing recorded vehicle data and for simulating different vehicle tunings are offered.

Series-based ECUs
Series-based developments with sheet-metal housings and plastic connectors constitute the entry level into motor-sport ECUs. The range of functions is less complex than in high-end ECUs and can therefore also be easily handled by smaller teams. These systems are frequently used in Formula 3, in marque cups and in near-series motor-racing classes, where many GT3 class customer sports cars are used.

High-end ECUs
Top-end models among the ECUs have all-aluminum milled housings and motor-sport connectors (Figure 3). The housings are powder-coated to protect the surface. The number of connector pins and hence of inputs and outputs is high, and the number of controllable cylinders is frequently high too. Some systems have customer code areas, in which customers can store their own software and link with the basic software. Communication channels to CAN and LIN bus systems as well as telemetry connections and internal data memories are standard.

Working with these systems calls for a high level of specialized knowledge, which as a rule can only be brought to bear by works teams. Typical areas of application for these ECUs are the World Rally Championship (WRC), the World Endurance Championship (WEC), and the Deutsche Tourenwagen Masters (DTM).

Pure motor-sport developments

As well as the high-end ECUs, further pure motor-sport developments are featured in the Bosch Motorsport portfolio. These include, for example, lap-trigger systems with which the times of complete laps or lap segments are measured and telemetry systems for data transfer from the racing car to the box. Driver displays replace all the instruments in the dashboard, are freely programmable, and have switchable display pages. They are frequently equipped with data memories.

High-pressure fuel-injection systems and their valve injectors often require a significantly higher operating voltage than the conventional vehicle electrical system can provide. This gap is filled by the power supply unit which is used in many Formula 1 cars and delivers voltages of up to 90 V.

Safety and comfort
Electronic systems from Bosch however not only deliver better acceleration, but also better deceleration and increased safety and comfort in racing cars.

The Bosch motor-sport ABS systems come with different control characteristics which the driver can select by means of a rotary switch in the dashboard. Here too the ECU software is open and can be changed where necessary. Pre-parameterized plug-and-play versions are offered for certain cup cars. The experts from Bosch lend the customers their sup-

Figure 3: High-end ECU with milled housing and motor-sport connectors

port during individual tuning of the ABS systems on the test bench or on the racetrack.

A radar-based accident-avoidance system uses visual signals to warn against passing cars; these systems are particularly helpful when it is raining or at night.

The Bosch Power-Box replaces all the relays and fuses in a racing car and enables the relay switching points to be changed on a laptop computer without a mechanic having to undo a screw or exchange a component. The laptop computer here also replaces the tool box.

In the case of systematic troubleshooting it is very helpful to be able to measure specifically the signal flow of individual cables in the wiring harness. Here a specifically developed breakout panel, which is switched between the wiring harness and the ECU, provides sterling service.

Figure 4: Spark-plug variants for racing use
a) Racing spark plug with 8 mm thread, toothing for special tool and platinum electrode.
b) Stripped-back spark plug for subsequent processing by the motor-racing customer.

Customer-specific extra-small series

Bosch hand-makes in small numbers motor-sport wiring harnesses which network the systems in a racing car with each other. They have the customary motor-sport connectors and are delivered to the customer after exhaustive functional tests.

Motor-sport spark plugs only have the basic idea in common with the mass-produced components. Electrodes made of pure platinum permit operation at significantly higher temperatures. Thread diameters reduced to 8 mm allow the engine developers plenty of freedom in fashioning the combustion chambers and the cooling ducts (Figure 4). Thread length, width across flats and other sizes are designed by arrangement with the customer. This results in hand-made sample spark plugs which are specially customized to the existing engine concept.

As well as the ready-to-install spark plugs, Bosch offers its motor-racing customers the separate ceramic core of the spark plug for subsequent processing. The customer provides this “stripped-back spark plug” with their own shell, the design of which is among the best-kept secrets of the design engineers.

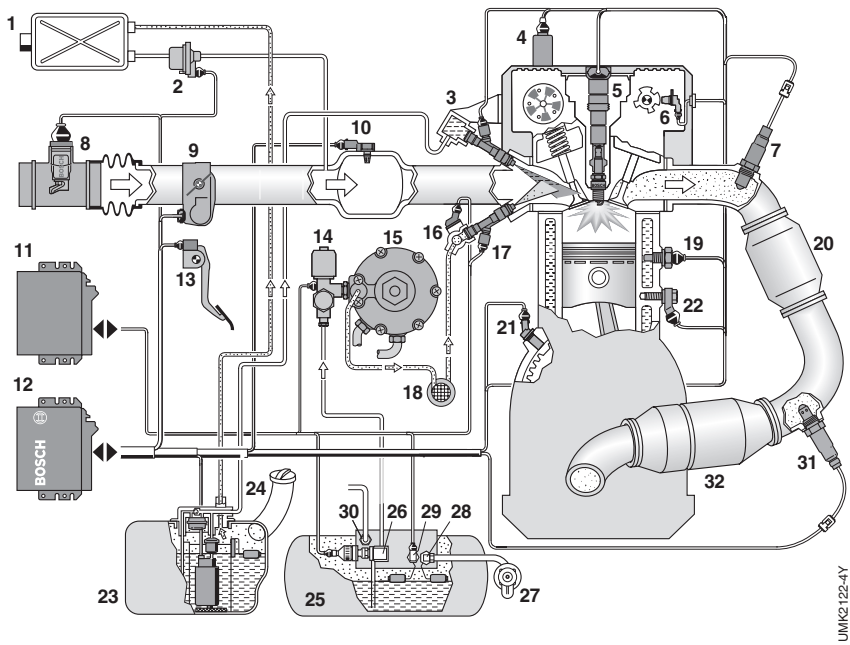
New directions

Mirroring developments in production-vehicle manufacturing, hybrid systems are increasingly being used in racing cars. Electric motors work in coordination with gasoline or diesel engines; recovered energy is buffered in electrical or mechanical accumulators.

Some motor-racing classes are already fully reliant on the purely electric drivetrain, as is demonstrated for example by Formula E cars, which race on city-center street circuits around the world.

In these new directions too the long tradition of exchanging experience and technology between series production and motor sport is being continued by Bosch.

LPG operation



Applications

Liquified petroleum gas (LPG) is obtained during the extraction of crude oil and natural gas and during different refinery processes. It is made up primarily of propane and butane (see Liquid petroleum gas).

As the conventional fuels gasoline and diesel have become more expensive in the last few years, the cheaper liquified petroleum gas – not least due to regional tax reductions (e.g. for Germany, Italy, Poland) – is becoming increasingly more widespread. Liquified petroleum gas is widely used in Europe and in South Korea, Australia, and China. At present (as at No-

vember 2016), there is estimated to be a population of more than 26 million LPG-fueled vehicles worldwide [1]. Up-to-date information on the number of LPG-fueled vehicles and the LPG filling-station network in Germany (currently around 75,350 filling stations worldwide, around 7,050 filling stations in Germany) can be found on the Internet (see [2] and [3]).

The additional volumetric consumption of LPG-fueled vehicles is, depending on engine concept, engine management and gas system 20 – 30 %, compared with gasoline-fueled vehicles. In spite of this additional costs, the running costs of LPG vehicles are cheaper than those of gasoline and diesel vehicles.

LPG systems are distinguished by their mixture formation with gaseous injection or liquid LPG injection and by the ECU concepts with one common or two separate engine ECUs (master/slave concept). Systems with venturi mixers (operating according to the carburetor principle) can only still be used in older vehicles or in markets with laxer exhaust-emission regulations.

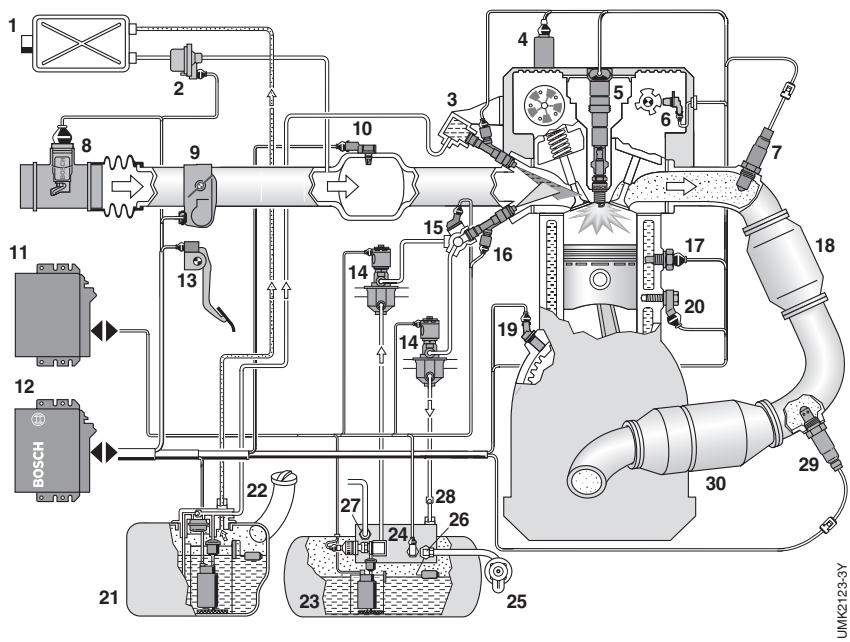
Vehicles with spark-ignition engines are virtually exclusively converted to bifuel LPG/gasoline operation. Most LPG systems are installed as a retrofit. In the meantime, however, vehicle manufacturers are also offering models with bifuel LPG/gasoline operation off the assembly line. In these vehicles, the LPG tank – as in the retrofit concepts – is installed for the most concepts in the spare-wheel compartment. The luggage-compartment load volume remains unchanged with this form of installation. The spare wheel is simply omitted and replaced by a blow-out repair kit (Tire-Fit).

Design

Storage of LPG

LPG can liquify at ambient temperatures of – 20 to +40 °C under pressure (3 – 15 bar), depending on the propane-to-butane mixture ratio. It is stored in a liquid state in steel tanks. The filling system of the LPG tanks incorporates a fill-volume restrictor which ensures that the fill volume does not exceed 80 % of the liquid phase of the maximum tank volume. This ensures that the internal tank pressure does not rise to unacceptable levels when the tank is subjected to heat. The tanks are subject (also in some non-European countries) to European safety regulations governing their properties, equipment specification and installation – currently ECE-R67-01 [4].

The safety devices of an LPG tank comprise a pressure-relief valve, an electromagnetic shutoff valve with integrated flow limiter (pipe-fracture protection), and optionally a thermal safety valve which allows the gas to escape under controlled conditions in the event of a fire.



Fuel delivery

The LPG is delivered from the tank to the engine in systems with gaseous injection by the internal tank pressure (LPG vapor pressure). Because this pressure drops as ambient temperature decreases, the operation of such systems is partly limited with regard to their suitability for winter operation.

In systems with liquid injection, the LPG is delivered by an LPG fuel-supply pump installed in the LPG tank which generates a delivery pressure in addition to the internal tank pressure. In terms of their suitability for winter operation, these systems are comparable with gasoline injection systems.

Components
The following components are integrated into LPG vehicles (Figures 1 and 2):
– LPG filler neck with integrated non-return valve,
– Steel tank (cylindrical or toroidal),
– Pressure-relief valve (27 bar),
– LPG level sensor,
– Valve with integrated 80 % tank filler stop,
– Electromagnetic shutoff valve (in the tank),
– LPG shutoff valve (in the engine compartment),
– Evaporator with pressure regulator (only for systems with gaseous LPG injection),
– Pressure regulator (optional in systems with liquid LPG injection),
– LPG fuel rail with gas injectors,
– Pressure and temperature sensors (on the rail),
– LPG filter,
– If necessary, a slave ECU,
– Demand-controlled LPG supply pump (only in systems with liquid LPG injection).

LPG systems

Systems with gaseous LPG injection

Operating principle

The LPG is delivered in liquid state from the tank via the electromagnetic shutoff valve to the engine compartment (Figure 1), where an additional shutoff valve is installed. After this, the LPG is converted into the gaseous state with pressures of 0.5 to 3.5 bar in the evaporator and the pressure regulator. The evaporator is heated by the engine coolant in order to compensate for the cooling encountered during the phase transition. The gaseous LPG is directed from the evaporator through a pressure-resistant flexible hose to the LPG rail and from here injected by the gas injectors into the intake manifold.

The air-intake section of the basic engine remains unchanged except for the connection of the LPG gas injectors to the intake manifold.

Mixture formation

Mixture formation is effected in the same manner as conventional multipoint gasoline injection. The LPG rail supplies the individual gas injectors with gaseous LPG. Engine management determines the required injected fuel quantity, which is corrected by means of λ control. The injected fuel quantity is additionally corrected by means of the pressure and the temperature of the fuel in the LPG rail.

LPG injection displaces some of the inducted air volume in the intake manifold, which results in charge losses in non-turbocharged engines. Engine performance reduced by a factor of 2–4% compared with gasoline operation can thus be expected for LPG operation.

Systems with LPG liquid injection into the intake manifold

Operating principle

In systems with LPG liquid injection into the intake manifold (Figure 2) the LPG ECU regulates the system pressure via a fuel pump installed in the LPG tank.

Some systems may also need a pressure regulator to regulate the injection pressure. Because of the tendency for vapor bubbles to form in the fuel system, systems with LPG liquid injection must be fitted with a tank return line in order if necessary to expel vapor bubbles that occur.

Mixture formation

As with conventional multipoint gasoline injection, the LPG is injected into the intake manifold in front of the engine intake valves. The evaporation that occurs as the LPG is injected (according to the Joule-Thomson effect) lowers the temperature of the inducted air/gas mixture, which has a positive impact on the engine's volumetric efficiency and performance figures.

Advantages of LPG liquid injection

LPG liquid injection offers the following advantages:

- Gas operation is also possible at extremely low temperatures.
- Monofuel gas operation is possible.
- Engine start in LPG mode is also possible in bifuel systems.
- A better cylinder charge is obtained thanks to the cooling effect in the intake manifold and combustion chamber, thus producing identical engine-performance figures to gasoline without further measures. Engines with LPG liquid injection can even deliver slightly higher performance figures when compared with gasoline operation.

Systems with direct LPG liquid injection into the combustion chamber

LPG behaves very similar to gasoline at higher system pressures. Therefore LPG direct injection (LPG-DI) into the combustion chamber is also possible. LPG direct injection offers some significant advantages:

- A better exhaust-gas composition is obtained (virtually no particulate emissions) with comparable engine-performance figures.
- Very good over all thermodynamic behavior.

LPG direct liquid injection into the combustion chamber is possible in all modern gasoline engines with direct injection. Such systems are currently still in the development phase (see e.g. [5]).

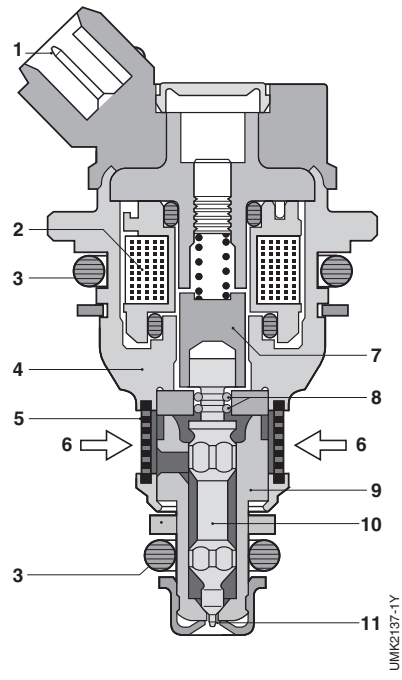
Exhaust emissions

With regard to the limited pollutant components HC, CO and NO_x, the use of LPG as fuel in modern spark-ignition engines offers some advantages over gasoline operation. The situation when it comes to CO_2 emissions is even better. Here, LPG vehicles can achieve a reduction of approximately 10 %. This reduction is founded on the lower carbon content in LPG. Furthermore, when compared with diesel engines, there are virtually no particulates. LPG drives also have advantages when it comes to other exhaust-gas components which are not limited by law but which are harmful to health. Thus, for instance, LPG drives emit significantly lower amounts of aromatic hydrocarbons (e.g. benzene).

Unlike engines fueled by CNG (Compressed Natural Gas), engines fueled by LPG are not subject to any particular demands on the exhaust-gas treatment system of the existing gasoline concept. The essential exhaust-gas components of LPG operation are comparable with those of gasoline operation.

Engine management for LPG systems

Both double-ECU concepts (one ECU for gasoline operation and one for LPG operation) and single-ECU concepts (gasoline and gas functions integrated into a single ECU) are used. Because the vehicles are bifuel, the driver can select between gasoline and LPG operation using a switch.



The level sensor installed in the LPG tank signals the current LPG tank level to the engine-management system. A combined low-pressure and temperature sensor mounted on the gas rail enables the engine-management system to correct the injection timing in such a way that a stoichiometric mixture can be pilot-controlled in the intake manifold even if the gas density fluctuates. The engine-management systems uses the values from the λ sensor and different adaptation algorithms to adapt the mixture formation for different gas qualities. Even functions for switching between gas and gasoline operation are integrated.

The other sensors and actuators of the engine-management system are for the most part identical to those in a gasoline engine.

Systems with LPG liquid injection into the combustion chamber require, in addition to the functions for mixture formation and gas-quality adaptation, functions for controlling the LPG fuel pump.

Components

LPG gaseous injector

Function and requirements

When LPG is injected in the gaseous state of aggregation, the given energy density and the low gas pressures resulting from the state of aggregation of approx. 0.5 to 3.5 bar dictate that the following parameters must be taken into account in the design of LPG injection valves:

– Configuration of the injection valves for large gas volumes,
– Adaptation of the sealing mechanisms and materials to the gaseous medium,
– Consideration of potentially aggressive fuel contaminants in the choice of material.

Design and operating principle

Essentially, the design and function of a gas injector configured for operation with gaseous LPG are very similar to those of a CNG injector (see Engines fueled by natural gas).

LPG liquid injector

Function and requirements

In systems where the LPG is injected in the liquid state of aggregation the LPG must be kept in the liquid state in the entire pipe and rail system by means of pressure build-up by a pump installed in the LPG tank. Only in this state can it be injected.

LPG injectors must satisfy the following requirements:

– Operation at variable pressures of 2 to 25 bar.
– Absolute tightness in the case of systemic pressure variability (e.g. on shutdown of gas operation and spontaneously occurring pressure peaks due to the LPG evaporating in the rail system).
– Possibility of a flushing process to eliminate vapor bubbles that occur (e.g. during hot start or switching from gasoline to LPG operation with the engine at operating temperature).

Design and operating principle

LPG injectors (Figure 3) are, in response to the above-mentioned requirements, designed according to the bottom-feed principle. The injector is designed in such a way that the fitting for the fuel inlet into the injector housing is as close as possible to the injector outlet. This layout enables the valve to be easily flushed with fresh fuel in order to quickly remove possible vapor bubbles.

The fuel injectors normally used in gasoline engines, on the other hand, operate for the most part according to the top-feed principle. Because of the supply of fresh fuel located at the top end of the injector housing, the flush process for the purpose of removing vapor bubbles in the injector would be very diffecult or not possible at all. Under such conditions it would not be possible to provide a correct metering of the fuel quantity and thus optimum combustion, which is why the top-feed principle is not suitable for use in liquid LPG injection.

Installation position

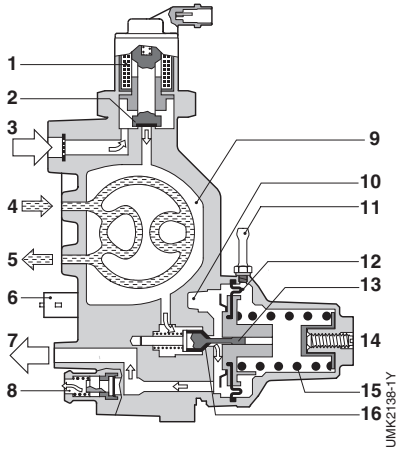
The position of the LPG injectors in the intake manifold is subject to special design requirements according to the generation of cold by the evaporation of the LPG during the injection process (as a result of the Joule-Thompson effect). The liquid LPG evaporates abruptly on entry into the intake manifold and extracts the required energy in the form of heat out of the fresh air in the intake manifold. This specific-point cold in the intake manifold can cause unwelcome operating phenomena (e.g. misfires), which can be put down among other things to the formation of ice crystals.

LPG filler neck

Neck variants

The filler neck is not internationally standardized. For this reason, different fueling adapters are required from country to country. Four different types of LPG fuel nozzle are used in filling stations. Different filler necks are therefore needed depending on the field of application. The following necks are widely used:

– ACME neck (named for the American trapezoidal-thread standardization) is used in Germany, Belgium, Ireland, England, Luxembourg, Scotland, Austria, China, Canada, USA, Australia, and Switzerland.
– DISH neck (named for its dish shape) is used in Denmark, France, Poland, Greece, Hungary, Italy, Austria, Portugal, the Czech Republic, Turkey, China, Korea, and Switzerland.
– Bayonet neck is used in the Netherlands, Belgium and the UK.
– Euronozzle is currently used in Spain only.



The Euronozzle is supposed to replace all the other necks on a Europewide basis in future. The EU Regulation for this standardized neck has not yet been adopted by the majority of EU member states.

Design

Each filler neck in the vehicle is designed in such a way that the LPG vehicle can be refueled at all LPG filling stations by using a suitable adapter.

Evaporator for systems with gaseous LPG injection

Function

Evaporators are used in systems with gaseous LPG injection. The LPG is delivered to the evaporator by the vapor pressure in the gas tank via an electromagnetic shutoff valve.

The evaporator is one of the main components of every LPG injection system and performs two functions: Firstly, the liquid gas is converted from the liquid to the gaseous state in the first part of the evaporator. Secondly, the pressure of the gaseous LPG is then regulated to approx. 1 bar differential pressure in relation to the intake manifold. This pressure, with which the injection valves are supplied, must be kept constant through all the operating states and the varying vapor pressures of the different LPG qualities within minimum tolerances. The most widely used evaporators are those with single-stage pressure regulation. Figure 4 shows an evaporator with single-stage pressure regulation.

Operating principle
The LPG enters through the inlet connection into the evaporation area. This consists of a labyrinth that is heated by the vehicle's heating circuit to convert the incoming liquid gas into the gaseous state. Pressure of 4 to 15 bar are achieved here. The pressure varies depending on the temperature of the engine coolant and the composition of the LPG (mixture ratio of propane and butane).

The now gaseous medium passes through a transfer passage into the pressure-regulation area, which is closed by a diaphragm. A pre-tensioned spring is seated on the back of the diaphragm. The pre-tension can be adjusted with an adjusting screw in order to effect deviations from the factory output-pressure pre-setting.

The diaphragm is connected via a lever mechanism to a valve on the transfer-passage connection. When the pressure increases, the movement of the diaphragm actuates a control rod, which in turn alters the opening cross-section at the outlet of the pressure-regulation area. Thus the supply is reduced or closed off and no more gas can flow. When the gas pressure decreases in response to increased fuel reduction by the engine, the diaphragm is moved in the opposite direction. The valve is opened via the lever mechanism to allow gas to flow until again an equilibrium of forces acts on the diaphragm and the lever mechanism can close the transfer passage again.

An important characteristic of the quality of the evaporator is the lowest possible fluctuation of the operating pressure in different engine operating states together with the highest possible control precision over the operating time.

In certain countries, owing to contaminants in the LPG, the manufacturer recommends that the diaphragm be replaced after a certain operating time.

Intake-manifold vacuum support
In addition, the response of evaporator pressure regulation is optimized by connecting the intake-manifold pressure to the area above the diaphragm.

Operating values
The inlet pressure is 4 to 15 bar, depending on ambient temperature and gas quality. The output pressure is 0.5 to 3.5 bar, depending on the setting.

Electromagnetic shutoff valve and temperature sensor
The electromagnetic shutoff valve interrupts the gas supply when the engine is not in gas mode. The changeover from gasoline to LPG operation is initiated by the engine ECU as a function of the engine coolant temperature. The minimum coolant-temperature value for changeover is selected to ensure reliable evaporation of the LPG in the evaporator. A temperature sensor is integrated in the evaporator coolant circuit for this purpose. A cold start in gas mode is not possible with these systems.

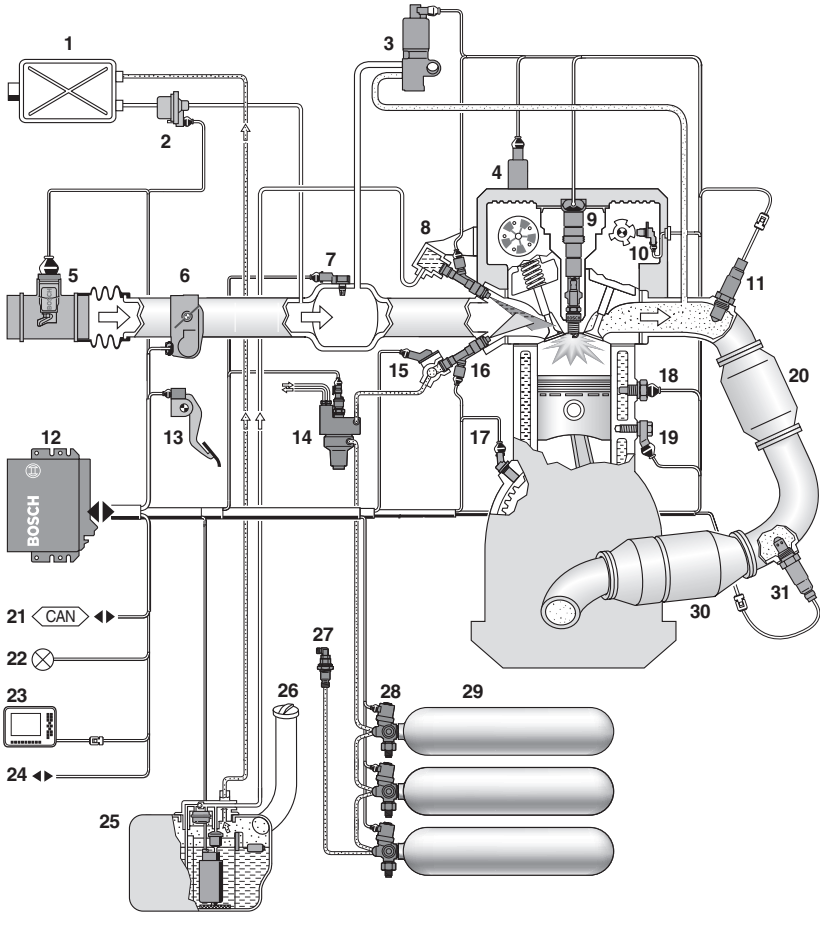
Engines fueled by natural gas

Applications

In view of the worldwide efforts to reduce CO_2 emissions (carbon dioxide), natural gas is becoming increasingly important as an alternative fuel. Compressed natural gas (CNG), not to be confused with liquified petroleum gas (LPG), consists primarily of methane. Liquified petroleum gas, on the other hand, consists of propane and butane (see fuels).

Emissions
Compared to gasoline, the combustion of CNG produces approximately 25 % less CO_2. CNG thus generates the lowest local CO_2 emissions of the fossil fuels. Because of the lower CO_2 emissions, the petroleum tax on CNG is reduced in many countries.

Use of biogas
Using biogas (biomethane) can achieve a regenerative fuel supply that further reduces global greenhouse-gas emissions. Biomethane can be produced from plant remains, organic waste and liquid manure, or alternatively from electricity generated from renewable sources. Here, hydrogen is obtained by electrolysis from water and then reacts in a chemical reaction with CO_2 to produce methane. This methane gas obtained from renewable sources is called solar gas, wind gas or simply RE gas (renewable-energy gas).



Natural-gas vehicles
Various vehicle manufacturers have in the meantime started to offer natural-gas versions of automobile models from the factory. This ensures that the larger CNG tanks are accommodated more efficiently and conveniently, thereby preventing – as is practically inevitable when these tanks are installed subsequently – the loss of luggage-compartment volume.

The latest information on natural-gas vehicles and the filling-station network in Germany and Europe can be found at the Internet addresses [1] and [2]. Natural-gas vehicles are, for the most part, bifuel vehicles which allow the driver to switch between natural-gas and gasoline operation. There are variants in the form of monovalent vehicles and the concepts referred to as “Monovalent plus”, in which the engine is optimized for natural-gas operation so as to be able to utilize to optimum effect all the favorable properties of natural gas (higher knock resistance, lower CO_2 and pollutant emissions). “Monovalent plus” vehicles still feature a small gasoline tank (less than 15 *l*) so that they can continue to be driven in gasoline mode in the event of there being no natural-gas filling station nearby.

Storage of natural gas
Natural gas can be stored in compressed form at a pressure of 200 bar as CNG (compressed natural gas) or in liquid form at –162 °C as LNG (liquified natural gas). In view of the great expense involved in storing the gas in liquid form, storing the gas in compressed form at 200 bar has become the standard method. In spite of being stored at high-pressure, natural gas has a lower energy-storage density than gasoline such that a tank with four times the volume is required for the same energy content.

Design

Components
Natural-gas automobiles are equipped almost exclusively with spark-ignition engines. They are extended to include the following natural-gas components (Figure 1, [3]):
– Natural-gas filler neck,
– Natural-gas tanks,
– High-pressure shutoff valves on the natural-gas tanks,
– Natural-gas pressure-control module with integrated gas shutoff valve and high-pressure sensor,
– Gas rail with natural-gas injectors and combined natural-gas low-pressure and temperature sensor.

Operating principle
The air drawn in by the engine is routed via the air-mass meter and the electronically actuated throttle valve to the intake manifold. From there, it enters the combustion chamber through the intake valves (Figure 1). The gas stored in the natural-gas tank at 200 bar flows through a high-pressure shutoff valve on the tank into the natural-gas pressure-control module, which lowers the gas pressure to a constant operating pressure of approx. 5 to 10 bar (absolute). It then flows through a flexible low-pressure line into a common gas rail that supplies the natural-gas injectors.

Engine management for natural-gas vehicles
Both double-ECU concepts (one ECU for gasoline operation and one for natural-gas operation) and single-ECU concepts (gasoline and gas functions integrated into a single ECU) are used. In some bifuel vehicles, the driver can use a switch to select between gas and gasoline operation. In most models, the switchover occurs automatically and the vehicle is driven in natural-gas mode until the tank contents are used up. Then the vehicle is switched over automatically to gasoline mode.

The high-temperature sensor mounted on the pressure-control module supplies the engine-management system with information on the current fill level of the natural-gas tank and also facilitates leakage diagnostics. The combined natural-gas low-pressure and temperature sensor fitted on the gas rail enables the engine-management system to correct the valve injection timing in such a way that a stoichiometric mixture can be pilot-controlled in the intake manifold even if the gas density fluctuates. The engine-management system uses an adaptation algorithm to adapt to changing gas qualities.

The other sensors and actuators of the engine-management system are mostly identical to those in a gasoline engine.

Mixture formation
Virtually exclusively bifuel and "Monovalent plus" vehicles are available today. These vehicles can operate both on natural gas and on gasoline. Either manifold injection or gasoline direct injection may be used to inject the gasoline.

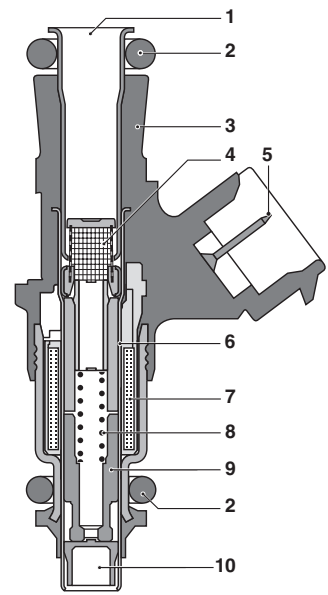
Natural-gas manifold injection
In most natural-gas engines, the gas is injected, as with gasoline injection, into the intake manifold. The low-pressure gas rail supplies the injectors, which inject natural gas at intermittent intervals into the intake manifold. Mixture formation is improved in comparison with gasoline injection, as natural gas, because of the completely gaseous supply of fuel, does not condense on the intake-manifold walls and does not deposit a film there. This has a positive effect on emissions, particularly during the warm-up phase.

Non-supercharged engines that are fueled by natural gas generally have a 10 to 15 % lower output. This is due to the lower volumetric efficiency attributed to displacement of the inducted air caused by the injected natural gas. The vehicle engines can however be optimized specially for natural gas as the fuel. The extremely high knock resistance of natural gas (up to 130 RON) provides for higher engine compression and is ideally suited to supercharging. In this way, the volumetric-efficiency losses can even be overcompensated. Combined with reduced piston displacement (downsizing), efficiency increases due to additional dethrottling and reduced friction.

Natural-gas direct injection
Natural gas can also be injected directly into the combustion chamber. In this way, the volumetric-efficiency losses can be completely avoided and in turbocharged engines the supercharging efficiency, especially at low speeds, can be improved by scavenging. Scavenging involves engine operation with extended overlapping of the intake- and exhaust-valve opening times. The drawbacks of natural-gas direct injection are the greater complexity of the injectors (tightness, temperature stability) and the fact that, due to the necessary higher natural-gas injection pressure dictated by the concept, the tank cannot be drained as far as in engines with natural-gas manifold injection.

Exhaust emissions
Compared with gasoline engines, natural-gas vehicles are characterized by approximately 25 % lower CO_2 emissions. The reason for this is the better hydrogen/carbon ratio (H/C ratio) of almost 4:1 (gasoline: approximately 2:1). This results in the creation of more water and less CO_2 during combustion.

Apart from the virtually particulate-free combustion, in conjunction with a three-way closed-loop catalytic converter, only very low levels of the pollutants NO_x, CO and HC are produced. As a rule, the catalytic converter has a higher precious-metal load than is the case in gasoline engines, enabling it to better convert the HC emissions in the exhaust gas that mainly consist of chemically stable methane and to counteract the higher "light-off temperature" (minimum temperature of the catalytic converter for conversion) for natural gas. Methane is, however, classified as nontoxic.



Natural-gas vehicles comply with the current exhaust-emission limits, while trucks and natural-gas buses also comply with the EEV limits (Enhanced Environmentally friendly Vehicle, [4]). The natural-gas engine offers distinct advantages over gasoline and diesel engines, also in particular with regard to the non-limited pollutant emissions.

Components

Natural-gas injector for manifold injection
Function
In order to supply the internal-combustion engine with gaseous fuel, it is necessary to meter through the natural-gas injectors a much greater volume of gas than gasoline in a conventional gasoline engine. This requirement places specific demands on the design of the natural-gas injector, which must be adapted to the greater gas volume in its cross-sections. Even the high flow velocities that are encountered call for a special form of flow routing in order to reduce pressure losses in the injector.

In highly supercharged engines, the intake-manifold pressure can rise up to 2.5 bar (absolute). In order to suppress the influence of the intake-manifold pres-

Figure 2: Natural-gas injector (Bosch)

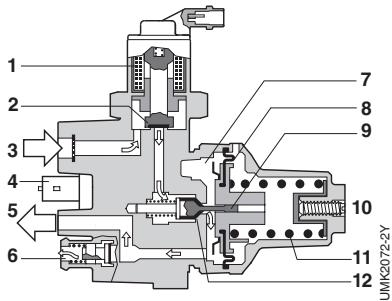
sure on the mass flow, it is necessary for the pressure ahead of the nozzle at the narrowest cross-section (throttling point) accepted as the nozzle above critical to be at least twice as high as the maximum intake-manifold pressure (pressure after the nozzle). The gas then flows at the speed of sound, irrespective of the absolute pressure after the nozzle. The mass flow is therefore not influenced by the variable intake-manifold pressure. While possible pressure losses ahead of the throttling point are taken into account, a minimum operating pressure of 7 bar (absolute) has proven to be advantageous.



Design and operating principle
The solenoid armature (Figure 2) is guided in a sleeve. The armature has fuel flowing through it on the inside and has an elastomer seal at the discharge end. This seal closes on the valve seat and thereby seals off the fuel supply from the intake manifold. When energized, the solenoid coil effects the necessary force to lift the solenoid armature and open the metering cross-section (throttling point in the valve seat). When the coil is at zero current, the valve spring holds the injector closed.

Flow-optimized geometry
Thanks to design measures in the routing of the flow, the pressure loss is minimized ahead of the throttling point in order to ensure the greatest possible mass flow. Furthermore, the narrowest cross-section and thus the throttling point is located at the discharge end after the seal. The speed of sound prevails here such that the valve represents approximately an ideal nozzle in physical terms.

Sealing geometry
The natural-gas injector is fitted with an elastomer seal and is similar in terms of its seal-seat geometry to shutoff valves for pneumatic applications. The elastomer increases the tightness of the seal against metallic needle valves.

Damping in the elastomer also prevents "rebounding", i.e. a repeated, unwanted opening of the solenoid armature during the closing operation, and thus increases metering precision.

Figure 3: Pressure-control module

6 Safety pressure-relief valve,
7 Low-pressure chamber,
8 Pressure diaphragm with mounting,
9 Control rod,
10 Adjusting screw,
11 Spring,
12 Control plunger and throttling orifice.

Pressure-control module
Function
The function of the pressure-control module is to reduce the pressure of the natural gas from tank pressure (up to 200 bar) to the nominal operating pressure (typically 5 to 10 bar). At the same time, the operating pressure should be kept constant within specific tolerances through all operating states or, depending on the engine's operating point, regulated to a specified pressure. The typical operating pressure of present-day system is usually about 5 to 10 bar (absolute). There are also systems which operate at pressures starting from 2 bar ranging up to 11 bar.

Design
Mechanical version:
Today, mainly mechanical diaphragm- or plunger-type pressure regulators are used. Pressure reduction is effected by means of throttle action and can occur either in one single stage or in several stages.

Figure 3 shows the sectional view of a single-stage diaphragm-type pressure regulator. A sinter filter (pore size approx. 40 µm), a gas shutoff valve, and a high-pressure sensor are integrated into the pressure-control module on the high-pressure side. The sinter filter is designed to retain solid particulates in the gas flow. The gas shutoff valve enables the gas flow to be interrupted, for example when the vehicle is stopped. The high-pressure sensor is used to determine the natural-gas supply in the tank and for diagnostics.

A pressure-relief valve is mounted on the pressure regulator on the low-pressure side. In the event of a fault in the pressure regulator, this valve prevents damage to components in the low-pressure system.

In normal control operation, the gas cools down very dramatically as it expands as a result of the Joule-Thompson effect. In order to prevent freezing, the pressure-control module has an integrated heater, which is connected to the vehicle's heating circuit (not shown in the figure).

The controlled operating pressure is dependent on the diaphragm size and the initial spring tension. To adjust the pressure level, the initial spring tension is set and sealed by means of an adjusting screw in the factory.

Electromechanical version:
As well as purely mechanical pressure-control modules there are also electromechanical versions. These typically consist of an initial mechanical pressure-control stage, which reduces the tank pressure to a mean pressure of approximately 20 bar. In a second stage the pressure is further reduced by an electromagnetically actuated control valve to the operated pressure specified by the engine-management system, and electronically regulated. The advantages of electromechanical pressure regulators are the increased pressure-control precision and the variability of the control pressure. In this way, the injection pressure can be decreased and thus the metering precision of the natural-gas injectors increased in engine low-load phases, e.g. at idle.

Operating principle of mechanical pressure-control module
The gas flows from the high-pressure side through a variable throttling orifice into the low-pressure chamber, where the diaphragm is situated. The diaphragm controls the opening cross-section of the throttle via a control rod. When the pressure in the low-pressure chamber is low, the diaphragm is forced by the spring in the direction of the throttling orifice, which opens to allow the pressure to increase on the low-pressure side. In the event of excessive pressure in the low-pressure chamber, the spring is compressed more sharply and the throttling orifice closes. The decreasing cross-section of the throttling orifice reduces the pressure on the low-pressure side. In stationary operation, the throttling cross-section required for the operating pressure is set, while the pressure in the low-pressure chamber remains extensively constant.

Minimal operating-pressure fluctuations in the event of load changes testify to the quality of the pressure regulator.

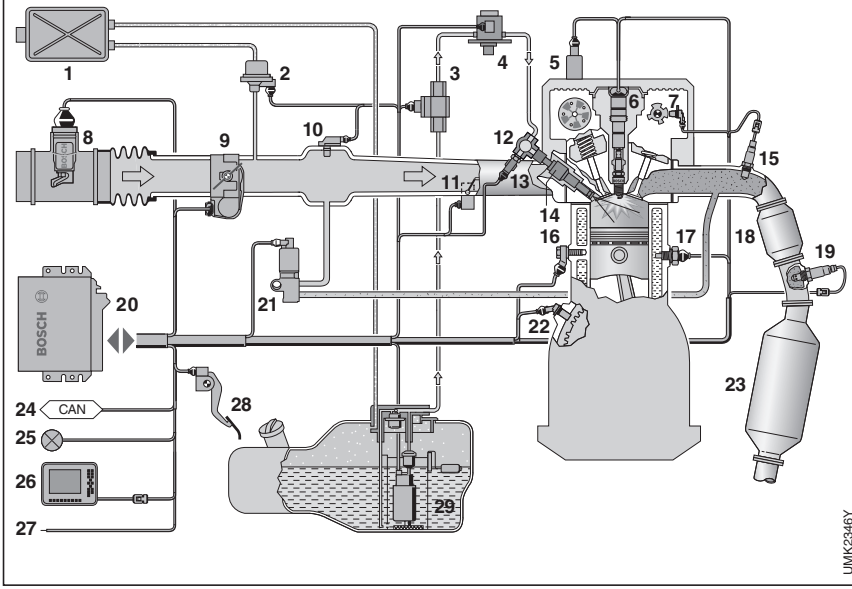
Engines fueled by alcohol

Applications



Motivation

Ever-shrinking fossil-fuel resources and the heightened demand for reduced carbon-dioxide emissions necessitate a rethink of tried-and-tested drive concepts. Rising crude-oil prices make alternative energies increasingly economical and there is the increasing public perception that sustained mobility also requires a sustained energy basis.

In Brazil, where ethanol has been used as a fuel since the 1980s and is available as E 24 (ethanol/gasoline mixture with 24 % ethanol content) and E 100 (pure ethanol) at filling stations (Table 1), approximately 50 % of fuel demand is covered. Alongside this, the USA and Europe have in the last few years increased their activities to promote E 85 as an alternative fuel type. Thus, aside from the potential to reduce CO_2, the focus is also aimed at securing reliability of supply and making fuel

supply independent of fossil sources and imports.

System description
Flex-fuel systems are engine-management and component systems which can be operated with any mixture ratios of gasoline and ethanol between two limit values. These mixture ratios are created in the fuel tank by pumping in fuels with varying ethanol content. On the one hand, the capacity of a system to detect varying ethanol content in the fuel and to adapt its behavior (e.g., injection and ignition) accordingly plays a role. On the other hand, the question of component suitability is very important in making safe, robust operation possible over the entire service life demanded and expected by vehicle users.

Figure 1 shows the system diagram of a gasoline engine for flex-fuel operation. It is to a large extent the same as a conventional gasoline engine with gasoline direct injection.

Ethanol as an alternative fuel

Sustainability
The potential to reduce CO_2 emissions is established in part by the more favorable ratio of carbon to hydrogen content of alcohol fuels, but primarily by the positive CO_2 balance in the course of extraction from renewable raw materials. It is however important here to consider the source of the produced alcohol fuel. Thus, for example, the extraction of methanol from coal (by means of the CTL process, Coal to Liquid) has an extremely poor CO_2 balance, whereas the extraction of ethanol from parts of plants has a positive balance.

Markets for flex-fuel vehicles
Today, the admixture of methanol in appreciable quantities plays, on account of local factors, a role only in China. Moreover, methanol, because it is toxic and harmful to health, must be viewed as highly critical. In the following, flex-fuel operation refers to operation with ethanol fuels.

Table 1: Composition of ethanol fuels

Fuel	E0…E5	E 10	E 24	E 85	E 100
Maximum ethanol content	5 %	10 %	24 %	85 %	93 %
Maximum water content	<1 %	<1 %	1 %	1 %	7 %
Minimum gasoline content	95 %	90 %	76 %	15 %	0 %
Relative energy content referred to gasoline	100 %	97 %	91 %	70 %	61 %
Regional distribution	Europe	USA, EU	Brazil	USA, Sweden, partly EU	Brazil

Table 2: Properties of ethanol

Characteristic	Unit	Gasoline	Ethanol	Effects
Energy density (per volume)	kJ//	32,500	21,200	– greater injected fuel quantity required
Energy density (per mass)	kJ/kg	43,900	26,800	– critical for cold start
Air/fuel ratio	–	14.8	9.0	– more wall film + more power, better efficiency (greater air cooling)
Boiling point	°C	25 to 215	78	
Enthalpy of evaporation	kJ/kg	380 to 500	904	
Octane number	RON	>91	108	+ higher knock limit + more power, higher efficiency
H/C ratio	–	2.3	3	

Flex-fuel refers to mixtures of gasoline and ethanol in any variable ratio. Today, a distinction is drawn primarily between two mixture ranges of ethanol mixtures in the flex-fuel sector: Mixtures with mixture ratios between pure gasoline and E 85 (in Europe particularly in Sweden and in North America) and between E 24 and E 100 in Brazil. The lower limit towards E 18 is currently being extended in Brazil.

Another specific feature is that E 100 fuel according to the Brazilian standard (Resolution ANP #19 – Technical Regulation, [1]) may contain up to 7.5 % water (EHC, Hydrated Ethanol Fuel), but in real terms in the field contains 10 to 15 % water. Also associated with this increased water content is increased conductivity and the increased presence of salts. This is the reason why there are two separate variants of a component for the E 85 and E 100 application cases and also specific adaptations are made in the electronic engine management. It is important here than an E 85 system is not suitable for E 100.

Essentially, flex-fuel systems are implemented with manifold and direct injection. In the case of direct injection it is possible in particular to use the high knock resistance of ethanol to good effect, which is advantageous with regard to the full-load quantity demand due to less fuel enrichment.

Properties of ethanol and resulting requirements

The specific properties of ethanol that deviate from regular gasoline are set out in Table 2. These impact on system performance and on the components in the system that come directly or indirectly into contact with fuel.

Important factors are the lower energy density (greater quantity demand per unit of air) and the deviating stoichiometry of ethanol caused by the chemical composition (oxygen is already contained in part), which results in dramatically increased fuel-system delivery and injected fuel quantities. Critical to the starting response at very low temperatures are the high boiling temperature of 78 °C and the high heat of evaporation compared with the low-boiling fractions of gasoline. However, for operation at high engine temperatures and at the knock limit, advantageous effects are also to be expected due to the high heat of evaporation and better knock resistance.

These mentioned properties of ethanol and their effects make it necessary to adapt the internal-combustion engine itself, but also the engine-management system and its components accordingly. It is also important that the ethanol fuels not be present as pure fuels with a fixed (and thus known) ethanol content in the fuel tank, but that the mixing of different ethanol fuels lead to any mixture ratios. The mixtures can moreover also be supplied by regionally and seasonally deviating ethanol admixtures by the filling stations and in the USA by “blender pumps” in the system. Thus, a reliable and accurate “on-board recognition” of the current ethanol content is required.

The higher corrosivity of ethanol must be taken into account for the components installed in a system. To achieve evaporation limit values the higher permeation tendency of ethanol molecules through pipe and component materials plays a significant role.

Flex-fuel concepts for the markets

Vehicle manufacturers pursue different engine concepts and marketing strategies for the regions. With regard to the degree of adaptation of the systems there are therefore different aspects which conform to the aimed-for strategy.

Markets

USA market

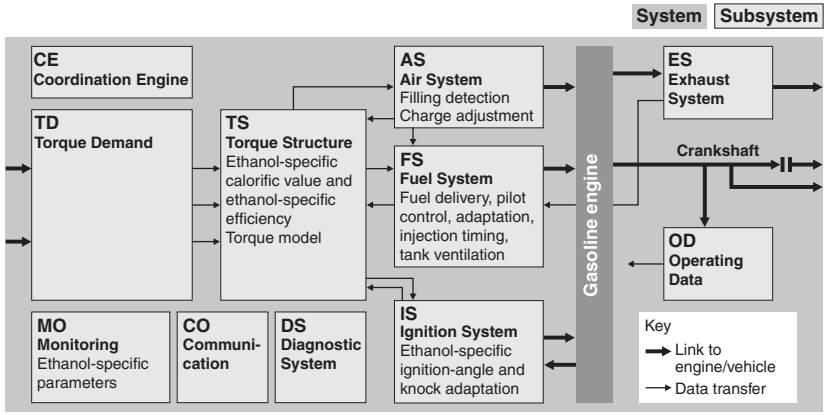
In the US market as a matter of priority only those adaptations which are necessary to be able to offer the vehicles as flex-fuel vehicles are carried out. This involves the fundamental compatibility for flex-fuel without specifically exploiting the advantageous ethanol properties. In real vehicle operation it is used only occasionally with higher and variable ethanol contents.

European market

In contrast, a different concept is pursued in Europe whereby both the increased efficiency of the engine and the enhanced performance in E 85 operation are exploited as advantages, and are emphasized in the marketing of the vehicle.

Brazilian market

Only in Brazil is it possible up to now to observe the last logically consistent step where the engine manufacturers also increase the compression ratios of the engines since in this market the fuels offered already generally contain at least 24 % ethanol and consequently a higher octane number (and thus a higher knock resistance) is obtained.



System adaptations

Extensive adaptations are required in the management system of the engine ECU and its functions. Specifically, the following engine-management functions are affected (Figure 2):

- Air system: e.g. filling detection and cylinder-charge control,
- Fuel system: e.g. quantity pilot control and injection timing, mixture adaptation,
- Exhaust system: e.g. enabling of mixture control,
- Ignition system: e.g. moments of ignition, ignition energy,
- Torque patterns: e.g. deviating efficiency with regard to λ and ignition,
- Diagnostic system and monitoring; e.g. fuel-quality detection, diagnostic thresholds.

When it comes to system adaptation the deviating properties of ethanol with regard to gasoline must be taken into account in order to avoid diminished system performance or to achieve improved perfor-

Figure 2: Software structure of engine management for flex-fuel operation

mance in partial ranges. The properties listed in Table 3 can be used to good effect, while those listed in Table 4 necessarily require an adaptation.

In part, however, new developments of functionalities are required. The following are mentioned here by way of example:
– Special cold-start strategies for achieving emission limits at lower temperatures (e.g. –7 °C) and for fundamentally ensuring engine starting at very low temperatures (–30 °C).
– Detection of a more pronounced impingement of fuel in the engine oil and interception of increase degassing during warm-up.
– Detection of alternating ethanol contents in the fuel tank and diagnosis of ethanol detection (sensor-based or sensorless).

Table 3: Advantageous use of ethanol properties (with regard to gasoline)

Properties of ethanol	Advantageous use
Higher knock resistance	Optimum ignition, better efficiency, more power
Higher enthalpy of evaporation	Better charge
Faster combustion	Optimum maximum combustion
Lower combustion temperatures	Reduced component protection with lower consumption

Flex-fuel components

Flex-fuel systems are virtually identical in design to gasoline injection systems; however, the demands imposed on the components differ. With regard to component suitability, it is necessary to consider both the fuel-carrying components and those components that potentially come into contact with fuel vapors or combustion gases of ethanol. An overview of the components to be adapted in a flex-fuel system is provided in Table 5.

Changes in the components must be made with regard to the following influences:
– corrosion of metallic materials,
– swelling or embrittlement of plastic and rubber parts,
– functional capability of gaskets,
– increased permeation of fuel molecules through fuel-carrying components.

This is done specifically by means of the following measures:
– use of special alloys (e.g. stainless steels),
– surface coating of metallic materials, particularly in mechanically stressed contact pairs (above all on aluminum materials, e.g., Nikasil coatings of nickel and silicon carbide for aluminum engine blocks),
– use of adapted plastic and rubber compounds,

Table 4: Disadvantageous consequences of ethanol properties (with regard to gasoline)

Properties of ethanol	Disadvantageous consequences
Higher enthalpy of evaporation	Increased requirements imposed on cold start below 10 °C, larger wall film in cold operation
Higher stoichiometric consumption	Greater required injected fuel quantities, longer injection periods, repercussions for the combustion process, greater fuel impingement in the engine oil during cold start
Changed H/C ratio	More water impingement, later dew-point end of λ sensor

Table 5: Overview of ethanol-specific components

Component	Adaptation
Fuel-supply module	Fuel pump for E 85 or E 100, insulated electrical connections, Fuel-level sensor ethanol-resistant
Pressure regulator	Ethanol-resistant version
Fuel rail	Ethanol-resistant version
Intake-manifold fuel injector	Extended metering range
High-pressure injector	Stainless-steel versions, adapted metering range
High-pressure pump	Stainless-steel versions, adapted metering range

– selection of specific gasket and filter materials,
– design adaptations,
– electric insulation of electrical contacts in the fuel tank (electric fuel pump, fuel-level sensor) for E 100 due to the water content of up to 15 %.

Increased requirements with regard to greater flow rates must be taken into account for specific components. This is particularly important in relation to the fuel injectors since the maximum flow rate is necessary for the increased demand in ethanol operation, but still the minimum metering quantity occurs in gasoline operation. This adaptation is effected by the selection of a greater flow rate from the range of variants. The unchanged minimum quantity is implemented by a shortened activation duration.

Electronic Diesel Control

Description of the engine-management system

The diesel combustion process requires on principle an injection of fuel into the combustion chamber. Modern diesel engines operate with direct injection; the cylinders have a common high-pressure pump and a high-pressure accumulator constantly under high pressure (up to 3000 bar) that is common to all the cylinders (common rail). Injection is initiated by the opening of the fuel injectors, which are activated electronically. Electronic engine management is an absolute precondition for the common-rail injection process.

Furthermore, the statutory requirements with regard to emissions and customer expectations in relation to a modern vehicle can only be fulfilled with an electronic engine-management system. The open- and closed-loop control system – both for the earlier injection systems and for the current common-rail system – is referred to by Bosch as Electronic Diesel Control (EDC).

Figure 1: Components for Electronic Diesel Control (EDC) of a common-rail system

Requirements

The primary and obvious purpose of the engine-management system is to deliver the desired power (i.e., torque times rotational speed) to the diesel engine's output shaft. Further requirements include facilitating the best possible engine operation with regard to fuel consumption (and consequently CO_2 emissions), exhaust-gas emissions, power development and driving comfort, and diagnosing the status of the ECU, the sensors, and the actuators. Furthermore, the engine-management system must protect the engine and the drivetrain against unacceptable operating conditions and overloading.

To achieve this, many operating parameters must be acquired with sensors and processed with algorithms – these are computing processes that take place according to an established scheme. The results are signal curves for activating the actuators. Electronic Diesel Control (EDC) refers to the full range of sensors, engine management by engine control unit, and actuators (Figure 1). Sometimes the engine control unit in itself is referred to as EDC.

Requirements with regard to function groups
The requirements for the individual engine function groups can be derived from the requirements with regard to the engine.

Detection of driver input
– Accelerator-pedal sensors (the accelerator-pedal position is detected for safety reasons with redundant sensors).

Requirements with regard to the injection system
– High injection pressures for atomizing the fuel and reducing the raw particulate emissions,
– rate-of-discharge curve control (multiple injection, pilot injection, and secondary injection) to improve combustion, emissions, and noise,
– variation of injected fuel quantity and start of injection to suit every operating condition,
– tight tolerances for injection time and injected fuel quantity and maintenance of high precision over the service life of the system.

Requirements with regard to the air system
– Single- or multi-stage supercharging with intercooling (charge-air cooling),
– controlled exhaust-gas recirculation with cooling to reduce NO_x emissions,
– if necessary additional low-pressure exhaust-gas recirculation (EGR) to improve the cylinder charge compared with pure high-pressure EGR.

Requirements with regard to the exhaust system
– Exhaust-gas treatment with oxidation-type catalytic converter, particulate filter, NO_x storage catalytic converter, and selective catalytic reduction (SCR) or both,
– regeneration of the catalytic converters,
– rapid heating of the catalytic converters after engine start.

Requirements with regard to CO_2 emissions
– Operation of the engine in the optimum program map,
– start/stop functions,
– thermal management,
– consumption-optimized auxiliary systems, e.g., speed-controlled water pump or electric fans,
– controlled generator operation (for recuperation in coasting/overrun mode).

Other requirements
– Rapid engine start, irrespective of the ambient conditions,
– idle-speed control to load-independent setpoint value,
– comfort and convenience functions such as cruise control, speed limiting,
– comprehensive diagnostics in real time.

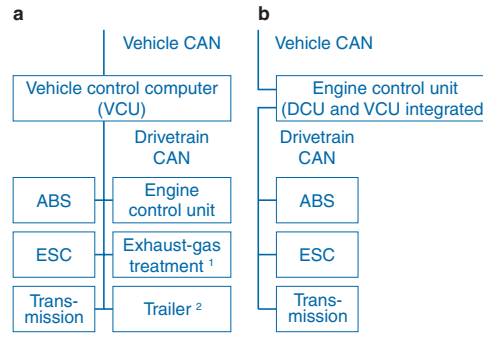
Operating principle and architecture

Modern vehicles have a multitude of (up to 100) ECUs which are connected to each other via communication buses (usually CAN buses). Engine management is integrated in the architecture of the overall vehicle system so that data from other electronic systems such as for example antilock braking system (ABS), transmission-shift control or driving-dynamics control are taken into consideration in the open- and closed-loop control of the diesel engine. These can be control interventions on the torque level (e.g., engine-torque reduction when engaging the automatic transmission, adapting the engine torque to the slip of the wheels) or even status information (e.g., injection enable by the vehicle immobilizer).

A number of tasks can also be combined in an ECU, depending on the strategy and philosophy of the vehicle manufacturer. The number of sensors and actuators connected to the engine control unit is dependent on the architecture of electronic systems (see Architecture of electronic systems). The number of functions can be within wide limits, i.e., between the extremes "injection control unit" on the one side and "engine management with integrated vehicle control and exhaust-gas treatment" on the other. Figure 2 shows examples of executed systems.

All influencing variables have an impact on the amount of fuel to be injected and the start of injection. They therefore leave their mark on predefined algorithms with which the corresponding control variables are calculated in the ECU and from them the activation signals for the actuators are generated. In the process no states that lead to a vehicle operating condition that is not wanted by the driver may occur during vehicle operation. This is made possible by a comprehensive monitoring concept which must detect occurring deviations in real time and with regard to possible effect introduce appropriate measures (e.g., torque limitation or emergency operation in the idle-speed range). To this end the ECU contains a monitoring module in addition to the main computer (see Electronic control unit (ECU)).

System blocks



The complete Electronic Diesel Control (EDC) system – consisting of sensors and setpoint generators, the ECU, and the associated actuators (Figure 1) – is subdivided into different blocks, which in each case form a functional or structural unit. These blocks are called system blocks.

Sensors

The electronic engine control unit uses sensors to acquire the operating data required for open- and closed-loop engine control which are converted into electrical signals so that they can be processed in

Figure 2: Vehicle architecture

a) Architecture with vehicle control computer and exhaust-gas treatment ECU,

[1] SCR systems with DCU,
[2] Commercial vehicles only.

the “ECU” system block. Sensors detect physical and chemical quantities and thereby provide information about the engine's current operating condition. Examples of such sensors are:

Driver-input detection:
– accelerator-pedal position,
– brake switch.

Vehicle-condition detection:
– driving speed,
– clutch switch,
– brake pressure.

Ambient conditions:
– air temperature,
– air humidity,
– atmospheric pressure.

Engine-condition detection:
– speed sensor for detecting the crankshaft position and calculating the engine speed,
– phase sensor for detecting the camshaft position,
– intake-air temperature,
– air mass,
– boost (charge-air) pressure,
– charge-air temperature,
– coolant temperature,
– excess-air factor (via λ sensor).

Condition, exhaust-gas treatment (integrated systems):
– temperature, pressure, and tank fill level of urea/water solution,
– catalytic-converter temperatures,
– particulate-filter differential pressure.

Electronic control unit (ECU)
The signals of the sensors and setpoint generators are processed in the ECU according to predefined mathematical computing rules (control algorithms). Input variables (e.g., fuel quantity) are calculated via the algorithms and parameters stored in the ECU and to this end the electrical output signals are generated for the respective actuators (e.g., solenoid valve in the injector). The ECU also serves as an interface to other electronic systems (e.g., antilock braking system (ABS) and diagnostics).

Actuators
The third system block comprises the actuators, which convert the electrical output signals from the ECU into mechanical quantities. Examples of actuators:

Driver information:
– warning lamps (e.g., malfunction indicator lamp),
– status displays.

The discrete lights and displays are increasingly being replaced by electronic displays, which receive their information via a data bus.

Diesel injection:
– fuel injectors,
– metering unit,
– pressure-control valve.

Air system:
– EGR valve (exhaust-gas recirculation),
– EGR-cooler bypass,
– charge-pressure actuator for VTG (variable turbine geometry),
– λ sensor heating,
– exhaust-gas flap.

Exhaust-gas treatment:
– SCR heater for tank and lines,
– SCR pumps,
– SCR valves,
– HCI metering and valves (Hydro Carbon Injection, diesel injection into the exhaust-gas system).

Engine cooling and engine protection:
– fan,
– water pump,
– oil pump,
– thermostat.

Other:
– starter,
– engine brake.

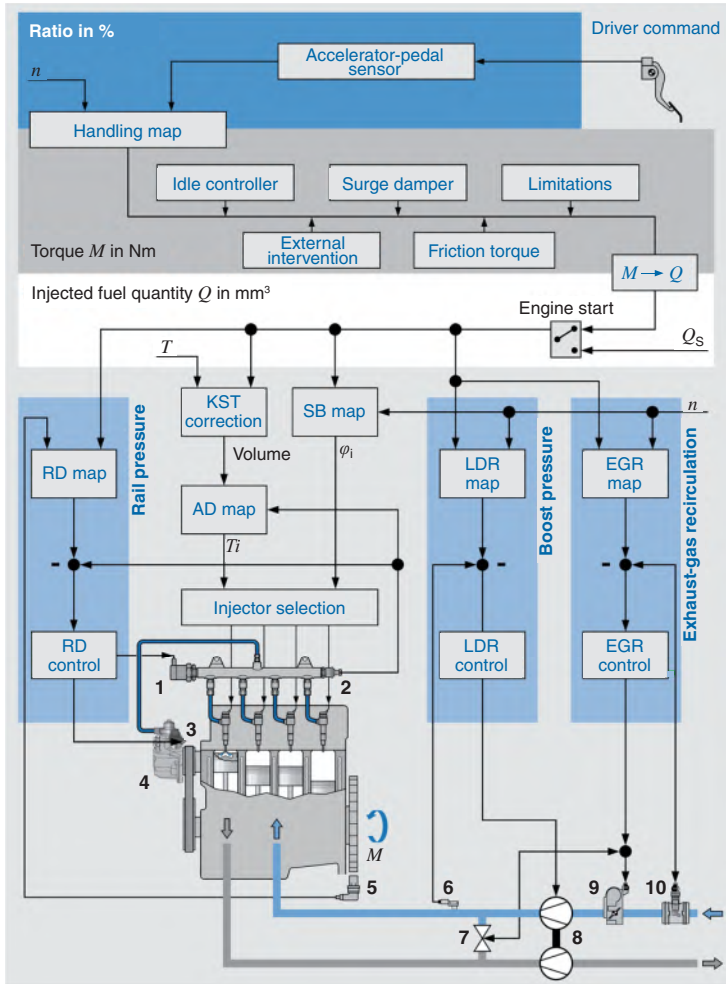
Data processing

Operating principle
The main function of Electronic Diesel Control (EDC) is to control the injected fuel quantity, the start of injection, and the injection pressure. The engine control unit activates various actuators in all systems. For all components to operate efficiently, the EDC functions must be precisely matched to every vehicle and every engine (through application and calibration). This is the only way to optimize component interaction.

The ECU analyzes the incoming signals from the sensors and limits them to the permissible voltage level. Some input signals are also checked for plausibility. Using these input signals together with stored program maps, the microcontroller in the ECU calculates injection timing and its duration. This information is then converted to a signal characteristic which is aligned to current crankshaft and camshaft positions. The computing program is part of the ECU software, which also comprises further functions. The required degree of accuracy together with the diesel engine's outstanding dynamic response requires high-level computing power.

The output signals are applied to output stages, which provide adequate power for the actuators (e.g., high-pressure solenoid valves for injection, EGR positioner, and charge-pressure actuator). Apart from this, a number of other auxiliary-function components (e.g., glow relay and air-conditioner compressor) are triggered. Faulty signal characteristics are detected by output-stage diagnosis functions for the solenoid valves.

Furthermore, signals are exchanged with other systems in the vehicle via the interfaces. The engine control unit monitors the complete fuel-injection system as part of a safety strategy.



Torque structure in the EDC
Historically, quantities were used to make calculations in the engine control unit; this approach has in the meantime become out-dated. All modern diesel-control systems operate with torque control because torque is the dominant physical variable in the drivetrain. All the power demands on the engine are coordinated and converted into a torque request. In the torque coordinator these demands are prioritized by internal and external consumers as well as further inputs with regard to engine efficiency. The driver when accelerating directly requests a torque to be set via the accelerator pedal (with an accelerator-pedal sensor) (Figure 3). Irrespective of this, other external vehicle systems request via the interfaces a torque which is obtained from the power demand of the components (e.g., air conditioner, alternator). The engine management calculates from this the resulting engine torque and triggers the actuators of the injection and air systems. This has the following advantages:

– No system has a direct influence on the individual engine-management functions (boost pressure, injection, preheating). The engine management can thus for the external requirements take into consideration higher-level optimization criteria (e.g., exhaust-gas emissions, fuel consumption) and then activate the engine in the best possible way.
– Many functions which do not directly concern the management of the engine can run uniformly for diesel- and gasoline-engine management systems. This facilitates the exchange of software.
– Expansions of the system can be quickly implemented.

The definitive sensor for determining the driver command is the accelerator pedal (accelerator-pedal position in %). The accelerator-pedal position is tracked into the driver-command torque (in Nm) via the handling map. In the subsequent "torque path" the influences of idle controller, governor, external interventions (e.g., slip-control torque reductions or torque increases), limitations, etc. are calculated in addition to the driver-command torque. The calculations are made depending on the type on the clutch-, transmission-, or engine-torque level. The final result is the command torque at the engine shaft. In conclusion, the requested internal engine torque is obtained by adding the temperature- and speed-dependent engine friction torques.

Examples of important functions in the EDC

Control of injection (metering) and of air mass

The required injected fuel quantity is calculated from the necessary internal torque. The required air quantity which must be made available by the air system, especially by supercharging, is calculated from this injected fuel quantity. Among others different physical operating times must be taken into account in the air and fuel systems. The fuel quantity can be adapted at the next firing cylinder while the air quantity can be determined by the operating times in the exhaust-gas turbocharger compressor.

Exhaust-gas recirculation is provided to improve emissions; the setpoint pressure of rail-pressure control depends on the engine operating point as well as on the desired quantity. In actual fact, very many further cross-connections and control operations must be taken into consideration, for example the desired quantity must be limited if the air-system is unable to supply the required air quantity quickly enough (for smoke limitation).

With regard to engine and exhaust-emission behavior the accuracy of injected fuel quantity and injection intervals is subject to closely toleranced requirements. Learning functions are increasingly used here.

Speed governing

Idle-speed control

The purpose of idle-speed control is to adjust a defined set speed at idle when the accelerator pedal is not pressed. This set speed can vary depending on the engine's operating condition; thus, for example, a higher idle speed is set for a cold engine than for a hot engine. The idle speed can also be increased for example when the vehicle system voltage is too low, the air conditioner is switched on or the vehicle is rolling. Because the engine is operated at idle relatively frequently in heavy traffic (e.g., “stop and go” or stopped at traffic lights), the idle speed should for emission and consumption reasons be as low as possible. However, this creates drawbacks for the engine's smooth running and starting performance. Idle-speed control must manage with very strongly fluctuating requirements in relation to the adjustment of the specified set speed.

The power demand of the auxiliary systems driven by the engine is variable within wide limits. The alternator for example draws much more power when the vehicle system voltage is low than when it is high; on top of this are demands on the air-conditioner compressor, the power-steering pump, high-pressure generation for diesel injection, etc. Added to these external load torques is the internal engine friction torque, which is very much dependent on the engine temperature. In the usual torque-controlled systems the torque demands of the auxiliary systems and the engine friction torque can be modeled and used as pilot control. The idle controller (minimum-speed governor) only then has to compensate the model inaccuracies.

Maximum-speed governing

The purpose of maximum-speed governing (also called speed regulation) is to protect the engine against unacceptably high rotational speeds. To this end the engine manufacturer lays down a maximum permissible speed which must not be exceeded for an extended period of time, as this would damage the engine. Speed regulation continuously reduces the command torque above the engine's rated-power operating point. Injection ceases shortly above the maximum engine speed. However, speed regulation must be effected as softly as possible (with a ramp function) so as to prevent jerky speed regulation of the engine when accelerating. This is all the more difficult to achieve the closer together the rated-power operating point and the maximum speed are.

Intermediate-speed regulation

Intermediate-speed regulation is used for commercial vehicles with power take-offs (e.g., crane operation) or for special vehicles (e.g., fire pump). When it is activated, the engine is regulated to an intermediate speed.

The speed can be input here via the cruise-control operating panel or via a communication interface.

Cruise control and road-speed limitation
The vehicle-speed controller enables the vehicle to drive at a constant speed. It regulates the vehicle's speed to a desired value without the driver having to press the accelerator pedal. This value can be adjusted via an operating lever or via steering-wheel buttons. The command torque is increased or decreased until the measured actual speed equals the set desired speed.

Road-speed limitation limits the maximum speed to a settable or legally prescribed value, even when the accelerator pedal continues to be pressed. This is an aid to the driver, who consequently cannot unintentionally exceed speed limits. For this purpose road-speed limitation limits the driver-command torque according to the maximum desired speed.

Surge damping control
In the event of sudden load changes the alteration of the engine torque causes the vehicle drivetrain to undergo bucking oscillations. Vehicle occupants perceive these bucking oscillations to be unpleasant periodic changes in acceleration. Surge damping control reduces these changes in acceleration. This is achieved by means of two separate measures:
– filtering of the torque desired by the driver,
– damping by means of active control.

Smooth-running control, fuel-balancing control
Not all the cylinders of an engine generate the same torque for an identical injection time. This can be down to differences in cylinder compression, differences in cylinder friction or differences in the hydraulic injection components. The consequences of these torque differences are irregular engine running and increased engine emissions. The purpose of smooth-running control or fuel-balancing control is to detect such differences with reference to the resulting speed fluctuations and balance these difference by means of a targeted adaptation of the injected fuel quantity of the cylinder in question.

Altitude correction
Atmospheric pressure decreases at increasing altitude. Consequently the cylinder charge of combustion air becomes smaller. The injected fuel quantity must therefore be reduced. If the same quantity were to be injected as at high atmospheric pressure, there would be heavy smoke emissions due to the air deficiency. The atmospheric pressure is detected by the ambient-pressure sensor in the ECU. In this way the injected fuel quantity can be reduced at high altitudes. The atmospheric pressure also influences boost-pressure control and torque limitation.

Shutdown
The upshot of the operating principle of auto-ignition is that a diesel engine can only be brought to a stop by interrupting the fuel supply. With Electronic Diesel Control the engine is shut down via the ECU input “injected fuel quantity zero” (e.g., no activation of the solenoid valves, closing of the metering unit). A soft shutdown (avoidance of “thumping” during shutdown) can be achieved through the closing of possible throttle valves or exhaust-gas flaps.

λ control
The wideband λ sensor in the exhaust pipe measures the residual oxygen content in the exhaust gas. The air/fuel ratio (excess-air factor λ) can be inferred from this. In a diesel engine (which is always operated with excess air, i.e., $\lambda > 1$), the signal from the λ sensor serves
– to improve the accuracy of exhaust-gas recirculation,
– to deliver full-load smoke limitation,
– to detect unwanted combustion.

Boost-pressure control
Boost-pressure control of the exhaust-gas turbocharger improves the torque characteristic in full-load operation and the charge cycle in part-load operation. The setpoint value for the boost pressure depends on the rotational speed, the injected fuel quantity, the coolant temperature, the air temperature, and the ambient-air pressure. It is compared with the actual value of the boost-pressure sensor. In the event of a control deviation the bypass valve or

the guide vanes of the turbocharger with variable turbine geometry are actuated via the ECU.

Fan activation
The engine control unit activates the engine's fan wheel above a certain engine temperature. The fan wheel continues to be operated for a certain amount of time even after the engine has come to a stop. This after-run time depends on the current coolant temperature and the load condition of the last driving cycle.

Exhaust-gas recirculation
Exhaust gas is directed into the engine's intake tract to reduce the NO_x emissions. This is done via a duct whose cross-section can be varied by an exhaust-gas recirculation valve. The EGR valve is activated for example by an electrical controller. It is difficult to measure the recirculated exhaust-gas flow due to the high temperature and pollutant content of the exhaust gas. Control is therefore effected indirectly via an air-mass meter in the fresh-air mass flow. Its measured value is compared in the ECU with the engine's theoretical air requirement. This is determined from various characteristic data (e.g., engine speed). The lower the actual measured fresh-air mass compared with the theoretical air requirement, the higher the recirculated exhaust-gas content.

Substitute functions
If individual input signals fail, the ECU lacks important information for the calculations. In this case activation is effected with the aid of substitute functions.

Example 1
The fuel temperature is required to calculate the injected fuel quantity. If the fuel-temperature sensor fails, the ECU computes with a substitute value which can be calculated for example using a model from the engine temperature, the ambient temperature, and the tank contents. This must be chosen so as not to give rise to excessive soot formation. This can cause the power to drop in some operating ranges in the event of a faulty fuel-temperature sensor.

Example 2
If the camshaft position sensor fails, the ECU uses the signal from the crankshaft speed sensor as a substitute value. Different vehicle manufacturers have different concepts which are used to determine via the crankshaft-signal characteristic when cylinder 1 is in the compression cycle. The restart, however, takes a little longer as a consequence of these substitute functions.

The different substitute functions may vary from vehicle manufacturer to vehicle manufacturer. All faults are stored by means of the diagnosis function and can be read out in the workshop.

Data exchange with other systems
The engine-management system can communicate via bus systems, such as for example the CAN bus (Controller Area Network), with the ECUs of other vehicle systems and use the information as input signals for control algorithms. The driving speed for example is only calculated in the ESC control unit (Electronic Stability Control) and communicated via the bus to other systems.

Application

Function and meaning of application
Application often also refers to the integration of a component or a subsystem in a higher-level system. Here the generic term application is usually also used for the adaptation of hardware components, while the term calibration is only used for the input of data for the functionalities stored in the ECU.

The application/calibration process of Electronic Diesel Control comprises the matching of different subsystems (e.g., injection system and exhaust-gas treatment system) to the complete system (here: drivetrain or powertrain) with the aim of simultaneously representing the different requirements applicable to the vehicle with regard to driving safety, emissions minimization (in the test cycle and under real driving conditions), durability, engine and component protection, the OBD system (on-board diagnostics) and the engine and vehicle characteristics established by the manufacturer (e.g., torque, max. power, noise, smooth running, response, and performance). In order to optimize these in part opposing objectives, a wealth of characteristic values, program maps, and characteristic curves are calibrated or applied.

The end result is a data record which after extensive testing for series production is stored with write protection in a read-only memory (e.g., flash EPROM). Several 10,000 calibration data are processed in modern engine-management systems. Processing takes place with dedicated tools in the laboratory, on engine and vehicle test benches, on test tracks under real driving conditions and during winter, summer, and altitude trials also under extreme conditions.

Low-pressure fuel supply

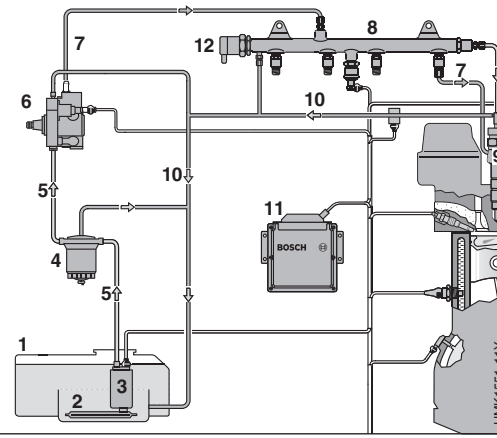
The function of the fuel-supply system is to store and filter the required fuel and to make fuel available to the fuel-injection installation at a specific supply pressure under all operating conditions. The fuel return flow is cooled in some applications. The fuel supply system comprises the following essential components (Figures 1 to 3): the fuel tank, the preliminary filter (not for unit-injector system for passenger cars), the presupply pump (optional, also in-tank pump for passenger cars), the fuel filter, the fuel pump (low pressure), the pressure-control valve (overflow valve), the fuel cooler (optional), and low-pressure fuel lines.

Individual components can be combined to form assemblies (e.g. fuel-supply pump with pressure limiter). In axial- and radial-piston distributor pumps and partially in the common-rail system, the fuel-supply pump is integrated into the high-pressure pump.

Essentially, the fuel-supply system differs greatly, depending on the fuel-injection system used, as the following figures for common rail (Figure 1), unit injector (Figure 2) and radial-piston pump (Figure 3) show.

Fuel supply and delivery

The function of the fuel pump in the low-pressure stage is to supply the high-pressure components with sufficient fuel in every operating state, with a low level of noise, at the required pressure, and over the entire service life of the vehicle. Different types are used, depending on the field of application.



Electric fuel pump

The structure of the electric fuel pump (Figure 4) is comparable to the design variations of the pumps used on spark-ignition engines (see Electric fuel pump). However, there are some different features:

– Roller-cell pumps are usually used for diesel applications (see Roller-cell pump),
– The electric motor of the pump is designed with carbon commutators instead of copper commutators.

Use of electric fuel pumps:
– Optional for distributor injection pumps (only in event of long fuel lines or great difference in height between fuel tank and fuel-injection pump)
– Unit-injector system (passenger cars)
– Common-rail system (passenger cars)

Gear pump

The gear pump is mounted directly onto the engine or, in the case of a common rail, it is integrated into the high-pressure pump. It is driven mechanically by way of a clutch, a gear wheel, or a toothed belt.

The primary components are two intermeshing, counter-rotating gear wheels (Figure 5) which deliver the fuel into the

tooth spaces from the suction side to the pressure side. The line of contact of the gear wheels provides the seal between the suction and pressure sides and prevents fuel from flowing back.

The delivery quantity is roughly proportional to the engine speed. At high rotational speeds, therefore, the quantity is limited by throttle action on the intake side or by an overflow valve on the pressure side, which discharges the feed volume to the inlet inside the pump. This prevents unnecessarily high flows in the vehicle's conduit system.

Applications:
– For single-cylinder pump systems for commercial vehicles (unit-injector and unit-pump system, individual injection pump (PF))
– for common-rail systems (commercial vehicles, in part for passenger cars).

Vane-type supply pump

The vane-type supply pump (Figure 6) is mounted on the drive shaft in the distributor injection pump. The impeller is centered on the drive shaft and supported by a Woodruff key. An eccentric ring mounted in bearings in the housing surrounds the impeller.

The fuel passes through the inlet passage and a kidney-shaped recess into the space created by the impeller, the

vane and the eccentric ring. The centrifugal force generated by the motion of rotation presses the four vanes of the impeller outwards against the eccentric ring. The fuel between the underside of the vanes and the impeller supports this outward movement of the vanes. The rotary motion forces the fuel located between the vanes into the upper kidney-shaped recess and through a bore to the outlet.

Application: Integrated presupply pump in the distributor injection pump.

Locking-vane pump

In a locking-vane pump (Figure 7), springs press two locking vanes against a rotor. As the rotor turns, the volume is increased on the suction side and fuel is drawn into two chambers. The volume is reduced on the pressure side and fuel is delivered from the two chambers. The locking-vane pump delivers fuels at very low speeds.

Application: Unit-injector system for passenger cars.

Tandem fuel pump

The tandem fuel pump (Figure 8) is an assembly consisting of a fuel pump and a vacuum pump, for example, for the brake booster. From a functional perspective, these are two separate pumps, which, however, are driven by a common drive shaft. It is integrated into the engine cylinder head and driven by the engine camshaft.

The fuel pump itself is either a locking-vane pump or a gear pump, and even at low speeds (cranking speeds) delivers enough fuel to ensure that the engine starts reliably. The pump's delivery quantity is proportional to the rotational speed.

The pump contains a variety of valves and throttling orifices. The pump's maximum delivery quantity is limited by the suction throttling orifice so that not too much fuel is delivered. The pressure-relief valve limits the maximum pressure in the high-pressure stage. Vapor bubbles in the fuel feed are eliminated in the fuel-return throttling bore. If there is air in the fuel system (e.g. if the vehicle has been driven until the fuel tank is empty), the low-pressure control valve remains

closed. The air is forced out of the fuel system through the bypass by the pressure of the pumped fuel.

Application: Unit-injector system for passenger cars.

Low-pressure control valve
The pressure-control valve (Figure 9, also called overflow restriction) is built into the fuel return, for common-rail usually into the high-pressure pump. It provides an adequate operating pressure in the low-pressure stage of the injection systems under all operating conditions and ensures that the pumps are filled uniformly.

For example, the accumulator plunger of the valve for the unit injector and unit pump opens at the initial opening pressure of 300 to 350 kPa (3 to 3.5 bar). A compression spring compensates for minor pressure variations in accumulator volume. At an opening pressure of 4 to 4.5 bar, an edge seal opens and produces a noticeable increase in flow rate.

There are two screws with different spring-force settings for presetting the opening pressure.

Fuel cooler
The high pressure in the injector of the unit-injector system for passenger cars and some common-rail systems heats up the fuel to such an extent that it has to be cooled before it flows back. The fuel returning from the injector flows through the fuel cooler (heat exchanger) and dissipates thermal energy to the coolant in the fuel-cooling circuit. This is separate from the engine-cooling circuit because the coolant temperature of an engine running at operating temperature is too high to cool the fuel. The fuel-cooling circuit is connected to the engine-cooling circuit at the compensating reservoir. This helps to keep the fuel-cooling circuit filled and compensates for any changes in volume caused by temperature fluctuations (Figure 10).

In part, common-rail uses other cooling concepts (such as fuel-air heat exchangers on the floor of the vehicle). Due to the reduced power loss, however, newer common-rail systems with quantity-controlled high-pressure pumps are largely being used without fuel coolers.

Diesel filter

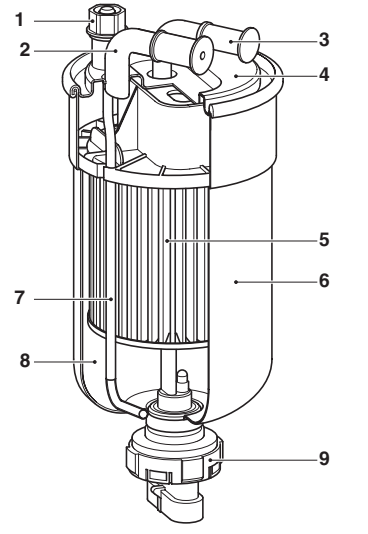
Function

As in spark-ignition (SI) engines, it is essential in a diesel engine to ensure that the fuel system is protected against contamination. Contaminants are introduced into the system during refueling or can get into the tank via the tank ventilation and thus into the fuel itself. The function of the fuel filter is to reduce contamination from particulates so as to protect the fuel-injection system.

Compared with gasoline-injection systems, diesel fuel-injection systems require increased wear protection and finer filters to cater for the much higher injection pressures. Diesel fuel is also more heavily contaminated than gasoline.

Design

Diesel filters are designed as easy-change filters (Figure 1). Spin-on filters, in-line filters and nonmetal filter elements are widely used as replacement parts in aluminum, plastic or sheet-steel filter cases (to comply with increased requirements in crashes). Spiral vee-shape filter elements are the preferred choice. The diesel fuel filter is installed in the low-pressure circuit: in suction systems upstream of the fuel-supply pump and in pressure systems downstream of the electric fuel pump. The trend is now towards pressure systems.



Requirements

In the last few years, the requirements for filter fineness have become more stringent owing to the introduction of common-rail systems with higher injection pressures and advanced unit-injector systems for passenger cars and commercial vehicles. Depending on the application (fuel contamination, periods of engine standstill), the new systems require a filtration efficiency of between 85 % and 98.6 % (particulate interval 3 to 5 µm, ISO/TS 13353 [1] and ISO 19438 [2]). The fuel filters fitted to the latest generation of automobiles must be capable of storing larger volumes of particulates due to the longer service intervals, and of separating superfine particulates efficiently. This can only be achieved by using special filter media, e.g. consisting of multiple layers made of synthetic microfiber. These filter media exploit the effects of a fine prefilter, and guarantee maximum particulate-retention capability by separating particulates inside each filter layer.

Typical replacement intervals today are between 60,000 and 90,000 km. These intervals are significantly shortened in markets where the diesel quality is poor, such as Eastern Europe, China,

7 Tube to drain,
8 Water accumulation chamber,
9 Water-level and temperature sensors.

India, and the USA. Likewise, when biodiesel is used, halving the replacement interval is recommended.

Water separation

A second essential function of the diesel filter is to separate emulsified and free water in order to prevent corrosion damage. An effective water separation of more than 93 % at rated flow (testing as per ISO 4020 [3]) is particularly important for distributor injection pumps and common-rail systems. Water separation takes place by coalescence on the filter medium (formation of droplets due to the different surface tensions of water and fuel). Separated water collects in the chamber at the bottom of the filter housing (Figure 1). Conductivity sensors are used in some cases to monitor the water level. The water is drained manually by opening a water drain plug or pressing a pushbutton switch.

For extra heavy-duty requirements, it is beneficial to fit an additional preliminary filter with water separator on the suction or pressure side. Preliminary filters of this type are mostly used for commercial vehicles in countries where diesel quality is poor.

Modular additional functions

New-generation diesel fuel filters integrate modular additional functions such as, for example, fuel preheating to prevent paraffin clogging during winter operation. Fuel preheating can be effected electrically or by utilizing the hot fuel return flow from the engine. In the first instance, PTC heaters (Positive Temperature Coefficient) are installed in the filter. The second instance requires the fitting of a bimetal valve or a wax expansion element which opens at low temperatures and allows fuel to flow back to the filter.

Further additional functions are maintenance indication by way of differential-pressure measurement and filling and venting devices.

Common-rail fuel-injection system

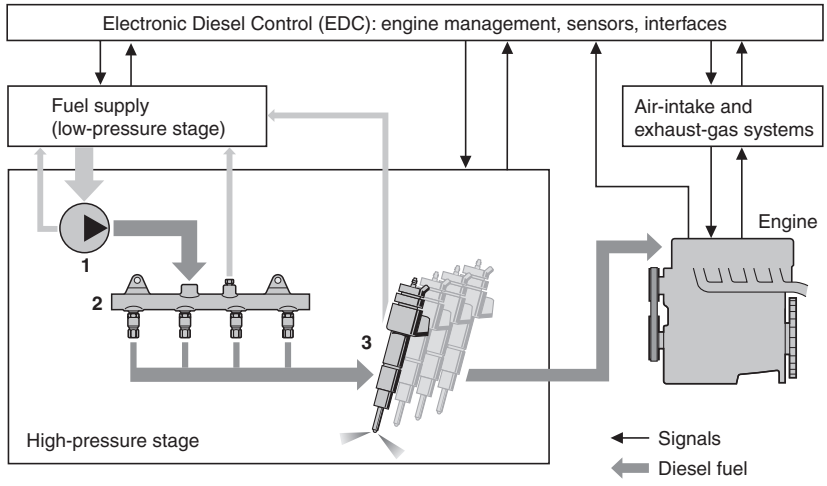
System overview

Requirements

The demands placed on diesel-engine fuel-injection systems are continually increasing. Higher injection pressures, faster injector switching times, and a variable rate-of-discharge curve modified to the engine operating state have made the diesel engine economical, clean, and powerful.

The main advantage of the common-rail system (CR) over conventional fuel-injection systems is its ability to vary injection pressure and timing over a broad scale. This was achieved by separating pressure generation (in the high-pressure pump) from the fuel-injection system (injectors). The rail here acts as a pressure accumulator (Figure 1).

The common-rail system is a highly flexible system for adapting fuel injection to the engine. This is achieved by an injection pressure adapted to the operating status of 200 to 2,500 bar, a variable start of injection, and the possibility of using pre-injection and secondary-injection events (even highly retarded secondary-injection events are possible). In this way, the common-rail system helps to raise specific power output, lower fuel consumption, reduce noise emission, and decrease pollutant emission in diesel engines.



Common rail is today the most commonly used fuel-injection system for modern passenger-car and commercial-vehicle diesel engines.

Design

The common-rail system consists of the following main component groups (Figure 1): the low-pressure system comprising the components of the fuel-supply system, the high-pressure system comprising the high-pressure pump, the rail, the injectors and the high-pressure fuel lines, and Electronic Diesel Control (EDC).

The key components of the common-rail system are the injectors connected to the rail. They are fitted with a rapid-action valve (solenoid valve or piezo actuator) which opens and closes the nozzle. This

Figure 1: System areas of engine management with the common-rail fuel-injection system

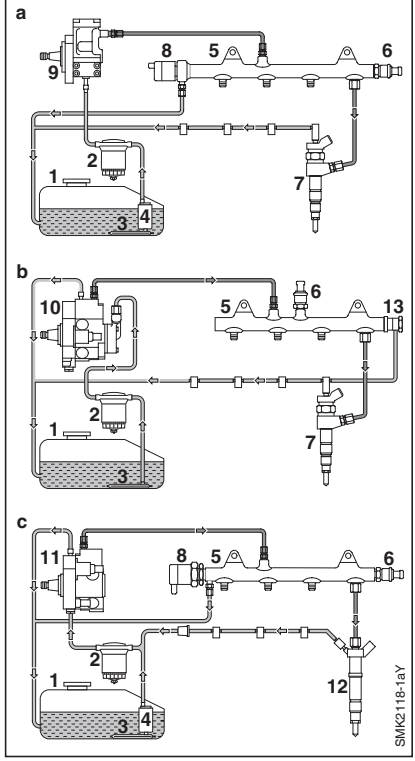
permits control of the injection process for each cylinder.

Fuel supply
In common-rail systems for passenger cars and light-duty commercial vehicles, electric fuel pumps or gear pumps are used to deliver fuel to the high-pressure pump. It is exclusively gear pumps that are used for heavy-duty commercial vehicles (see Low-pressure fuel supply).



Systems with electric fuel pump
Systems with an electric fuel pump are increasingly gaining acceptance in the passenger-car market. There are several reasons for this:
– Using a controlled electric fuel pump results in a lower power demand (CO_2 advantage).
– As well as supplying the fuel-injection system, an electric fuel pump permits in parallel the operation of suction jet pumps in the tank; these pumps fill the swirl pot and thus ensure the presence of fuel in the intake area (see Fuel-delivery module).
– The fact that the pressure build-up in the low-pressure system is not dependent on engine speed improves the starting response.

The electric fuel pump is usually part of the in-tank unit (in the fuel tank) or occasionally is fitted in the fuel line (in-line). It intakes fuel via a pre-filter and delivers it to the high-pressure pump at a pressure of 4 to 6 bar (Figures 2a and 2c). The maximum delivery rate is, depending on engine performance, 150 to 240 *l*/h.

Systems with gear pump
The gear pump is flanged to the high-pressure pump and is driven by its input shaft (Figure 2b). In this way, the gear pump starts delivery only after the engine has started. Delivery rate is dependent on the engine speed and reaches rates up to 400 *l*/h at pressures up to 7 bar.

Combination systems
There are also applications where the two pump types are used. The electric fuel pump improves starting response, in

particular for hot starts, since the delivery rate of the gear pump is lower when the fuel is hot, and therefore, thinner, and at low pump speeds. In addition, the electric fuel pump ensures the operation of suction jet pumps in the tank.

Combination systems are however rarely used, due to the increased costs and the increased power demand for two pumps.

Fuel filtering

In passenger-car systems with an electric fuel pump the fuel filter is located on the pressure side between the electric fuel pump and the high-pressure pump. In systems with a gear pump the fuel filter is fitted between the fuel tank and the gear pump. In contrast, the fuel filter (fine filter) is fitted on the pressure side in commercial-vehicle systems. For this reason, an exterior fuel inlet is required, in particular when the gear pump is flanged to the high-pressure pump (Figure 3).

Pressure generation

In the common-rail pressure-accumulator fuel-injection system, the functions of pressure generation and fuel injection are separate. The injection pressure is generated independent of the engine speed and the injected fuel quantity. Electronic Diesel Control controls each of the components.

The functions of pressure generation and fuel injection are separated by the rail's accumulator volume. The pressurized fuel is held in the accumulator volume ready for injection.

A continuously operating high-pressure pump driven by the engine produces the desired injection pressure. Pressure in the fuel rail is maintained irrespective of engine speed or injected fuel quantity.

The high-pressure pump is a radial-piston pump. On commercial vehicles, in contrast to passenger cars, an in-line pump is sometimes fitted.

Pressure control

Different procedures are used for pressure control.

Control on the high-pressure side

The desired rail pressure is regulated on the high-pressure side by a pressure-control valve (Figure 2a). Fuel not required for injection flows back to the low-pressure circuit via the pressure-control valve. This type of control loop allows rail pressure to react rapidly to changes in operating point (e.g. in the event of load changes).

Fuel-delivery control on the suction side
Another way of controlling rail pressure is to control fuel delivery on the suction side (Figures 2b and 3). The metering unit flanged on the high-pressure pump makes sure that the pump delivers exactly the right quantity of fuel to the fuel rail in order to maintain the injection pressure required by the system. In a fault situation, the pressure-relief valve prevents rail pressure from exceeding a maximum. Fuel-delivery control on the suction side reduces the quantity of fuel under high pressure and lowers the power input of the pump. This has a positive impact on fuel consumption. At the same time, the temperature of the fuel flowing back to the fuel tank is reduced in contrast to the control method on the high-pressure side.

Two-actuator system
The two-actuator system (Figure 2c) combines pressure control on the suction side via the metering unit and control on the high-pressure side via the pressure-control valve, thus marrying the advantages of suction-side fuel-delivery control with the dynamic response of control on the high-pressure side. Another advantage compared with control on the low-pressure side only is that the high-pressure side is also controllable when the engine is cold. The high-pressure pump then delivers more fuel than is injected and pressure is controlled by the pressure-control valve. Compression heats the fuel, thus eliminating the need for an additional fuel heater.

Fuel injection
The injectors spray fuel directly into the engine's combustion chambers. They are supplied by short high-pressure fuel lines connected to the fuel rail. The engine control unit controls the switching valve integrated into the injector to open and close the injector nozzle.

The injector opening times and system pressure determine the quantity of fuel delivered. At a constant pressure, the fuel quantity delivered is proportional to the switching time of the solenoid valve. This is, therefore, independent of engine and pump speeds (time-based fuel injection).

Hydraulic performance potential
Separating the functions of pressure generation and fuel injection opens up further degrees of freedom in the combustion process compared with conventional fuel-injection systems; the injection pressure is more or less freely selectable within the program map.

The common-rail system allows a further reduction in exhaust-gas emissions by introducing pre-injection events and multiple injection events and also attenuating combustion noise significantly. Multiple injection events of up to seven per injection cycle can be generated by triggering the rapid-action switching valve several times. Hydraulic pressure is used to augment nozzle-needle closing, ensuring rapid termination of the injection process.

Control and regulation
Operating principle
The engine control unit detects the accelerator-pedal position and the current operating states of the engine and vehicle by means of sensors (see "Electronic Diesel Control"). The data collected includes: the crankshaft speed and the crankshaft angle, the rail pressure, the charge-air pressure, the intake-air, coolant and fuel temperature, the inducted air mass, and the wheel speed (for calculating the driving speed). The electronic control unit evaluates the input signals. In sync with combustion, it calculates the triggering signals for the pressure-control valve or the metering unit, the injectors, and the other actuators (e.g. the EGR valve, exhaust-gas turbocharger actuators, etc.).

Basic functions
The basic functions involve the precise control of diesel-fuel injection timing and fuel quantity at the reference pressure. In this way, they ensure that the diesel engine has low consumption and smooth running characteristics.

Correction functions for calculating injection time
A number of correction functions are available to compensate for tolerances between the fuel-injection system and the engine.

Fuel-balancing control
These tolerances result in different torque build-up of individual cylinders. The consequences of these torque differences are irregular engine running and increased exhaust-gas emissions. Injected-fuel-quantity corrections are calculated from the resulting speed fluctuations. Smooth running is increased by specifically adapting the injection time for each cylinder (smooth-running control).

Injector delivery compensation
Injector delivery compensation enables the fuel-quantity deviations of brand-new injectors to be corrected. To this end a wide range of measured data is recorded during injector production for each injector and then applied to the injector in the form of a data matrix code. Information about the lift behavior is also added for a piezo in-line injector. These test data are transmitted during vehicle production to the engine ECU. These values are used during engine operation to compensate deviations in metering and switching performance.

Zero delivery calibration
To achieve both noise reduction and emission targets it is particularly important to be safely in control of small pre-injections over the service life of the vehicle. Injector fuel-quantity drifts must therefore be compensated. To this end a small quantity of fuel is specifically injected into a cylinder in overrun conditions. The speed sensor detects the resulting torque increase as a small dynamic change in speed. This torque increase which is not felt by the driver is clearly linked to the injected fuel quantity. The process is repeated in succession for all the cylinders and for different operating points. A learning algorithm establishes the smallest changes in the pre-injection quantity and corrects the activation duration for the injectors accordingly for all the pre-injections.

Fuel-quantity mean-value adaptation
The deviation of the actually injected fuel quantity from the setpoint value is required to correctly adapt exhaust-gas recirculation and charge-air pressure. Fuel-quantity mean-value adaptation determines the value for the fuel quantity averaged over all the cylinders from the signals from the λ sensor and the air-mass meter. Correction values for the injected fuel quantity are calculated from the comparison of setpoint and actual values.

Supplementary functions
Additional open- and closed-loop control functions perform the tasks of reducing exhaust-gas emissions and fuel consumption, or providing added safety and convenience. Examples of such functions are control of exhaust-gas recirculation, boost-pressure control, cruise control, and the electronic vehicle immobilizer.

The integration of Electronic Diesel Control in a vehicle's overall system network facilitates the exchange of data with, for example, transmission control or air conditioning. A diagnosis interface facilitates the analysis of stored system data when the vehicle is serviced.

Injectors

Solenoid-valve injectors

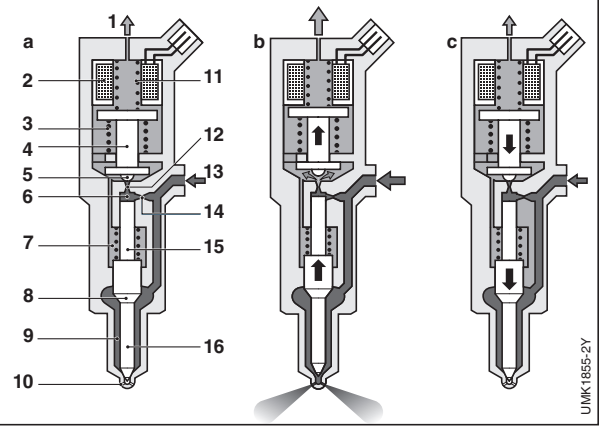
Design and operating principle

The solenoid-valve injector can be subdivided into a number of function modules: the injection nozzle, the hydraulic servo valve to actuate the valve plunger, the nozzle needle, and the solenoid valve.

The fuel is routed from the high-pressure port (Figure 4a) via an inlet passage to the injection nozzle and via the inlet restrictor into the valve control chamber. The valve control chamber is connected by the outlet restrictor, which can be opened by the solenoid valve, to the fuel return.

The function of the injector can be subdivided into four operating states when the engine and the high-pressure pump are operating. The operating states are caused by the balance of forces acting on the injector components. The nozzle spring closes the nozzle when the engine is not running and there is no pressure in the rail.

All the solenoid-valve injectors have a hydraulic port on the solenoid group for the return flow to the low-pressure system. The return flow is made up of the control quantity (only while the valve is open) and the leakage of the guides at the nozzle, the valve plunger, and the solenoid valve when a pressure-compensated valve is used (see Injector variants). To increase hydraulic efficiency, injectors with a maximum injection pressure greater than 2,000 bar have no leakage at the nozzle guide and valve plunger.



Nozzle closed (rest position)

In its rest position, the solenoid valve is not triggered (Figure 4a). The solenoid valve, in response to the force of the solenoid-valve spring, closes the valve seat, thereby stopping the flow through the outlet restrictor. Inside of the valve control chamber, the pressure rises to the pressure in the fuel rail. The same pressure is also present in the nozzle chamber. The forces acting on the end faces of the control plunger resulting from the fuel-rail pressure and the force of the nozzle spring hold the nozzle needle in the closed position against the opening force acting on the pressure shoulder of the needle.

Figure 4: Functioning principle of solenoid-valve injector (schematic representation)

a) Nozzle closed (rest position), b) Nozzle opens (start of injection),
c) Nozzle closes (end of injection).

1 Fuel return, 2 Solenoid coil (solenoid valve), 3 Overstroke spring, 4 Solenoid armature, 5 Valve seat, here with pressure-loaded ball valve, 6 Valve control chamber, 7 Nozzle spring, 8 Pressure shoulder of nozzle needle, 9 Chamber volume of injection nozzle, 10 Nozzle-body seat with injection orifices, 11 Solenoid-valve spring, 12 Outlet restrictor, 13 High-pressure port, 14 Inlet restrictor, 15 Valve plunger (control plunger), 16 Injection-nozzle needle.

Nozzle opens (start of injection)
During the opening phase of triggering (Figure 7) the magnetic force of the electromagnet exceeds the spring force of the solenoid-valve spring. The armature opens the valve completely in the ensuing pick-up-current phase. This releases the flow through the outlet restrictor (Figure 4b).

The rapid opening of the solenoid valve and the required rapid switching times are achieved by controlling solenoid-valve triggering in the ECU at high voltages and currents (Figure 7). After a short time, the increased pickup current is reduced to a lower holding current.

When the outlet restrictor opens, fuel flows from the valve control chamber to the armature chamber and then via the fuel-return line to the fuel tank. The pressure in the valve control chamber drops. Fuel flows continuously through the inlet restrictor into the control chamber. This prevents the pressure in the control chamber from dropping completely. The flows of the outlet and inlet restrictors are adapted to the dynamic response (switching times) of the solenoid valve. The pressure at the nozzle needle remains at the level of that in the rail. The reduction in pressure in the valve-control chamber reduces the force acting on the control plunger and opens the nozzle needle. Fuel injection commences.

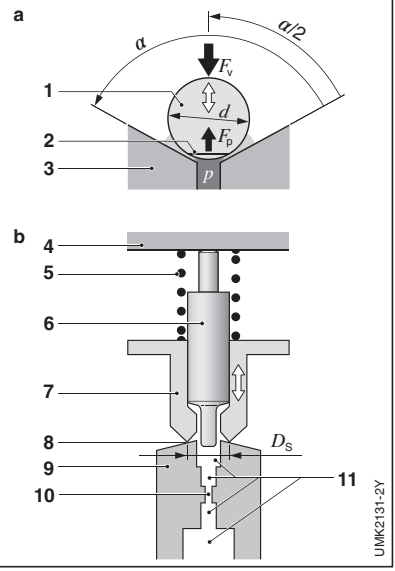
Nozzle open
The rate of movement of the nozzle needle is determined by the difference in the flow rates through the inlet and outlet restrictors and by the area ratios at the nozzle needle and valve plunger. Fuel is injected into the combustion chamber at a pressure approaching that in the fuel rail.

The balance of forces in the injector is similar to that during the opening phase. At a given rail pressure, the fuel quantity injected is proportional to the length of time that the solenoid valve is open. This is entirely independent of the engine or pump speed (time-based injection system).

Nozzle closes (end of injection)
When the solenoid valve is no longer triggered, the solenoid-valve spring presses the armature down, closes the valve seat, and thus stops the flow through the outlet restrictor (Figure 4c). When the outlet restrictor closes, pressure in the control chamber rises again to that in the fuel rail via the inlet restrictor. The higher pressure exerts a greater force on the control plunger. The force on the valve-control chamber and the nozzle-spring force then exceed the force acting on the nozzle needle, and the nozzle needle moves in the direction of the nozzle-body seat. The flow from the inlet restrictor and the area ratios at the nozzle needle and valve plunger determine the speed with which the nozzle needle closes. The fuel-injection cycle comes to an end when the nozzle needle is resting against its seat, thus closing off the injection orifices.

This indirect method is used to trigger the nozzle needle by means of a hydraulic servo system because the forces required to open the nozzle needle rapidly cannot be generated directly by the solenoid valve. The control quantity required in addition to the injected fuel quantity passes through the valve control chamber restrictors into the fuel return.

Multiple injections of up to ten injection pulses are possible (pilot injection, main injection, secondary injection) within one injection cycle with the latest injector types. The minimum possible time interval is approximately 150 µs.



Injector variants
A distinction is made between two different valve concepts with solenoid-valve injectors:
– Injectors with a pressure-loaded ball valve (valve forces act against the applied rail pressure),
– Injectors with a pressure-compensated valve (valve forces are virtually independent of the rail pressure).

Pressure-loaded ball valve
In the case of a pressure-loaded ball valve, the pressure of the compressed fuel acts on the area resulting from valve-seat angle and ball diameter (Figure 5a, see also Figure 4). This pressure generates an opening force. The spring force must be at least of sufficient magnitude that valve remains closed in the non-active state. In practice, the spring force is approximately 15% greater than the hydraulic force at maximum injection pressure in order on the

one hand to achieve a sufficient dynamic response when the valve closes, and on the other hand to ensure sufficient leak-tightness when closed.

Pressure-compensated valve
In the case of a pressure-compensated valve, there is no area on which the pressure acts and a force can be generated in the opening direction (Figure 5b).

Bosch offers solenoid-valve injectors for passenger cars and light commercial vehicles up to 1,800 bar with a pressure-loaded ball valve. To meet the highest demands in modern diesel engines pressure-compensated valves are used from 1,800 bar, since a maximum valve opening cross-section can also be attained at these high pressures. This improves the hydraulic stability of the servo valve with which the needle lift is controlled. In addition, the valve lift is also significantly reduced at high rail pressures in order also to achieve the required dynamic response for injection pressures in excess of 1,600 bar and to reduce the sensitivity of the valve dynamic response to external influences. The required minimum time intervals between two injections are achieved on account of the high dynamic response. The power demand for triggering the solenoid valves can also be reduced.

These injector variants with a pressure-compensated valve have a potential for rail pressures in excess of 2,000 bar. There is also the possibility of damping pressure pulsations in the injector with a mini-volume and thereby increasing metering precision in the case of multiple injections.

Further development of solenoid-valve injectors
The further development of solenoid-valve injectors is currently being driven in two directions:
– higher maximum permissible injection pressures,
– improving metering precision and reducing the injected-fuel-quantity tolerances.

Higher injection pressures
By increasing the injection pressure, it is possible, with the same engine power, to improve combustion by reducing the injection-orifice diameter at the nozzle and to lower the untreated emissions that arise in the combustion chamber. Solenoid-valve injectors are currently available for a maximum pressure of 2,500 bar.

Metering precision
To improve the metering precision of the injected fuel quantity, sensors are available with which the opening time of the valve and the nozzle needle can be measured and a control loop can be established with software programmed in the engine ECU. Then the opening time of the solenoid valve and consequently the opening time of the nozzle needle can be regulated via the activation period. In this way, it is possible to eliminate to a large extent the deviation of the injected fuel quantity through external influences (e.g., fuel temperatures and viscosity) and through influences in the injector (e.g., wear on the components).

In Bosch solenoid-valve injectors this sensor is integrated in the solenoid of the pressure-compensated valve (Figure 6). The pressure in the valve control chamber is transferred via the armature pin and the pressure distributor to a piezo sensor; the piezo sensor uses the pressure force to generate an electrical signal. This is transmitted via an additional pin in the injector connector to the engine ECU, where it is evaluated.

The pressure characteristic in the control chamber correlates with the opening of the valve and the closing of the nozzle needle. In this way, a control loop can be established to regulate the injected fuel quantities.

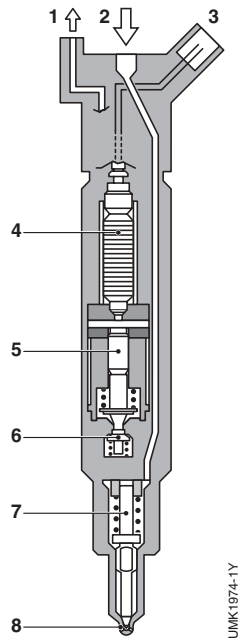
d Holding-current phase,
e Switch-off.



Triggering the solenoid-valve injector
Triggering of the solenoid valve is divided into five phases (Figure 7; the following details apply to injectors with a pressure-loaded ball valve; small values are sufficient for pressure-compensated valves).

Initially, in order to ensure tight tolerances and high levels of reproducibility for the injected fuel quantity, the current for opening the solenoid valve features a steep, precisely defined flank and increases rapidly up to approx. 20 A (opening phase). This is achieved by means of a booster voltage of up to 50 V which is generated in the ECU and stored in a capacitor (boost-voltage store). When this voltage is applied across the solenoid valve, the current increases several times faster than it does when only battery voltage is used. During the pickup-current phase, battery voltage is applied to the solenoid valve. Current control limits pickup current to approx. 20 A.

In order to reduce power loss in the ECU and injector, the current is dropped to approx. 13 A in the holding-current phase. The energy which becomes available when pickup current is reduced to holding current is routed to the booster-voltage capacitor.

The solenoid valve is closed when the current is switched off, and energy is also released in the process. This energy is also routed to the booster-voltage capacitor. The difference between the energy drawn from the booster-voltage capacitor and the energy returned to it is routed to the booster-voltage capacitor via a step-up chopper integrated in the ECU from the vehicle electrical system. Recharging from the vehicle electrical system is performed until the original voltage level required to open the solenoid valve is reached.

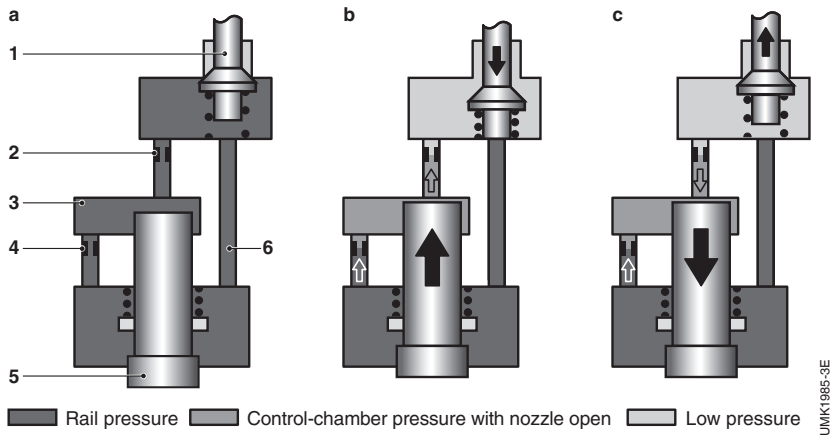
Piezo inline injector
Design and requirements
The design of the piezo inline injector is divided into its main modules in the schematic (Figure 8):
– actuator module (piezo actuator and encapsulation, contact, components for support and force transmission of the actuator),
– hydraulic coupler,
– servo valve (control valve), and
– nozzle module.

A direct response of the nozzle needle to piezo-actuator operation is achieved by coupling the servo valve closely to the nozzle needle. The delay between the electric start of triggering and hydraulic response of the nozzle needle is about 150 µs. At the same time, on account of the high switching force of the piezo actuator, a servo-valve flight time (time between end stops) of just 50 µs and a practically bounce-free switching time are achieved. This meets the contradictory requirements with regard to high nozzle-needle speeds and extremely small reproducible injected fuel quantities.

Similarly to the solenoid-valve injector, a control quantity is terminated via the servo valve to activate an injection. Necessitated by the design, however, the piezo inline

injector otherwise contains no leakage points between the high-pressure and low-pressure circuits. The result is an increase in the hydraulic efficiency of the overall system.

Up to eight injection pulses can be set per injection cycle. In this way, the injection can be adapted to the requirements of the respective engine operating point. The maximum possible number of injection pulses decreases in the upper rpm range.



Operating principle of the servo valve

The nozzle needle on a piezo inline injector is controlled indirectly by the servo valve. The desired injected fuel quantity is set, taking into account the prevailing rail pressure, via the activation duration of the valve. In its non-triggered state, the injector is in the starting position and the servo valve is closed (Figure 9a), i.e., the high-pressure section is separated from the low-pressure section. The nozzle is kept closed by the rail pressure exerted in the control chamber.

When the piezo actuator is triggered, it increases in length and this increase is transmitted via the hydraulic coupler to the servo valve. This process opens the servo valve and closes the bypass passage (Figure 9b). The flow-rate ratio between the outlet and inlet restrictors lowers pressure in the control chamber and the nozzle opens. The control quantity flows via the servo valve to the low-pressure circuit of the overall system and from there back to the fuel tank.

To start the closing process, the actuator is discharged, and the servo valve closes to release the bypass passage at the same time (Figure 9c). The control chamber is then refilled by reversing the inlet and outlet restrictors, and the nozzle needle is closed again. The injection process is completed as soon as the nozzle needle reaches the nozzle seat again.

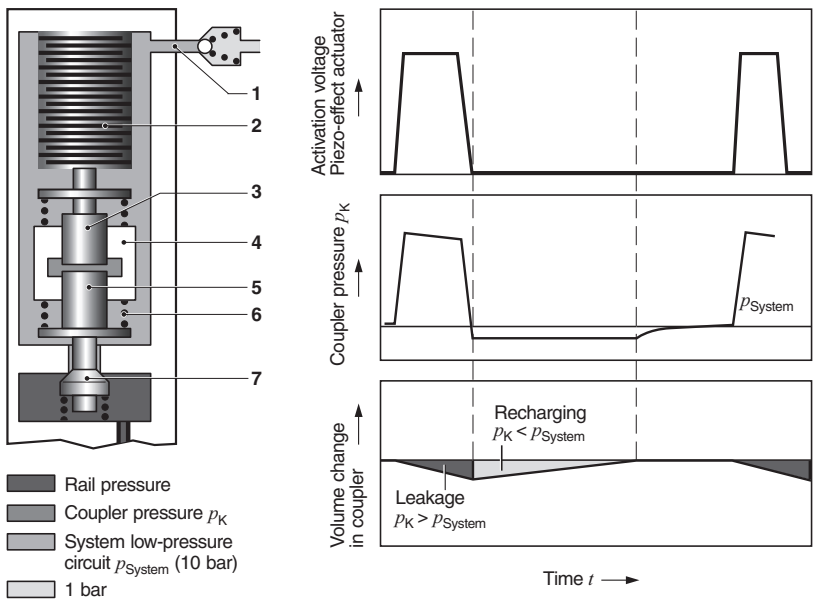
4 Inlet restrictor, 5 Nozzle needle, 6 Bypass.

Operating principle of the hydraulic coupler



Another vital component in the piezo inline injector is the hydraulic coupler (Figure 10). It provides for compensation of length tolerances of the steel and ceramic components (e.g., caused by the varying thermal expansion of ceramic and steel or by clamping forces on the holder body). On the other hand, it adjusts the translation of actuator stroke and actuator force to the level required on the servo-valve side. The translation ratio is obtained from the diameters of the coupler plunger and valve plunger.

The actuator module and the hydraulic coupler are immersed in the diesel fuel flow, which through the system low-pressure circuit at the injector return is at a pressure of about 10 bar. When the actuator is not triggered, pressure in the hydraulic coupler is in equilibrium with its surroundings, and the coupler does not exert any force on the valve pin. Changes in length caused by temperature or clamping forces acting on the holder body are compensated by small leakages that flow via the guide clearances of the coupler and valve plungers between the coupler gap and the coupler surrounding area. This maintains a coupling of forces between the piezo actuator and the servo valve at all times.

A voltage dependent on the rail pressure (110 to 160 V) is applied to the actuator in order to create an injection event. This causes the pressure in the coupler to increase and a switching force to be exerted on the valve pin. The servo valve opens if this switching force exceeds the closing force on the valve pin caused by the rail pressure. On account of the higher

Figure 10: Operating principle of hydraulic coupler

pressure in the coupler than in the surroundings, a small leakage volume flows through the plunger guide clearances out of the coupler into the low-pressure circuit (10 bar) of the injector. Even when the coupler is repeatedly actuated in quick succession during an engine combustion cycle, there is no significant effect on the injector function when the coupler is drained.

The quantity missing in the hydraulic coupler is refilled in the pauses between the triggering pulses of the piezo actuator. This occurs in the reverse direction via the plunger guide clearance, whereby the valve-plunger spring generates a vacuum pressure of max. 10 bar inside the coupler against the surroundings. The guide clearances and the low-pressure level are matched to refill the hydraulic coupler entirely before the next engine combustion cycle starts.

Further development of piezo injectors

The further development of piezo injectors is being driven forward in two directions:

– higher maximum permissible injection pressures,
– shortening of the necessary idle times between the injections.

High-pressure pumps

Design and requirements

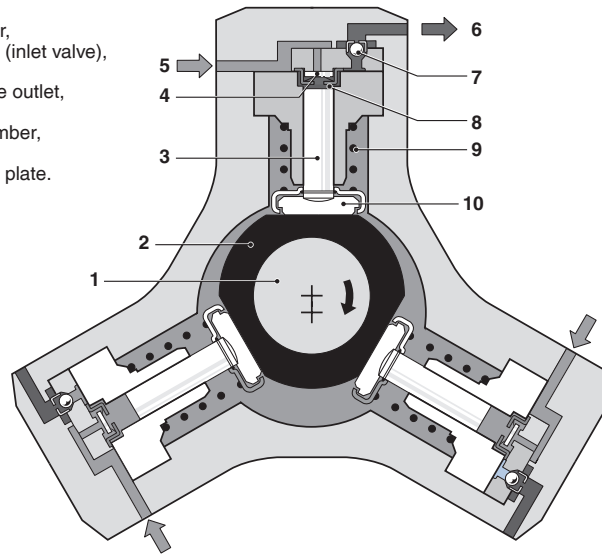
The high-pressure pump is the interface between the low-pressure and high-pressure stages of the common-rail system. Its function is to make sure there is always sufficient fuel under pressure in all engine operating conditions. At the same time, it must operate for the entire service life of the vehicle. This includes providing a fuel reserve that is required for quick engine starting and rapid pressure rise in the fuel rail.

The high-pressure pump generates a constant system pressure for the high-pressure accumulator (fuel rail) independent of fuel injection. For this reason, fuel – compared to conventional fuel-injection systems – is not compressed during the injection process.

3-, 2- and 1-plunger radial-piston pumps are used as the high-pressure pump to generate pressure. In a 3-plunger pump an eccentric shaft provides the stroke motion for the pump plungers, while in 2- and 1-plunger pumps this is provided by a camshaft. 2-plunger in-line fuel-injection pumps are also used in commercial vehicles.

Preferably, the high-pressure pump is fitted to the diesel engine at the same point as a conventional distributor injection pump. The pump is driven by the engine via coupling, gearwheels, chain, or toothed belt. Pump speed is therefore coupled to engine speed via a fixed gear ratio.

High-pressure pumps are used in a number of different designs in passenger cars and commercial vehicles. Within the pump generations there are versions that have different delivery rates (50 – 550 *l*/h) and delivery pressures (900 – 2,500 bar).



3-plunger radial-piston pump

Design

The drive shaft is centrally mounted in the housing of the high-pressure pump (Figures 11 and 12). The pump elements are arranged radially with respect to the

Figure 11: 3-plunger radial-piston pump (cross-section)

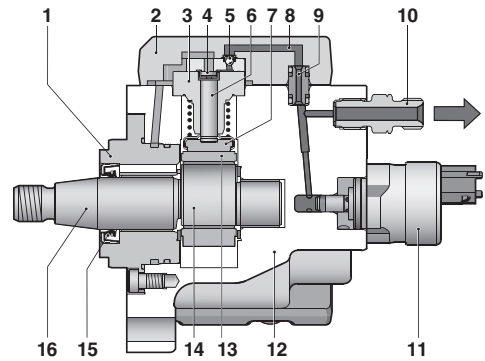
central bearing and offset by 120°. The polygon ring fitted to the drive-shaft eccentric forces the pump plunger to move up and down. Force is transmitted between the eccentric shaft and the pump plunger via the plunger base plate attached to the plunger base.

Fuel delivery and compression

The presupply pump – an electric fuel pump or a mechanically driven gear pump – delivers fuel via a filter and water separator to the inlet of the high-pressure pump. The inlet is located inside the pump on passenger-car systems with a gear pump flanged to the high-pressure pump. An overflow valve is fitted behind the inlet. If the delivery pressure of the presupply pump exceeds the opening pressure (0.5 – 1.5 bar) of the overflow valve, the fuel is pressed through the restriction bore of the overflow valve into the lubrication and cooling circuit of the high-pressure pump. With its eccentric, the drive shaft moves the pump plunger up and down to mimic the eccentric lift. Fuel passes through the suction valve into the element chamber and the pump plunger moves downward (induction stroke).

When the bottom-dead center of the pump plunger is exceeded, the suction valve closes, and the fuel in the element chamber can no longer escape. It can then be pressurized beyond the delivery pressure of the presupply pump. When the rising pressure exceeds the back pressure from the rail, the outlet valve opens and the compressed fuel passes into the high-pressure circuit. The high-pressure ports of the three pump elements are combined inside the pump housing so that only one high-pressure line runs to the rail.

The pump plunger continues to deliver fuel until it reaches its top-dead center position (delivery stroke). The pressure then drops so that the outlet valve closes. The pump plunger moves downward in response to the force of the valve spring and the remaining fuel in the dead volume is depressurized.



When the pressure in the element chamber drops below the difference between the pre-delivery pressure and the opening pressure of the suction valve, the suction valve reopens and the process starts over.

Transmission ratio

The delivery quantity of a high-pressure pump is proportional to its rotational speed. In turn, the pump speed is dependent on the engine speed. The transmission ratio between the engine and the pump is determined in the process of adapting the fuel-injection system to the engine so as to limit the volume of excess fuel delivered. At the same time, it makes sure that the engine's fuel de-

mand at WOT is covered to the full extent. Possible transmission ratios relative to the crankshaft are between 1:2 and 5:6, i.e. the high-pressure pump is geared up. Pump speed is thus higher than engine speed. Higher transmission ratios are required for commercial vehicles on account of the low engine speeds.

Delivery rate
As the high-pressure pump is designed for high delivery quantities, there is a surplus of pressurized fuel when the engine is idling or running in part-load range. This excess fuel is returned in first-generation systems to the fuel tank via the pressure-control valve seated on the rail or flanged to the pump. As the compressed fuel expands, the energy imparted by compression is lost; overall efficiency drops. Compressing and then expanding the fuel also heats the fuel.

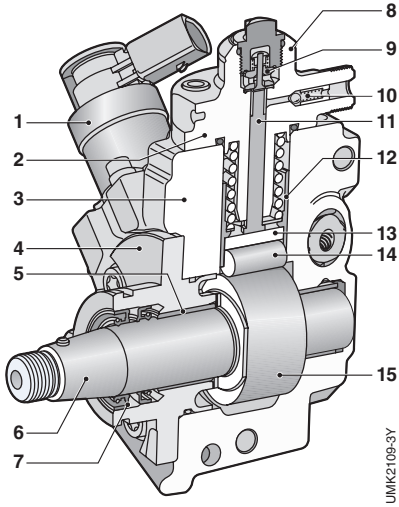
Demand control
An improvement in energy efficiency is possible by means of fuel-delivery control of the high-pressure pump on the fuel-delivery side (suction side). Fuel flowing into the pump elements is metered by an infinitely variable solenoid valve (metering unit) mounted on the high-pressure pump (Figure 13). This valve adapts the fuel quantity delivered to the rail to system demand via the metering slots in the plunger. The plunger operated by the solenoid valve frees up a metering orifice depending on its position via the metering slots. The solenoid valve is activated by means of a PWM signal (pulse width modulation).

This fuel-delivery control not only drops the performance demand of the high-pressure pump, it also reduces the maximum fuel temperature.



1- and 2-plunger radial-piston pumps

Requirements
The delivery stroke of the pump elements causes pressure pulsations in the rail which give rise to fluctuations in injected fuel quantity in the 3-plunger pumps. In order to comply with the ever more stringent emissions limits, precision of injection coupled with minimal fluctuations in injected fuel quantity is increasingly gaining in importance. 1- and 2-plunger radial-piston pumps facilitate injection-synchronous delivery, i.e. the delivery stroke of the pump elements is synchronous with the induction stroke of the engine cylinders. In this way, the pump delivery for each engine cylinder is always at the same crankshaft angle.

With one or two pump elements, all engines with three to eight cylinders can be injection-synchronously operated by adapting the transmission ratio of 1:2 to 1:1 between engine and pump speeds.

Design
This high-pressure pump is a radial-piston pump of 1- or 2-plunger design. Its components are (Figure 14):
– Aluminum housing, to which only low pressure is applied
– One or two pump elements with high-pressure-resistant steel cylinder heads with integrated high-pressure valve and high-pressure port
– Cam drive assembly with roller tappet, which converts the rotary motion of the camshaft via the cams (dual cam with 180° offset) into a stroke motion of the pump in the cylinder head. The camshaft is guided in the mounting flange and housing in two friction bearings.

The high pressure is generated in the pump element. 1- or 2-plunger pumps are used, depending on the engine's displacement and number of cylinders. Two pump elements are required to cover the fuel demand of larger engines. In the 2-plunger version, the pump elements are arranged in a vee configuration at 90° to each other.

The great overlap length between the cylinder wall and the pump plunger results in low leakage losses when the fuel is compressed. On the other hand, short leakage times result – on account of the high delivery frequency (two strokes per rotation per plunger) and the small dead volume in the cylinder head – in further optimization of efficiency and thus reduced fuel consumption.

The 90° vee configuration of the cylinder heads in the 2-plunger pump means that there is no overlapping of the induction strokes. The charge of the two pump elements is therefore identical (uniformity of delivery).

The high-pressure port is connected to the rail by way of one (in the 1-plunger pump) or two (in the 2-plunger pump) high-pressure lines. The high pressure is not condensed in the housing, but instead routed directly outwards from the cylinder head. The housing therefore does not require any high-pressure- and strength-increasing measures.

Low-pressure circuit
The total fuel delivered by the presupply pump (electric fuel pump or gear pump flanged to the high-pressure pump) is routed through the pump interior to the overflow valve and to the metering unit. The volume of fuel used for lubrication and cooling is thus greater than in previous pumps. The overflow valve regulates the pump internal pressure and thereby protects the housing against overpressure.

The entire low-pressure path is dethrottled on account of the large cross-sections in such a way as to ensure that the pump elements are filled even at high engine speeds. Fuel-quantity metering is

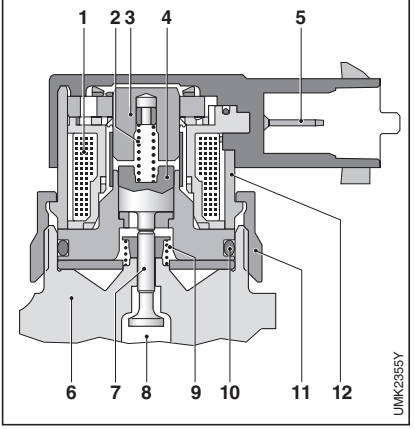
performed on the low-pressure side with the metering unit or the electric suction valve (see Demand control).

High-pressure circuit
The fuel pilot-controlled by the metering unit passes in the induction phase through the suction valve into the element chamber, and is compressed to high pressure during the ensuing delivery phase and delivered by the high-pressure valve and the high-pressure line to the rail.

Demand control with metering unit
The concept of the metering unit used on these pumps corresponds to that of the metering unit used for the 3-plunger radial-piston pump (Figure 13); however, they differ in their design.

Demand control with electric suction valve
The electric suction valve is, like the metering unit, a solenoid valve which is electrically activated. Unlike the metering unit, which is a proportional valve, the electric suction valve is a switching valve.

The electric suction valve is an actively controlled valve (Figure 15) that is seated in place of a conventional suction valve on the injection-pump cylinder head. The plunger chamber is filled with fuel in the high-pressure-pump suction phase. The suction valve is initially kept open during the delivery phase. The delivered fuel is routed back into the low-pressure circuit until the desired fuel quantity is reached in the plunger chamber. The suction valve is then closed and the fuel quantity remaining in the plunger chamber is delivered to the rail. The electric suction valve is activated as a function of the cam-rotation angle.



Design and function
The electric suction valve consists of the magnet group and the hydraulic module. The suction valve is open at zero current. In its non-activated state the suction valve is kept open via the armature spring against the hydraulic flow forces. When the suction valve is activated, the solenoid coil is energized to build up a magnetic field. The magnetic field generates a force in the armature which acts against the armature spring. If the magnetic force is greater than the spring force, the armature moves towards the pole body and thereby closes the suction valve.

Features of electric suction valve
The electric suction valve offers more flexibility in activation for high-efficiency engines. It is possible to determine with the cam-angle-dependent control process when the pump begins fuel delivery. This enables precise, dynamic rail-pressure control.

Active opening of the suction valve creates very slight throttling effects during the suction phase, which results in high hydraulic pump efficiency.

A further feature of the electric suction valve to be highlighted is its capacity not to deliver any fuel to the rail despite the pump being driven. This results in the possibility of engine cutout.

2-plunger in-line piston pump

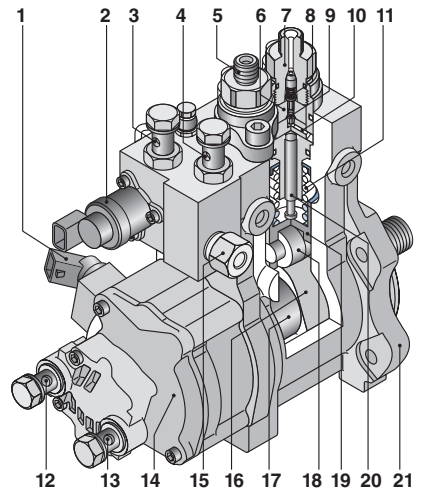
Design

This demand-controlled high-pressure pump for rail pressures up to 2,500 bar is only used in commercial vehicles. This is a 2-plunger pump with an in-line design, i.e. the two pump elements are arranged one after the other in relation to the camshaft axial direction (Figure 16). This high-pressure pump comes in both oil-lubricated and fuel-lubricated variants.

A spring seat forms the positive link between the roller tappet and the pump plunger. The rotary motion of the camshaft is converted via the cams into a stroke motion of the pump plungers. The plunger spring ensures pump-plunger return. The combined inlet and outlet valve is located at the top of the pump element.

A gear presupply pump with a high gear ratio is located on the camshaft extension. Its function is to draw fuel via the fuel inlet from the fuel tank and route it through the fuel outlet to the fuel fine filter. From there, the fuel passes through another line to the metering unit located on the upper section of the high-pressure pump.

Lube oil is supplied either directly via the mounting flange of the pump or via a side-mounted inlet. The lube oil is returned to the engine oil pan.



Operating principle

When the pump plunger moves from top dead center towards bottom dead center, the suction valve opens on account of the fuel pressure (pre-delivery pressure). The fuel is drawn into the element chamber in response to the downward movement of the pump plunger. The outlet valve is closed by the valve spring.

As the pump plunger moves upwards, the suction valve closes and the enclosed fuel is compressed. When the rail pressure is exceeded, the outlet valve opens and the fuel is delivered through the high-pressure port to the rail. This increases the pressure in the rail. The rail-pressure sensor measures the pressure, from which the engine ECU calculates the triggering signals (PWM) for the metering unit. The metering unit regulates the fuel quantity provided for compression according to the current demand.

Rail

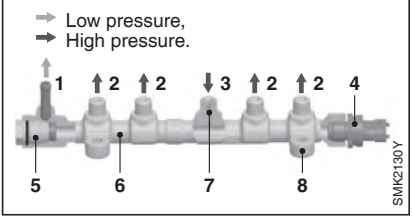
Function

The function of the rail is to maintain the fuel at high pressure. In so doing, the accumulator volume dampens pressure fluctuations caused by fuel pulses delivered by the pump and the fuel-injection cycles. This ensures that, when an injector opens, the injection pressure remains constant. On the one hand, the accumulator volume must be large enough to meet this requirement. On the other hand, it must be small enough to ensure a fast enough pressure rise on engine start.

Besides acting as a fuel accumulator, the fuel rail also distributes fuel to the injectors.

Application

The tubular rail can vary depending on the various constraints which determine the way it is fitted to the engine. It has connections for fitting the rail-pressure sensor and the pressure limiter or the pressure-control valve (Figure 17).



The pressurized fuel delivered by the high-pressure pump passes via one or two high-pressure fuel lines to the rail inlet. From there, it is distributed via high-pressure lines to the individual injectors. The cavity inside the fuel rail is permanently filled with pressurized fuel during engine operation.

The fuel pressure is controlled by means of Electronic Diesel Control (EDC), whereby the fuel pressure is measured by the rail-pressure sensor and – depending on the system – regulated by demand control or via the pressure-control valve to the desired value. The pressure limiter is used as an alternative to the pressure-control valve – depending on system requirements – and its function is to limit fuel pressure in the fuel rail to the maximum permissible pressure in the event of a fault.

Some rail types make use of restrictors in the inlet and outlet which additionally dampen pressure pulsations caused by pump delivery and injections. If fuel is now drawn from the rail for an injection, the pressure is the rail remains virtually constant.

Rail types

Two different rail types are used: the forged rail (hot-forged rail) and the welded rail (laser-welded rail). Both types are used by Bosch, the hot-forged rail being the preferred variant. The welded rail is used in series production up to 2,000 bar and is not subject to further development.

In the case of a hot-forged rail, the blank for machining is produced by forging from bar stock. The internal geometry and the rail interfaces of the rail body are produced by deep-hole boring, drilling and milling. A corrosion-resistant surface is then applied. Finally, the add-on components are mounted and functionally tested.

The forging process affords more possibilities in the shaping of the external geometry than laser welding. One advantage is the possibility of shaping the external geometry with regard to weight optimization.

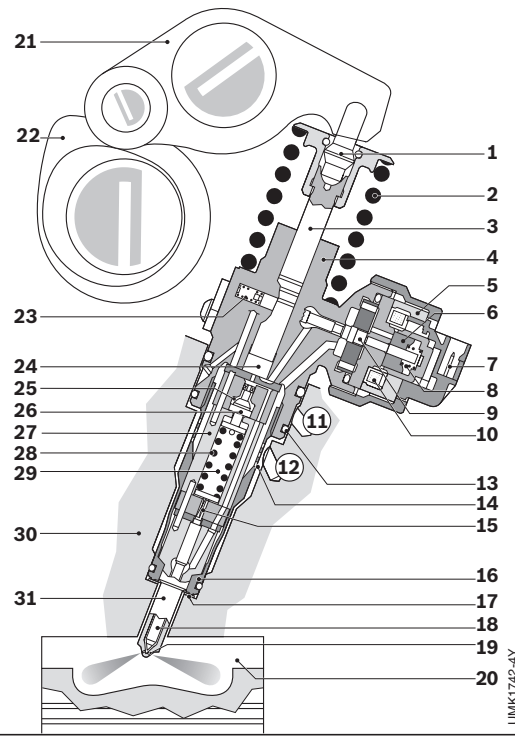
The forged rail is used for passenger-car and commercial-vehicle applications in series production up to 2,500 bar, and a further pressure increase is planned for the next generations.

Time-controlled single-cylinder pump systems

Unit-injector system for passenger cars

System requirements

The electronic controlled unit injector is a single-cylinder pump injection system with integrated high-pressure pump and injection nozzle (Figure 1). The high-pressure line required in other injection systems between the injection pump and the injection nozzle is omitted. This means that the system has particularly good hydraulic performance.



The unit injector is installed in the cylinder head between the valves, with the nozzle protruding into the combustion chamber. It is operated by rocker arms driven by the overhead engine camshaft. Each engine cylinder is allocated a separate unit injector. The start of injection and injection duration are calculated by an electronic control unit and controlled by the high-pressure solenoid valve mounted externally on the pump body.

The unit-injector system (UIS) is designed to meet the demands of modern direct-injection diesel engines with high levels of power density. It is characterized by its compact design, high injection pressures of up to 2,200 bar at full load, and mechanical-hydraulic pilot injection throughout the entire program-map range to substantially reduce combustion noise. The compact design enables a very low high pressure volume with correspondingly high hydraulic efficiency.

Unit-injector systems are no longer used for new developments.

Operating principle

Intake stroke

The unit injector is filled during the intake stroke of the upward-moving pump plunger. Fuel flows from the low-pressure stage of the fuel supply through the inlet holes into the unit injector. The fuel enters the high-pressure chamber when the solenoid-valve seat is opened.

Prestroke

The rotation of the actuating cam causes the pump plunger to move downwards. When the solenoid valve is still open, the fuel is forced back by the pump plunger from the high-pressure chamber into the low-pressure stage of the fuel supply. Heat is also dissipated from the unit injector (cooling) with the fuel as it flows back.

Delivery stroke and pilot injection

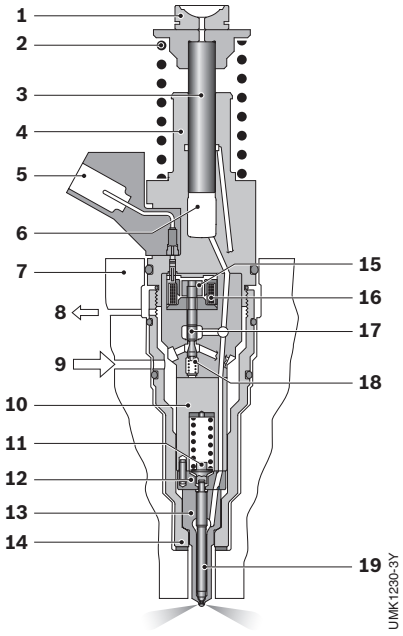
The electronic control unit energizes the coil of the solenoid valve at a particular point in time so that the solenoid-valve needle is pressed onto the solenoid-valve seat and the connection between high-pressure chamber and low-pressure stage is closed (beginning of injection period, BIP). The downward movement of the pump plunger increases the fuel pressure in the high-pressure chamber. The nozzle-opening pressure for pilot injection is approximately 180 bar. When this pressure is reached, the nozzle needle is raised and pilot injection begins. In this phase the nozzle-needle lift is hydraulically limited by a damping unit located between nozzle needle and nozzle spring so that the low injected fuel quantity required can be accurately metered. The accumulator plunger remains on its seat for the time being because the nozzle needle opens first due to its greater hydraulically effective area on which the pressure acts.

As the pressure increases, the accumulator plunger (bypass plunger) is forced downwards and now lifts off its seat. A connection is established between high-pressure chamber and accumulator chamber. The resulting pressure drop in the high-pressure chamber, the increased pressure in the accumulator chamber and the simultaneous increase in the pre-tension of the nozzle spring cause the nozzle needle to close. Pilot injection is terminated. However, the accumulator plunger does not return to its starting position because in its open state it offers the fuel pressure a greater working area than the nozzle needle.

Main injection

The continuing movement of the pump plunger causes the pressure in the high-pressure chamber to increase further. The nozzle-opening pressure for main injection is at approximately 300 bar higher than pilot injection. There are two reasons for this. Firstly, the excursion of the accumulator plunger increases the pre-tension of the nozzle spring. Secondly, due to the bypassing of the accumulator plunger fuel must be forced from the spring-retainer chamber via a restrictor into the low-pressure stage of the fuel supply so that the fuel in the spring-retainer chamber is compressed to a greater extent (pressure-backing). The pressure-backing level is derived from the size of the restrictor in the spring retainer and can be varied. It is therefore possible to achieve a sensible compromise between a low opening pressure for pilot injection (for noise reasons) and as high an opening pressure as possible for main injection, especially at part load (reducing emissions). The stroke and shaft diameter of the bypass plunger determine the length of the interval, the so-called injection interval, between the end of pilot injection and the start of main injection.

When the nozzle-opening pressure is reached, the nozzle needle is raised and fuel is injected into the combustion chamber (actual start of injection). The pressure during the entire injection process continues to rise due to the high delivery rate of the pump plunger.



The current flow through the solenoid-valve coil is deactivated to terminate main injection. The solenoid valve opens and releases the connection between high-pressure chamber and low-pressure stage. The pressure collapses. When the nozzle-closing pressure is undershot, the injection nozzle closes and the injection process ends. At this point the accumulator plunger also returns to its starting position. The remaining fuel is returned to the low-pressure stage during the continuing

downward movement of the pump plunger (residual stroke). Heat is also dissipated from the unit injector in the process.

Electronic control allows the values for the start of injection and the injected fuel quantity to be selected as desired from those stored in the program map. This feature, together with the high injection pressures, makes it possible to achieve high power densities combined with low emission levels and low fuel consumption.

Unit-injector system for commercial vehicles

The unit-injector system for commercial vehicles is largely the same as the system for passenger cars. Due to the larger dimensions for the commercial-vehicle system, the solenoid valve can be integrated in the unit-injector here (Figure 2).

With regard to main injection, the commercial-vehicle system has the same operating principle as the passenger-car system. The systems differ with regard to pilot injection. In the unit-injector System

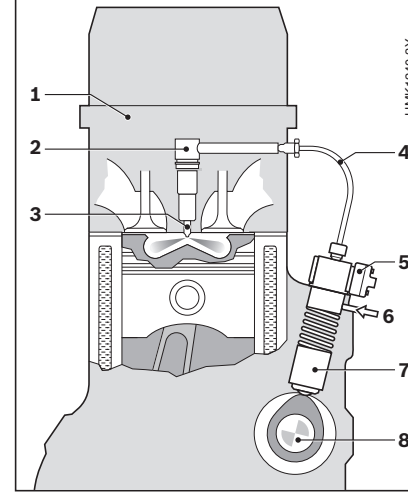
for commercial vehicles this can be electronically controlled in the lower speed and load range. This significantly reduces combustion noise and improves cold-starting performance.

Unit-pump system for commercial vehicles

The unit-pump system (UPS) is also a modular, time-controlled single-cylinder pump injection system, and is closely related to the unit-injector system. It is used in commercial-vehicle engines and in large engines. Each of the engine's cylinders is supplied by a separate module consisting of a high-pressure plug-in pump with integral, high-speed solenoid valve, a short high-pressure line, and an injection nozzle (Figures 3 and 4). This system is therefore also called Pump-Line-Nozzle (PLN). It permits injection pressures of up to 2,100 bar.

The separation of high-pressure generation and injection permits a simpler mounting on the engine. The hydraulic performance is nevertheless very good due to the shortest line possible. The unit pump is mounted on the side of the engine block. It is operated directly by an injection cam on the engine's camshaft via a roller tappet. The injection nozzle is installed with a nozzle holder in the cylinder head. The lines are made of high-strength, seamless steel tubes. They must be of equal length for the individual pumps of an engine.



The method of solenoid-valve actuation is the same as that of the unit-injector system. When the solenoid valve is open, the fuel can be drawn into the pump barrel during the pump plunger's intake stroke, and return during the delivery stroke. Only when the solenoid valve is energized, and thus closed, can pressure build up in the high-pressure system between the pump plunger and the nozzle during the pump-plunger delivery stroke. Fuel is injected into the combustion chamber of the engine once the nozzle-opening pressure is exceeded.

Electronic control

The solenoid valves are actuated by an electronic control unit. The ECU analyzes all of the relevant status parameters in the system relative to the engine and its environment, and defines the start of injection and injected fuel quantity for the operating state of the engine at any given time. The start of injection is also controlled by a BIP signal (beginning of injection period) in order to balance out the tolerances in the overall system. Start of injection is synchronized with engine piston position by analysis of the signals from an incremental trigger wheel.

In addition to the basic fuel-injection functions, there are further functions for improving driving smoothness (e.g. surge dampers, idle-speed governors, adaptive cylinder equalization). Diagnosis of the fuel-injection system and the engine is also included in the range of functions. The ECU communicates with other electronic vehicle components (e.g. antilock braking system (ABS), the traction control system (TCS) or transmission-shift control system) via a CAN data bus.

Diesel distributor injection pumps

Diesel distributor injection pumps were used in large numbers from 1962 until after 2000. These pumps are used in 3-, 4-, 5- and 6-cylinder diesel engines in passenger cars, tractors and light and medium commercial vehicles. They generate up to 50 kW per cylinder, depending on engine speed and combustion system. Distributor injection pumps for direct-injection (DI) engines achieve a peak injection pressure of up to 1,950 bar in the nozzle at engine speeds up to 4,500 rpm.

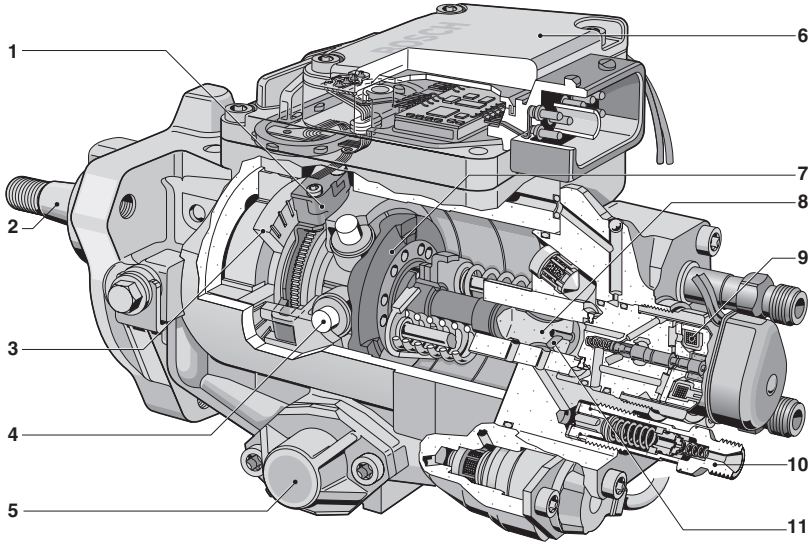
A distinction is made between distributor injection pumps with mechanical control, and those with an electronic governor available in port-controlled versions with a rotary-magnet actuator and versions with solenoid-valve open-loop control.

In passenger cars and commercial vehicles, distributor injection pumps have been superseded by common-rail systems.

Axial-piston distributor pumps

Body

Fuel-supply pump



If no presupply pump is fitted in the fuel-injection system, this integral vane-type supply pump draws fuel from the tank and, together with a pressure-control valve, generates an internal pump pressure which increases with engine speed.

High-pressure pump

The axial-piston distributor pump (VE pump) incorporates only one pump element for all cylinders. The distributor plunger displaces the fuel during its axial stroke and rotates at the same time to distribute the fuel through passages to the individual high-pressure connections (Figure 1).

Figure 1: Solenoid-valve-controlled axial-piston distributor pump

1 Angle-of-rotation sensor, 2 Drive shaft, 3 Support ring of vane-type supply pump, 4 Roller ring, 5 Timing device, 6 Pump control unit, 7 Cam plate, 8 Distributor plunger, 9 High-pressure solenoid valve, 10 High-pressure connection, 11 Distributor bore.

A clutch unit transfers the rotation of the drive shaft to the cam plate and the distributor plunger fixed to it. When doing so, the claws of the drive shaft and the cam plate grip into the yoke positioned in between. The cam lifts on the underside of the cam plate turn against the rollers of the roller ring. As a result, the cam plate and distributor plunger perform a stroke movement in addition to the rotation. During each rotation of the drive shaft, the distributor plunger completes a number of strokes equal to the number of engine cylinders to be supplied.

The pump delivers fuel for as long as the spill port in the distributor plunger remains closed off during the working stroke. Delivery ends when the spill port is uncovered by the control collar (Figure 2).

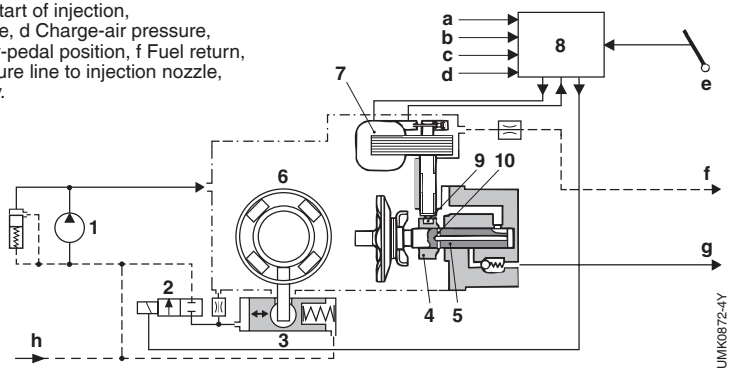
Electronic control for distributor injection pumps with rotary-magnet actuator

In contrast to the mechanically controlled distributor injection pump, the pump with rotary-magnet actuator has an electronic governor and an electronically controlled timing device (Figure 2).

Electronic governor

An eccentrically mounted ball head provides the connection between the distributor injection pump control collar and the rotary-magnet actuator. The actuator's rotary setting determines the position of the control collar, and with it the effective stroke of the pump. A non-contacting position sensor is connected to the rotary-magnet actuator.

The control unit receives various signals from the sensors: accelerator-pedal position; engine speed; air, coolant and fuel temperature; charge-air pressure; atmospheric pressure; etc. It uses these input variables to determine the correct injected fuel quantity, which is then converted to a specific control-collar position with the aid of program maps stored in the unit's memory. The control unit varies the excitation current to the rotary-magnet actuator until it receives a signal indicating convergence between the set-point and actual values for control-collar position.



Electronically controlled timing device

The hydraulic timing device with the timing-device solenoid valve rotates the roller ring, depending on the load state and engine speed in such a way that the

h Fuel supply.

start of delivery – in relation to the engine piston position – is advanced or retarded. The signal from a sensor in the nozzle-holder assembly, which indicates when the nozzle begins to open, is compared with a programmed setpoint value. The timing-device solenoid valve connected to the working chamber of the plunger in the timing device varies the pressure above the timing-device plunger and thus the position of the timing device. The actuation clock ratio of the timing-device solenoid valve is varied until the setpoint and actual values agree.

Electronic control for solenoid-valve-controlled distributor injection pumps

In the case of solenoid-valve-controlled distributor injection pumps (Figure 1), the fuel is metered by a high-pressure solenoid valve which directly closes off the pump's element chamber. This permits even greater flexibility in fuel metering and for varying the start of injection. The main assemblies are the high-pressure solenoid valve, the ECU, and the incremental angle/time system for angle/time control of the solenoid valve using an angle-of-rotation sensor integrated in the pump.

The solenoid valve closes to define the start of delivery, which then continues until the valve opens. The injected fuel quantity is determined by the length of time the valve remains closed. Solenoid-valve control permits rapid opening and closing of the element chamber independently of engine speed. In contrast to mechanically governed pumps and pumps with a rotary-magnet actuator, direct triggering by means of solenoid valves results in lower dead volumes, improved high-pressure sealing, and therefore greater efficiency.

The fuel-injection pump is equipped with its own, integral control unit for precise start-of-delivery control and fuel metering. Individual pump program maps and example-specific calibration data are stored in this ECU.

The engine control unit determines the start of injection and delivery on the basis of engine operating parameters, and sends this data to the pump control unit via the data bus. The system can control both the start of injection and the start of delivery.

The pump control unit also receives the injected fuel quantity signal via the data bus. This signal is generated by the engine control unit according to the accelerator-pedal signal and other parameters for torque demand. In the pump control unit, the injected fuel quantity signal and the pump speed for a given start of delivery are taken as the input variables for the pump map on which the corresponding actuation period is stored as degrees of cam rotation.

And finally, the actuation of the high-pressure solenoid valve and the desired period of actuation are determined on the basis of the angle-of-rotation sensor integrated in the distributor injection pump. This sensor is used for angle/time control. It consists of a magnetoresistive sensor and a reluctor ring divided into 3° increments interrupted by a reference mark for each cylinder. The sensor determines the precise angle of cam rotation at which the solenoid valve opens and closes. This requires the pump control unit to convert timing data to angular position data and vice versa.

The low fuel-delivery rates at the start of injection, which result from the design of the distributor injection pump, are further reduced by the use of a two-spring nozzle holder. With a hot engine, these low delivery rates permit low basic noise levels.

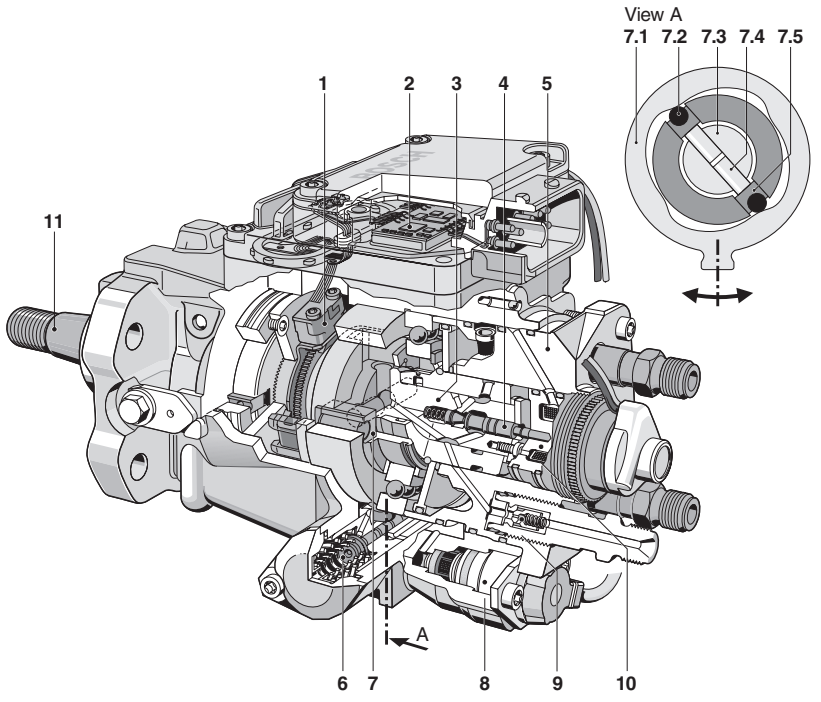
Pilot injection

Pilot injection allows the combustion noise to be further reduced without sacrificing the objects of the system's design which aim at generating maximum power output at the rated-power operating point. Pilot injection does not require additional hardware. Within a matter of milliseconds, the electronic control unit actuates the solenoid valve twice in rapid succession. For the first injection, only a small amount of fuel is discharged to condition the combustion chamber. The solenoid valve controls the injected fuel quantity with a high degree of precision and dynamic response. Typical pilot-injection fuel quantities are 1.5 mm^3.

Radial-piston distributor pumps

Body

High-pressure pump



The radial-piston high-pressure pump (VR pump, Figure 3) is driven directly by the distributor-pump drive shaft. It comprises the cam ring, the roller supports and rollers, the delivery plunger, the drive plate, and the front section (head) of the distributor shaft.

The drive shaft drives the drive plate by means of radially positioned guide slots. The guide slots simultaneously act as the locating slots for the roller supports. The roller supports and the rollers held by them run around the inner cam profile of the cam ring that surrounds the drive shaft. The number of cams corresponds to the number of cylinders in the engine.

The drive plate drives the distributor shaft. The head of the distributor shaft holds the delivery plungers which are aligned radially to the drive-shaft axis (hence the name “radial-piston distributor pump”).

Figure 3: Solenoid-valve-controlled radial-piston distributor pump

1 Sensor (angle/time system), 2 Pump control unit, 3 Distributor shaft, 4 Solenoid-valve needle, 5 Valve body, 6 Timing device, 7 Radial-piston pump, 7.1 Cam ring, 7.2 Roller, 7.3 Distributor shaft, 7.4 Delivery plunger, 7.5 Roller support, 8 Timing-device solenoid valve, 9 Delivery valve, 10 High-pressure solenoid valve, 11 Drive shaft.

The delivery plungers rest against the roller supports. As the roller supports are forced outwards by centrifugal forces, the deliver plungers follow the profile of the cam ring and describe a cyclical-reciprocating motion.

When the delivery plungers are pushed inwards by the cams, the volume in the central plunger chamber between the delivery plungers is reduced. This compresses and pumps the fuel when the solenoid valve is closed. The fuel is directed through passages in the distributor shaft at defined times to the appropriate outlet delivery valves.

As the cam-drive design employs a direct, positive link, flexibility and compliance remain minimal, so the performance potential is greater. Fuel delivery is shared between at least two radial plungers. The small inertial forces involved mean that steep (fast) cam profiles are possible. The fuel-delivery rate can be further increased by increasing the number of delivery plungers.

Radial-piston distributor pumps for direct-injection engines achieve element-chamber pressures up to 1,100 bar and pressures in the nozzle up to 1,950 bar.

Electronic control system

High-pressure solenoid valve

The high-pressure solenoid valve opens and closes in response to the triggering signals of the pump control unit. The length of time it remains closed determines the delivery period of the high-pressure pump. This means that the fuel quantity can be very precisely metered for each individual cylinder.

The high-pressure solenoid valve is controlled by regulating the current. The pump control unit identifies the contact of the valve needle in the valve seat using the current curve. This allows the exact point at which fuel delivery starts to be calculated and the start of injection to be controlled very precisely.

Timing devices

The hydraulically assisted timing device rotates the cam ring in such a way that the start of delivery – in relation to the engine piston position – is advanced or retarded. The interaction between the high-pressure solenoid valve and the timing device thus varies the start of injection and the injection pattern to suit the operating status of the engine.

The cam ring engages in a cross-slot in the timing-device plunger by means of an adjuster lug so that the axial movement of the timing-device plunger causes the cam ring to rotate. In the center of the timing-device plunger is a control collar which opens and closes the control ports in the timing-device plunger. In axial alignment there is a spring-loaded hydraulic control plunger which defines the required position for the control collar. Under the control of the pump control unit, the timing-device solenoid valve modulates the pressure acting on the control plunger.

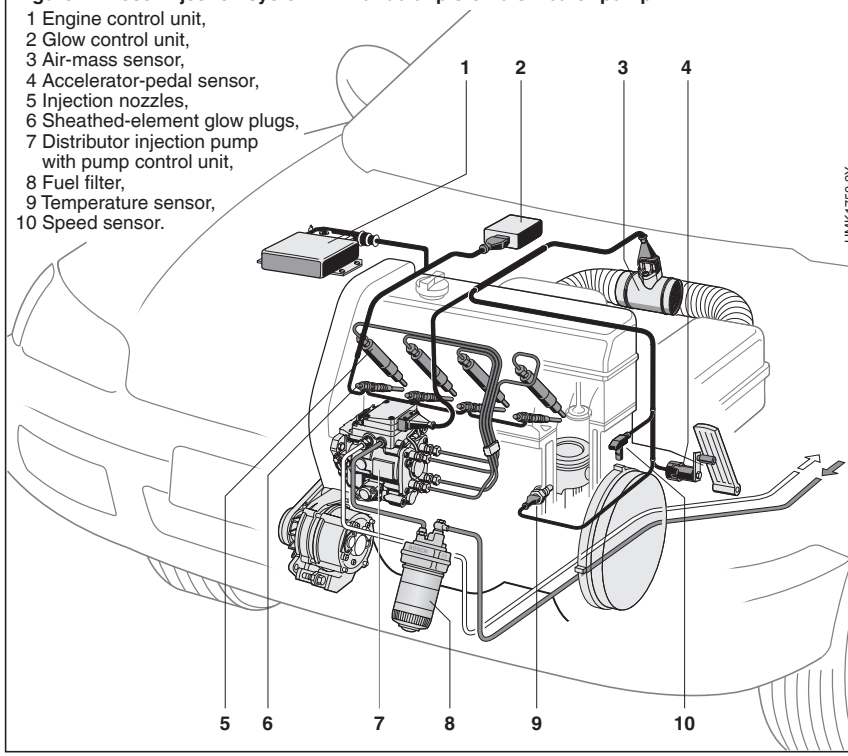
This hydraulically assisted timing device can apply higher displacement forces than the hydraulic timing device of the axial-piston distributor pump.

The timing-device solenoid valve acts as a variable throttle. It can vary continuously the control pressure so that the control plunger can assume any position between the fully advanced and fully retarded positions.

Version with full electronic circuitry on injection pump

The latest generation of distributor injection pumps are compact, self-contained systems incorporating an electronic control unit to control both the pump and the engine-management functions. As a separate engine control unit is no longer required, the fuel-injection system requires fewer connectors and the wiring harness is less complex, thus making installation simpler.

Fuel-injection system



The injection pump is a component part of the fuel-injection system (Figure 4). A diesel fuel-injection system comprises the fuel-supply system (low-pressure stage), the high-pressure component, the injection components and the control system. The fuel-supply system accumulates and filters the fuel. If necessary, an additional fuel pump is present. The injection pump with the lines is the high-pressure component. It generates the high pressure and distributes it at the right time to the corresponding engine cylinders.

In distributor-pump injection systems, the injection component comprises the injection nozzles and the nozzle holders. These nozzle-holder assemblies come in a wide range of types. One nozzle-holder assembly is used on each cylinder. They are mounted with brackets or with hollow screws in the cylinder head. The functions of the injection nozzles are to inject metered quantities of fuel and to prepare the fuel, to shape the injection pattern, and to provide a seal against the combustion chamber. Each injection nozzle consists of the nozzle body with several injection orifices (up to 0.12 mm) and the nozzle needle. The needle is guided in the nozzle-body guide bore to ensure correct alignment between the injection orifices (which are at different angles in the nozzle body) and the engine combustion chamber.

The mechanical or electronic control system for the distributor injection pump is mounted on the pump itself. Some systems have a separate engine control unit. Versions with electronic control are equipped with numerous sensors and setpoint generators.

Start-assist systems for diesel engines

Preheating systems for passenger cars and light commercial vehicles

Hot diesel engines start spontaneously at low outside temperatures. Here, the spontaneous ignition temperature for diesel fuel of 250 °C is achieved with the engine turning at starting speed by compression. Cold diesel engines require, depending on their compression ratio, start assistance with glow plugs at low ambient temperatures (Figure 2).

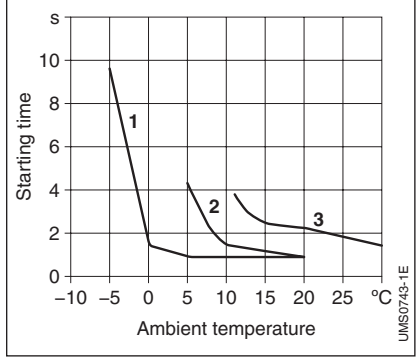
The use of preheating systems extends far beyond pure start assistance. Thus, in driving mode the glow plugs can be consistently activated when the engine is hot in order to optimize combustion in all operating states.

Design and function of a preheating system

Preheating systems (Figure 1) consist essentially of glow plugs (GLP), the glow control unit (GCU), and preheating software in the engine management. The low-voltage preheating systems mostly used today require glow plugs with nominal voltages below the vehicle system voltage whose heating output is adapted via the electronic glow control unit to the engine requirement.

In DI engines the glow plug extends into the main combustion chamber of the engine cylinder. The air/fuel mixture is directed past the hot tip of the glow plug. In combination with the heating of the intake air during the compression cycle,

Figure 2: Startability of a diesel engine (without preheating) as a function of compression ratio ε
1 ε = 18,
2 ε = 16,
3 ε = 14.



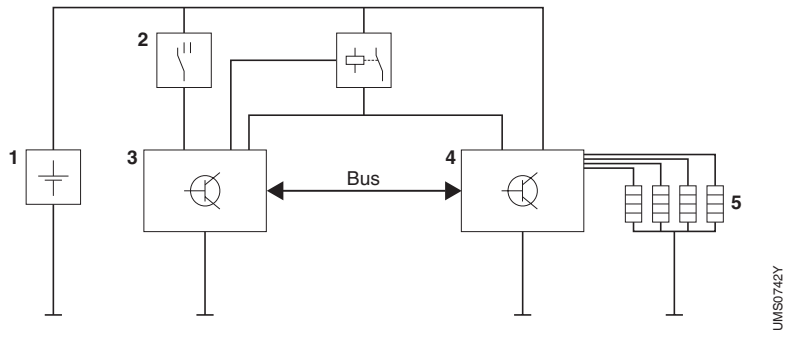


Figure 1: Preheating system
1 Battery, 2 Ignition/starting switch, 3 Engine ECU,
4 Glow control unit, 5 Glow plugs.

the ignition temperature is reached and the air/fuel mixture ignites.

The preheating software in the engine ECU starts and ends the preheating process as a function of the parameters stored in the software (e.g., ignition/starting switch on/off, coolant temperature). The glow control unit activates the glow plugs as directed by the engine ECU with vehicle system voltage via an electronic switch (transistor) during the preheating phases (pre-, standby, start, and post-heating). The supply voltage to the glow plugs is set with pulse-width-modulated activation to values below the vehicle system voltage. Direct operation at vehicle system voltage would destroy the glow element on account of the lower nominal voltage.

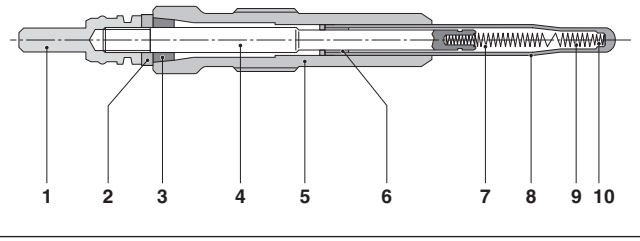
Preheating phases
- During preheating the glow plug is heated to operating temperature.
- During standby heating the preheating system maintains a temperature required for starting for a defined period.
- Start heating is applied while the engine is being revved up.
- The post-heating phase begins after starter release.
- Intermediate heating is activated after engine cooling due to coasting or to support particulate-filter regeneration.

In order to achieve as quickly as possible the heating temperature required for engine starting during pre-heating, the glow plugs are briefly operated in this phase with push voltage, which is above the glow-plug nominal voltage. The activating voltage is then reduced to the glow-plug nominal voltage during standby heating.

During start heating, the activation voltage is increased again in order to compensate for the cooling of the glow plug by the cold intake air. This is also possible in the post- and intermediate-heating phases. The required voltage is taken from a number of program maps that are adapted to each engine. The program maps contain among others the parameters engine speed, injected fuel quantity, time after starter release, and coolant temperature.

Map-controlled activation reliably prevents thermal overloading of the glow plugs in all engine operating states. The heating function implemented in the engine ECU contains an overheating-protection facility in the event of repeat heating.

These low-voltage preheating systems facilitate a rapid start similar to a gasoline engine down to approximately –30 °C.



Low-voltage metal glow plug

Design and characteristics

The main component in the sheathed-element glow plug is the tubular heating element (Figure 3). The tubular heating element consists of a hot-gas and corrosion-resistant element sheath which encloses a filament surrounded by compressed magnesium-oxide powder. This filament is made up of two resistors con-

Figure 3: Glow plug

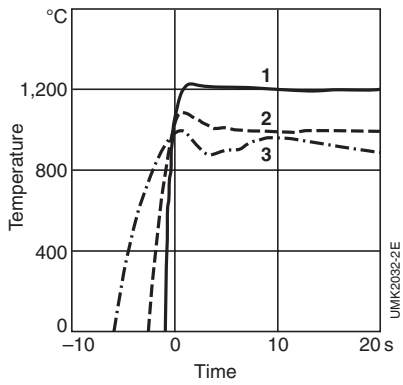
10 Heating filament.

nected in series – the heating filament located in the tip of the sheath and the control filament.

Whereas the heating filament has an electrical resistance that is independent of temperature, the control filament has a positive temperature coefficient (PTC). Its resistance increases as the temperature rises.



The heating filament is welded into the cap of the element sheath for grounding. The control filament is contacted at the terminal stud, which establishes the connection to the vehicle electrical system.

The glow element is tapered at the front in order to accommodate the heating filament closer to the element sheath. This allows preheating rates of up to 1,000 °C within 3 s with the push mode (Figure 4). The maximum heating temperature is in excess of 1,000 °C. The temperature during start-standby heating and in post-heating mode is approx. 980 °C.

Glow plugs with 11 V nominal voltage are practically no longer used in passenger cars due to their longer heat-up time.

Figure 4: Comparison of preheating curves, from t = 0 s with a flow velocity of 11 m/s

1 Low-voltage ceramic glow plug (e.g., 7 V nominal voltage),
2 Low-voltage metal glow plug (e.g., 5 V nominal voltage),
3 Metal glow plug (11 V nominal voltage).

Operation
When voltage is applied to the glow plug, most of the electrical energy of the heating filament is initially converted into heat. The temperature at the tip of the glow plug increases sharply. The temperature of the control filament – and with it also the impedance – increase with a time delay. The current draw and thus the total heating output of the glow plug decrease and the temperature approaches a steady-state condition. By controlling the operating voltage the temperature is kept below the critical level for the glow plug. Consequently, it can remain in operation for several minutes after the engine has started. This post-heating function results in a more effective engine cold-idle phase with substantially lower noise and emission output.

Reduced emissions in diesel engines with a low compression ratio

By lowering the compression ratio in modern diesel engines from $\varepsilon = 18$ to $\varepsilon = 16$, it is possible to reduce the NO_x and soot emissions while simultaneously increasing the specific power. However, the cold-starting and cold-idling performance is more difficult to control in these engines due to the lower compression. Temperatures at the glow plug of up to 1,250 °C are required in order to achieve minimum exhaust-gas opacity values and smooth running during cold starting and cold idling of these engines. Optimum combustion can only be achieved during the cold-running phase by post-heating lasting several minutes. These requirements can barely be satisfied with metal glow plugs.

Low-voltage ceramic glow plugs

Low-voltage ceramic glow plugs have glow elements made of a ceramic material that is highly resistant to temperatures. Ceramic heating-conductor tracks are embedded into the ceramic material. Their function is comparable to the filaments of metal glow plugs.

Due to their very high resistance to oxidation and thermal shocks, ceramic glow plugs enable an immediate start, as well as minute-long post-heating and inter-

mediate heating at up to 1,250 °C. They are designed for a nominal voltage of 7 V.

Glow control unit

The glow control unit sets the temperature at the glow plug stipulated by the engine management for the respective operating state. The supply voltage is pulse-width-modulated via a transistor for this purpose.

The glow control unit furthermore assumes functions like ground-offset compensation and protection against polarity reversal.

Applications

Low-voltage preheating systems require an application of the system matched to the respective engine in order to set the best temperature in each operating state and simultaneously protect the glow plug against being damaged by overvoltage. The respective activation voltage is stored in program maps.

Regulated preheating system

The regulated preheating system was developed to minimize the application outlay. Ceramic glow plugs exhibit within certain limits a linear behavior between their temperature and their resistance. This behavior is used by an algorithm to calculate in the ECU the current temperature actually applied at the glow element and to automatically adjust the desired temperature accordingly.

Flame start systems for commercial-vehicle diesel engines

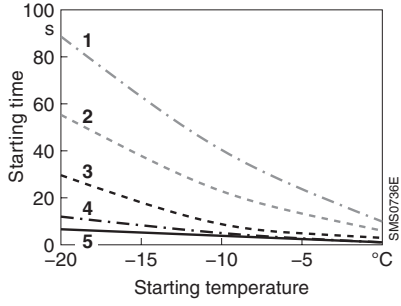
Requirements

Commercial-vehicle diesel engines can start down to temperatures of around –20 °C with start assistance. The start durations are dependent on the compression ratio ε and the fuel grade used (cetane number CN, Figure 5). To prevent misfiring and emissions of unburnt hydrocarbons (HC), it is however possible, depending on the compression ratio and the fuel grade used, to utilize already from a coolant temperature of 10 °C air preheating as start assistance (flame start system or grid heater).

Air preheating provides for safe, quick starting down to low outside temperatures. The battery and the starter are protected and fuel consumption is reduced in the starting and warm-up phases. At higher temperatures air preheating would not be necessary for safe starting, but does prevent the formation of white smoke (HC emission, Figure 6).

Figure 5: Starting times without start assistance as a function of compression ratio ε and cetane number CN

1 Starting-time curve for ε = 16.5 and CN = 41,
2 Starting-time curve for ε = 16.5 and CN = 45,
3 Starting-time curve for ε = 16.5 and CN = 51,
4 Starting-time curve for ε = 17.0 and CN = 51,
5 Starting-time curve for ε = 17.75 and CN = 51.



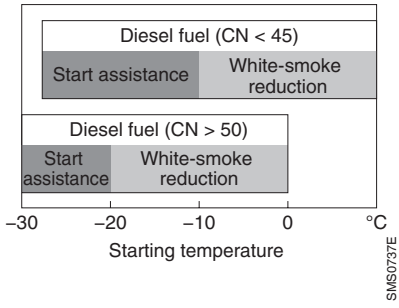


Figure 6: Use of start assistance for starting and to reduce HC emissions

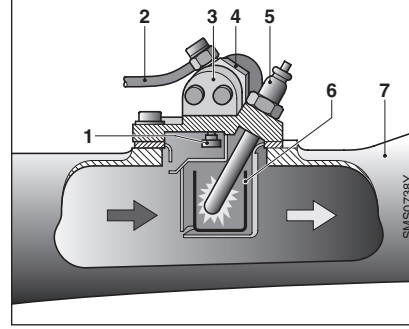
Design



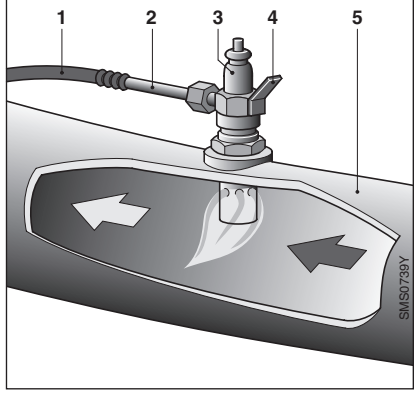
There are two different types of flame start system: the flame start system with burner chamber and the flame glow plug.

Flame start system with burner chamber

The flame start system with burner chamber (Figure 7) consists of a nozzle holder on which a solenoid valve, a nozzle and a rod-type glow plug are mounted. The nozzle holder is attached together with gaskets and the burner chamber by three screws to the charge-air housing.

Figure 7: Flame start system with burner chamber

1 Nozzle, 2 Fuel line,
3 Nozzle holder, 4 Solenoid valve,
5 Rod-type glow plug,
6 Burner chamber,
7 Charge-air housing.



The fuel is drawn after the fuel-system fuel filter and routed to the solenoid valve via a fuel line. The solenoid valve controls the fuel flow while the flame start system is in operation. The glow plug is supplied with electrical power by the flame-start control unit.

Flame glow plug
In contrast to the flame start system with burner chamber, the solenoid valve in the case of the flame glow plug is not mounted directly on the flame start system, but instead is connected by a fuel line to the flame glow plug. The flame glow plug also has a much more compact design (Figure 8).

The glow plug integrated in the flame glow plug is enclosed in a vaporizer tube in the upper area and extends up to the protective tube at the end of the flame glow plug (Figure 9). The fuel is drawn after the fuel filter, routed through the separately mounted solenoid valve, and supplied to the flame glow plug via the fuel line. The fuel enters the flame glow plug via the metering device – to control the fuel quantity. The flame-start control unit assumes the job of controlling the flame start system (current supply to the glow plug and switching on the solenoid valve).

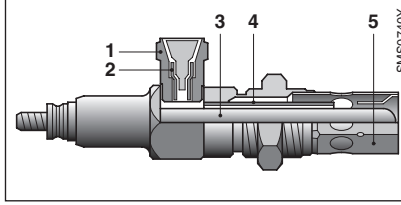


Figure 8: Installed flame glow plug
1 Fuel line,
2 Throttle line,
3 Flame glow plug,
4 Ground connection,
5 Charge-air tube.

Use of flame start systems
The flame start system with burner chamber is used primarily in commercial-vehicle engines with a displacement $V_H > 10\,l$, while the flame glow plug is used in engines with a displacement V_H of 4 to 10 l. The flame start system is installed in the engine charge-air tube in such a way that the heated intake air is uniformly distributed to all the cylinders.

Operating principle
The flame start system is activated below the switch-on temperature defined in the control unit. When the ignition key is turned to the Drive position, the "Flame start system" indicator lamp lights up and the glow plug is energized and preheated. The indicator lamp goes out after a preheating time dependent on the vehicle system voltage (approx. 25 s). The flame start system is operational and the engine can be started. At the outset of the starting operation the solenoid valve opens and the fuel flows to the hot glow plug, where it ignites. The flame that is now produced heats the intake air flowing past. The flame start system is operated after the engine start in the post-flaming time until a stable burn is guaranteed and shuts down according to the parameters defined in the control unit. The parameters for post-flaming are dependent on the coolant temperature.

Figure 9: Flame glow plug (Beru system)
1 Fuel-supply connection,
2 Metering device,
3 Glow plug,
4 Vaporizer tube,
5 Protective tube.

The flame start system is also shut down if the engine is started before the indicator lamp goes out or is not started within 30 seconds of the indicator lamp going out. In this case the driver can put the flame start system into operation again by turning the ignition key back and then turning into to the drive position again.

Control of the glow plug

Glow plug for the flame start system with burner chamber

The glow plug is preheated depending on the vehicle system voltage until a temperature of approximately 1,050 °C is reached. This is followed by the beginning of the period of start readiness (duration 30 s), during which the glow plug is cyclically energized. The cycle ratio is set depending on the current vehicle system voltage in such a way that the glow-plug temperature remains between 1,020 °C and 1,080 °C. With the glow plug in this temperature range the fuel is safely ignited and the glow plug itself is not exposed to thermal overload.

As soon as the engine is started, the solenoid valve opens, the fuel is directed through the nozzle and sprayed onto the spark-plug grooves, where it ignites. In this phase the cycle ratio of the glow plug is increased by the control unit so that the glow plug does not cool in response to the heat dissipated from the vaporizing fuel. This higher cycle ratio is maintained after starting for a further period of around 30 s until all the components are heated and the flame is safely burning. The glow plug is now additionally heated by the flame. The control unit decreases the cycle ratio again to protect against overheating. After post-flaming the glow plug is deactivated and monitored until it has cooled down entirely. Start and cold-running support by the flame start system is concluded.

Flame glow plug

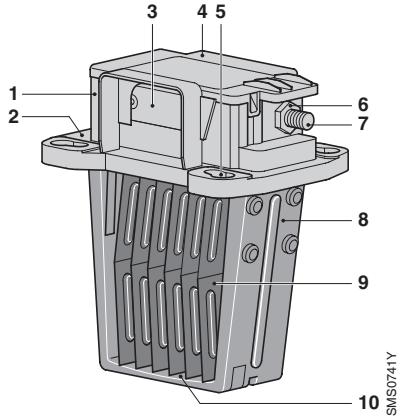
This glow plug is preheated in exactly the same way before starting, depending on the applied vehicle power supply. The preheating times are slightly longer than for the glow plug with burner chamber, since the vaporizer tube is additionally heated during preheating (see Figure 9). When the engine is started, the solenoid valve is opened, fuel flows via the fuel-supply connection and the metering device into the flame glow plug, strikes the hot glow plug, vaporizes between the glow plug and the vaporizer tube, and mixes with the air at the evaporator-tube outlet. The air/fuel mixture ignites at the hot glow plug. The flame produced emerges from the protective tube and heats the intake air flowing past.

After preheating the flame glow plug is likewise cyclically energized. The cycle ratio is decreased in the start-readiness period (30 s) and increased again when the engine is started. In this phase the cycle ratio for the flame glow plug is higher than for the flame start system with burner chamber, since the fuel is vaporized via the supplied electrical energy and not via the burning flame.

Cooling-down phase

The glow plug of the flame start system is monitored in the cooling-down phase. If preheating is performed again in this phase, the control unit calculates the preheating time from a program map depending on the cooling-down time and the voltage in such a way that the glow plug reached the temperature range described above.

Because the glow plugs have heating and control filaments (see Preheating systems for passenger-car diesel engines), the optimum preheating time is set as a function of the ambient conditions.



Grid heater for commercial-vehicle diesel engines

The grid heater is used as a further cold-start aid, particularly for engines which are started under aggravated starting conditions such as constant load when starting (e.g. for hydraulic output) or at altitudes above 2,000 m (e.g. snow groomers).

Design
The grid heater (Figure 10) consists of an electric heater element which is installed in the charge-air tube and powered by a relay. A separate ECU or the engine ECU switches on the grid heater on the basis of the stored parameters.

There are different versions which are used, depending on the engine displacement V_H and the vehicle system voltage (12 V or 24 V). Grid heaters with a power input of 1.8 kW are used for engines with a displacement V_H of 4 to 10 l, while grid heaters with a power input of 2.7 kW are used for engines with $V_H > 10\,l$.

Figure 10: Grid heater

3 Cover plate,
4 Cover,
5 Mounting bore,
6 Lock nut,
7 Connecting-thread bolt,
8 Retaining frame,
9 Heating filament,
10 Insulating plate.

Operating principle
Depending on the coolant and charge-air temperatures, the grid heater is preheated for periods varying in duration (preheating time t_v = 2 to 28 s) and remains active in the post-heating phase until stable engine running is ensured. The switch-on temperature is 5 °C for engines with V_H = 4 to 10 l and – 4° for engines with $V_H > 10\,l$.

Once the preheating time has elapsed, the indicator lamp goes out and the engine can be started. On starting the grid heater is switched off for approximately 2 s so as to make full battery capacity available to the starter. For start and idle support the grid heater is then switched back on and remains in operation until it is switched off after the applied post-heating time.

The grid heater remains in start readiness for only around 5 s (as opposed to 30 s for the flame start system) in order to conserve battery capacity.

Advantages and disadvantages of the grid heater
The grid heater offers the following advantages over the flame start system:
– The intake air is heated before starting
– There are shorter starting times thanks to good ignition conditions from the first revolution
– No burning of oxygen is required to heat the intake air

On the down side, the grid heater requires greater battery capacity.

Exhaust-gas treatment

Catalytic oxidation

The oldest catalytic method of exhaust-gas treatment is aimed at the oxidation of imperfectly combusted fuels. Carbon monoxide (CO) and imperfectly combusted hydrocarbons ($C_xH_yO_z$) – which also include soot and hydrogen (H_2) – are converted in this process with the oxidizing agents present in the exhaust gas, i.e. oxygen (O_2) in particular. These reactions correspond to the stoichiometries of the equations (A) through (D):

(A) $C_x + x\,O_2 \rightarrow x\,CO_2$,
(B) $2\,CO + O_2 \rightarrow 2\,CO_2$,
(C) $2\,H_2 + O_2 \rightarrow 2\,H_2O$,
(D) $4\,C_xH_yO_z + (4x+y-2z)\,O_2 \rightarrow 4x\,CO_2 + 2y\,H_2O$.

As a rule noble metals, their mixtures or their alloys in the form of nanoparticles serve as the catalytically active component. Platinum and palladium are frequently used.

A prerequisite for the most complete sequence of oxidation reactions as possible is an at least stoichiometric quantity of oxygen in the exhaust-gas flow. A catalytic converter can however passivate with high oxygen excess and low exhaust-gas temperatures. The elimination of imperfectly combusted fuels from the exhaust gas works particularly effectively when the catalytic converters and the engine application are matched to each other. The following conditions should be in place for this purpose:

– The engine exhibits low untreated emission of imperfectly combusted fuel, particularly in the cold-start phase.
– The engine application provides the catalytic converter with a balanced air/fuel ratio (lambda, λ).
– The oxidation catalytic converter is heated as quickly as possible by means of heating measures.
– The catalytic converter has a quantity of catalytically active and storing components matched to the emissions and exhaust-gas temperatures.
– The type and quantity of all the components are matched in such a way that the catalytic converter resists to a sufficient extent the loads of the vehicle application (thermal load, sulfur and other contaminations) over the aimed-for service life.

In addition, with an appropriate choice of components in such oxidation catalytic converters, nitrogen monoxide can be oxidized in accordance with reaction equation (E). As well as the importance of NO_2 to the SCR reaction (see Selective catalytic reduction) the emitted particulate matter can be reduced in accordance with the stoichiometry (F) with the created NO_2. Essentially, the hydrocarbons present in the particulates are oxidized using NO_2 in accordance with stoichiometry (D):

(E) $2\,NO + O_2 \rightarrow 2\,NO_2$,
(F) $C_x + 2x\,NO_2 \rightarrow x\,CO_2 + 2x\,NO$.

Without further exhaust-gas treatment measures it is not possible for a large number of vehicles to comply with strict particulate-emission limits (see for example EC Regulation 582/2011 [1]).

Filtration of particulates

To comply with the emission-control standard Euro 6c, a passenger car, irrespective of whether it is powered by a direct-injection gasoline engine or by a diesel engine, may not exceed the limit value for the particulate matter (PM) of 4.5 mg/km and the limit value for the particle number (PN) of $6 \cdot 10^{11}$ particles/km.

Particulate filter
Many vehicles need a particulate filter to achieve these limit values (Figure 1). These filters are for the most part ceramic honeycomb structures in which all the channels are alternately sealed at on end. Unlike other catalytic-converter honeycombs, it is therefore not possible to look through particulate filters. The exhaust gas must as it passes the honeycomb channels flow through the porous wall material (Figure 2). The pore structure of the ceramics is designed to accommodate the size of the particles. The most common particulate filters consist of silicon carbide (SiC), aluminum titanate (Al_2TiO_5), or cordierite ($Mg_2Al_3[AlSiO_5O_{18}]$). There are also special forms made of sintered metal.

Some of the residues of engine oil, fuel, combustion air, and engine attrition that collect in the particulate filter cannot be removed by combustion and, if suitably sized, remain as ash in the filter. On the other hand, soot and the organic compounds that adhere to it are combustible.

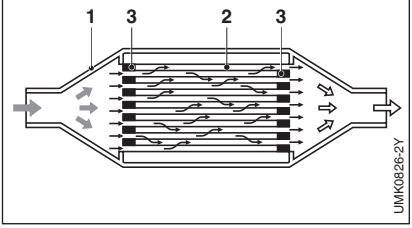
NO_2 and O_2 work as oxidizing agents. Oxidation with NO_2 works at exhaust-gas temperatures from around 200 to 250 °C. From around 450 °C NO prevails in the thermodynamic equilibrium of the nitrous fumes. Then there is little NO_2 in the exhaust gas.

Catalytically oxidizing coatings of particulate filters do not differ in their type and function fundamentally from other oxidation catalytic converters. They serve to set a favorable NO-NO_2 ratio, oxidize imperfectly combusted fuel, and catalyze the CO that is produced during soot burn-off.

Regeneration of the particulate filter
Soot is oxidized by oxygen only at temperatures above approximately 550 to 600 °C. Such temperatures exist in many diesel engines only with very high power outputs and hardly ever arise during the normal operation of some vehicles. Measures must therefore be taken to raise the exhaust-gas temperature. Combustion control of the engine, for example, is changed for this purpose.

Thermal measures
Important engine measures to increase exhaust-gas temperature are advanced burnoff or additive secondary injection, retarded main injection, retarded secondary injection, and intake-air throttling.

Figure 1: Diesel particulate filter
1 Housing,
2 Extruded honeycomb ceramic,
3 Ceramic plug.



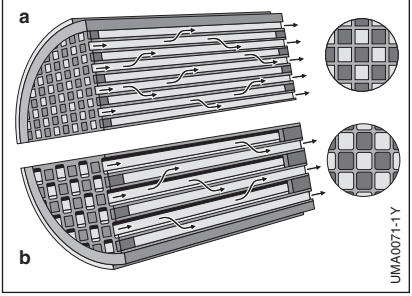


Figure 2: Designs of ceramic particulate filter
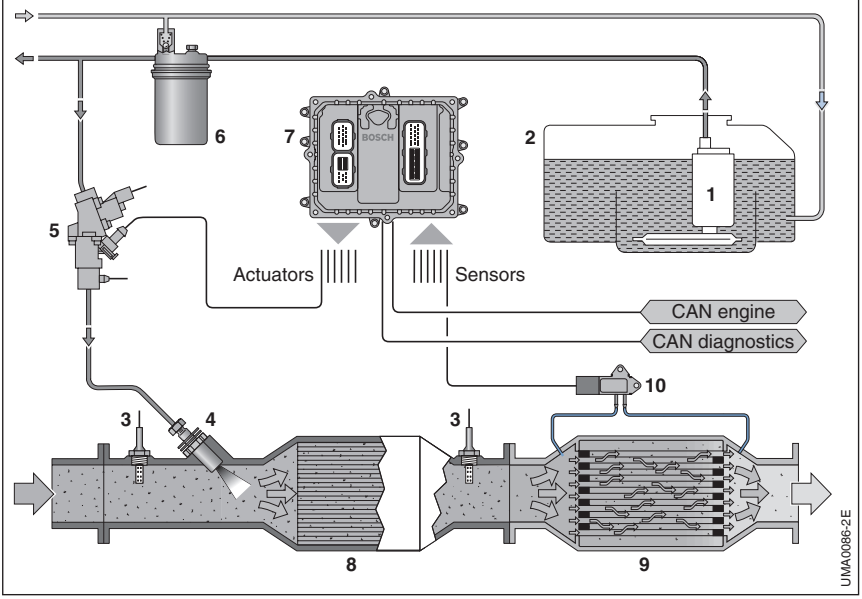
a) Square channel cross-section,
b) Octosquare design.



Depending on the engine operating point, one or several of these measures are triggered.

HCI system
As an alternative to injecting additional fuel into the engine cylinders, fuel can also be metered directly into the exhaust-gas system. The HCI system (Hydrocarbon Injection) serves this purpose. Here, the diesel fuel is for the most part injected ahead of an oxidizing catalytic converter and vaporized (Figure 3). The fuel vapors oxidize in the catalytic converter, resulting in an increase in the temperature of the exhaust-gas flow. The control algorithms of the HCI system are associated with soot-mass determination.

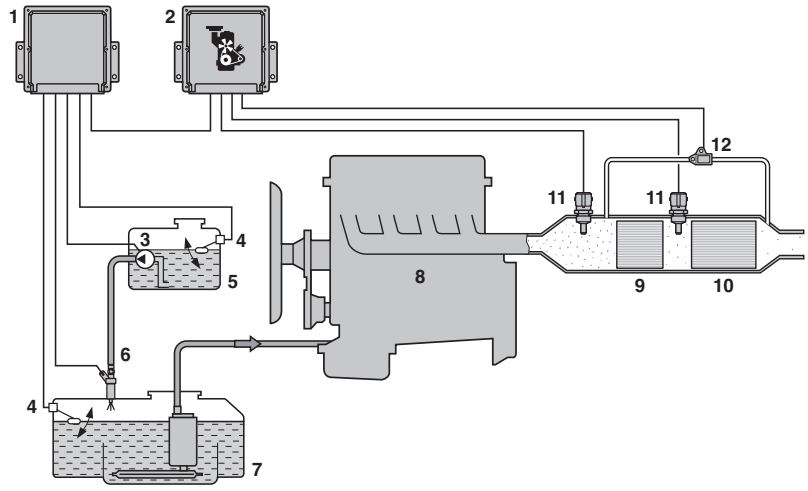
Additive system
In addition to the thermal measures to raise the exhaust-gas temperature, the ignition temperature of soot can also be reduced. This is done by catalytically active components which are finely distributed into the soot. These components are supplied as a fuel additive (Figure 4). Organometallic compounds are used, for example ferrocene. The finely distributed metal oxides formed from them reduce the ignition temperature of soot by up to 150 K. One drawback is the ash that is created from this fuel additive.

Saturation detection
Important factors in the design of particulate filters and their regeneration strategy are the amount of ash to be expected, the maximum soot load until regeneration is initiated, and the permissible exhaust-gas back pressure.

Figure 3: HCI system (Hydrocarbon Injection)
1 Fuel pump, 2 Fuel tank, 3 Temperature sensor, 4 HC metering module, 5 HC metering unit, 6 Fuel filter, 7 Engine ECU, 8 Diesel oxidation catalytic converter, 9 Diesel particulate filter, 10 Differential-pressure sensor.

Often two processes are used in parallel for saturation detection. The particulate filter's flow resistance is calculated from the pressure drop of the exhaust-gas flow detected with a differential-pressure sensor over the particulate filter. It can be related to the amount of soot stored in the particulate filter. In addition, a model is used to calculate the soot mass stored in the particulate filter. To this end, the soot-mass flow of the engine is integrated, where different corrections can be taken into consideration, e.g. for the soot oxidation of the particulates by NO_2.

Catalytic reduction of nitrous fumes



Requirements

Catalytic methods for reducing the NO_x emissions to comply with statutory requirements work particularly when vehicle design, engine application, and the components of the exhaust-gas treatment system are matched to each other. The following points must be taken into consideration here:

- The vehicle offers enough spacer to accommodate the necessary exhaust-gas treatment system. Special requirements with regard to the positioning of individual components in the vehicle must be observed (e.g. positioning near the engine).
- Exhaust-gas temperature, exhaust-gas mass flow, and exhaust-gas composition (NO_x, λ etc.) must be selectively and quickly regulated.
- The engine or a component of the exhaust system makes it possible to provide the amount of reducing agent

needed to reduce the untreated NO_x emissions.

The choice of a method of reducing NO_x suitable for a concrete vehicle application is therefore always a consideration of the complete system. The two NO_x storage catalytic converters and NO_x reduction catalytic converters described below can also be used together, for example to achieve high conversion rates.

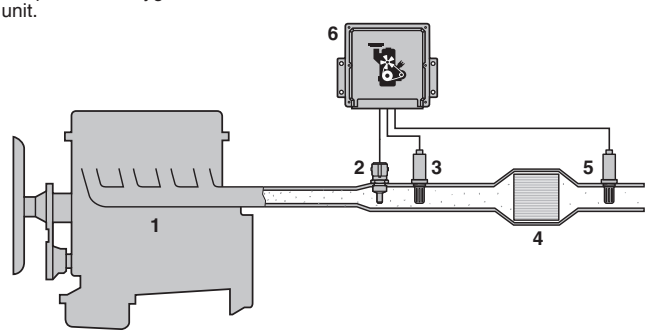
NO_x storage catalytic converter

The reduction of NO_x from the exhaust gas of diesel engines works under suitable conditions with an NO_x storage catalytic converter (NSC, NO_x Storage Catalyst; alternatively called LNT, Lean NO_x Trap) very similar to the three-way catalytic converter (TWC, Three-Way Catalyst) (Figure 5).

Engine-based λ control constitutes an alternation of oxygen-richer and low-oxygen exhaust-gas sequences for this purpose. The oxygen-enriched phase often lasts several minutes. An accordingly large amount of storage components is required to bind the NO_x created during this period. The NO_x previously bound to the storage components is reduced in the subsequent fuel-enriched sequence. This sequence, known as NSC regeneration, usually takes a few seconds.

The storage components desorb NO_x at high temperatures also without the exhaust gas being enriched.

The NSC method works in particularly at exhaust-gas temperatures of between around 180 °C and 400 °C. The NO_x conversion of the NSC method deteriorates at significantly higher temperatures.



Contamination by sulfur reduces the efficiency of the noble metals and the NO_x storage components. A storage catalytic converter must therefore be regularly desulfurated. High temperatures are required for this purpose. When it comes to the design of NO_x storage catalytic converters, particular attention must be given to their long-term behavior depending on the relevant engine application with the details of desulfuration.

Selective catalytic reduction

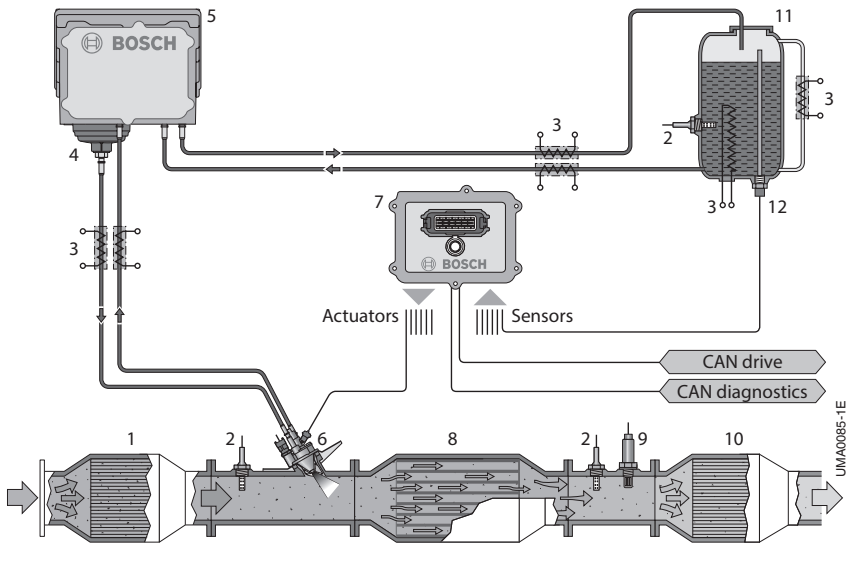
SCR method

The SCR method (Selective Catalytic Reduction) is based on the principle of adding a reducing agent to the exhaust gas (Figure 6). Diesel fuel is basically also suitable here. However, it has hitherto not been possible to develop a suitable SCR method based on diesel fuel as the reducing agent that provides for compliance with strict emission limits.

Figure 5: Schematic diagram of an exhaust-gas system with NO_x storage catalytic converter
1 Diesel engine, 2 Temperature sensor,
3 Wide-band λ sensor (LSU),
4 NO_x storage catalytic converter,
5 NO_x sensor or two-position λ oxygen sensor,
6 Engine control unit.

Gaseous ammonia (NH_3) is used in stationary combustion systems, e.g. in power stations, in the SCR method. NH_3 gas is avoided in motor vehicles for safety reasons. Instead, in motor vehicles for the most part an aqueous solution of urea ($(NH_2)_2CO$) is metered into the exhaust-system branch in the direction of flow ahead of the SCR catalytic converter (Figure 6). Such aqueous solutions are called for example AdBlue, DEF (Diesel Exhaust Fluid), or AUS 32 (Aqueous Urea Solution) (see urea/water solution).

Aside from special forms, SCR catalytic converters frequently consist of catalytically active coatings on ceramic honeycomb structures. Special ceramic particulate filters are also suitable for such coatings. Vanadium oxides and iron and copper zeolites are suitable for use as the catalytically active material.



Reaction equations

Ammonia reacts on the SCR catalytic converter with NO_x according to the following equations:

(G) $4\ NO + 4\ NH_3 + O_2 \rightarrow 4\ N_2 + 6\ H_2O$,
(H) $NO + NO_2 + 2\,NH_3 + H_2O + O_2 \rightarrow 2\,NH_4NO_3$,
(I) $NH_4NO_3 \rightarrow N_2O + 2\ H_2O$,
(J) $2\ NH_4NO_3 \rightarrow 2\ N_2 + 4\ H_2O + O_2$,
(K) $NO + NO_2 + 2\ NH_3 \rightarrow 2\ N_2 + 3\ H_2O$,
(L) $6\ NO_2 + 8\ NH_3 \rightarrow 7\ N_2 + 12\ H_2O$.

The reaction according to equation (G) is comparatively slow. It predominates if no or only little NO_2 is available to react with NH_3. If the energy of activation is not achieved to reduce the nitrous fumes, ammonium nitrate (NH_4NO_3) is created according to equation (H) in a secondary reaction. NH_4NO_3 decomposes at temperatures from approximately 170 °C according to equation (I). If it is heated very quickly, it decomposes ex-

Figure 6: Exhaust-gas system with catalytic reduction of nitrogen oxides (SCR)

plosively according to equation (J). If the exhaust-gas flow contains equal proportions of NO and NO_2, the faster reaction predominates according to equation (K) if its energy of activation is reached. Where there is a higher proportion of NO_2 in the exhaust gas, the reaction can according to equation (L) contribute significantly to the overall conversion.

Choice of SCR catalytic converter
The engine emissions and the NO_x conversion needed to achieve the emission limit and the exhaust-gas temperature in the relevant operating states are decisive factors in the choice of a suitable SCR catalytic converter. However, the sulfur content of the fuel used is also important. When it comes to the design of the SCR catalytic converter, attention must also be given in particular to its long-term stability depending on the concrete vehicle application, e.g. also with the details of desulfuration.

Metering of the reducing agent
SCR catalytic converters do have a certain NH_3 storage capacity, but essentially a quantity of urea/water solution equivalent to the instantaneous NO_x mass flow must be metered as precisely as possible and dispensed into the exhaust-system branch. If more reducing agent is dispensed than is converted in reduction with NO_x, it may result in unwanted NH_3 slip. This excess NH_3 can be oxidized by an additional oxidation catalytic converter at the end of the SCR catalytic converter. In the most favorable case, nitrogen and water are created at this NH_3 slip catalytic converter. Nitrogen oxides are created in secondary reactions in unfavorable circumstances.

Before entering each catalytic converter, the exhaust-gas mass flow must be distributed as uniformly as possible to the individual honeycomb channels. Uniform distribution of the fluids requires particular attention in the case of two-substance mixtures, i.e. if a second substance is added to the exhaust-gas flow, as is the case with the SCR method.

To facilitate the SCR reactions, ammonia must first be created from the aqueous urea solution. This occurs in a chronological sequence of different steps:
– determination of the metering quantity,
– delivery of the solution,
– dispensing of the metered volume,
– atomization and vaporization of the solution,
– decomposition of urea, and
– distribution of ammonia through the catalytic-converter cross-section.

The metering quantity is determined in a separate ECU of the exhaust-gas treatment systems (optionally integrated in the engine control unit) on the basis of stored data and data determined by exhaust-gas sensors (temperature sensor, NO_x sensor, NH_3 sensor, etc.). In the process the current NH_3 storage load of the catalytic converter is also calculated and taken into account as a rule. The data required for this calculation are determined in advance for the catalytic converter used in each case and stored as a program map in the ECU. To meter the required quantity as precisely as possible, it is necessary to bear in mind that ISO 22241-1 [2] defines the urea content of these solutions at 31.8 to 33.2 % by mass. Significant deviations in the urea-solution concentration can also arise as a result of their aging in the vehicle or incorrect storage. Quality sensors are therefore increasingly being used.

Delivery and metering modules
A delivery module as a rule consists of a liquid pump, e.g. a diaphragm pump. It provides the solution from the urea tank for metering. Since commercially available urea solutions freeze below –11 °C, all the components that are in contact with the solution must be able to withstand ice pressure. Some components have heating elements to melt the ice where necessary. The metered volume is dispensed via metering modules. These are primarily liquid nozzles, or more rarely air/fluid two-substance nozzles. The metering modules in contact with the hot exhaust

gas must be cooled to prevent the solution from vaporizing prematurely.

Vaporization of the solution is preceded by the distribution of the droplets sprayed into the exhaust-gas flow. The spray characteristic, i.e. the droplet size and its impulse, must be closely matched with temperature and flow conditions in the affected part of the exhaust-system branch. As a rule some of the droplets vaporize on hot surfaces of the exhaust system, e.g. on pipe walls or on gas mixers.

Release of ammonia
Vaporization of the droplets is followed by the release of ammonia due to the decomposition of urea. In the first thermolytic decomposition stage of urea, initially isocyanic acid (HNCO) is created as well as NH_3 under the conditions prevailing in the exhaust-system branch according to reaction equation (M):

(M) $(NH_2)_2CO \rightarrow NH_3 + HNCO$.

This decomposition of urea occurs above its melting temperature from approximately 133 °C. Under suitable conditions the isocyanic acid created in the first stage is subjected in a second stage to hydrolysis with the creation of ammonia and carbon dioxide according to equation (N):

(N) $HNCO + H_2O \rightarrow NH_3 + CO_2$.

This comparatively slow hydrolysis reaction is significant in the gaseous phase merely in the case of a long retention time of very small droplets, which vaporize already in the gaseous phase at accordingly high temperatures. Hydrolysis of isocyanic acid therefore occurs for the most part on surfaces. As well as the most uniform distribution as possible of the created ammonia into the exhaust-gas flow and its distribution as perfectly as possible through the catalytic-converter cross-section, it must also be borne in mind when designing that part of the exhaust-system branch into which the agent is metered that solid by-products may be created when urea decomposes. Surface temperatures of well over 300 °C are needed to eliminate their deposits.

On-Board Diagnostics (OBD)

OBD describes self-diagnostic systems for testing essential vehicle functions, including exhaust-gas treatment. A multitude of sensors and comprehensive software supply most of the information for these diagnoses. OBD has been subject to continuous further development over the past (more than) 20 years. Today OBD systems influence the vehicle's service-inspection program and the driver and the workshop are informed of malfunctions and recommended actions. The OBD requirements applicable in each case must be taken into account in the design of the exhaust-gas treatment system.

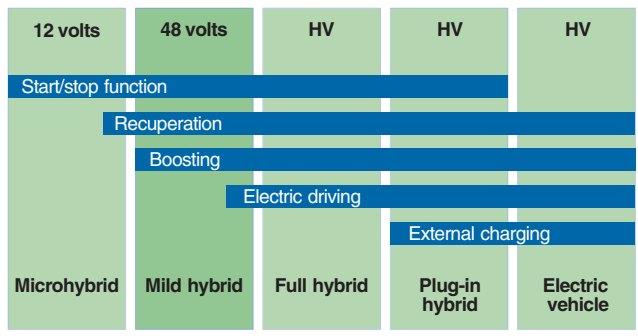
Electrification of the drive

Features

Definition Electromobility
Electromobility refers generally to that part of mobility for which electrical energy or power is used. It includes for example the operation of electrified trains and riding with electrically assisted bicycles. With regard to motor vehicles the following vehicles are assigned to electromobility in this Handbook:
– battery electric vehicles,
– vehicles with fuel cell,
– externally rechargeable hybrid vehicles, and
– hybrid vehicles which can cover significant distances by electric-only means.

This corresponds to a large extent to the definition from the Gabler Dictionary of Economics [1]). With regard to other definitions, only vehicles with an electric motor (electrical machine, e-machine) which draw their energy primarily from the mains-supply network may be assigned to electromobility. Consequently, fuel-cell vehicles which are run on hydrogen as their energy source are not assigned to electromobility.



Hybrid vehicles which can only cover short distances by electric means whose electrical machine therefore only has the task of supporting the internal-combustion engine are on no account assigned to electromobility.

Electric vehicles and hybrid vehicles in their different design variations have an electrical machine which acts in some way on the drivetrain. They are therefore referred to as electrified drives.

Development of electric drives in motor vehicles
History of electric drives
Electric drives in motor vehicles are not an invention of the last few years. The first carriage recognized as an electric vehicle was a tricycle by Gustave Trouvé in 1881. The first German vehicle with an electric drive was the Flocken electric car of 1888. In this period numerous manufacturers around the world developed properly functioning electrically powered vehicles. They were in competition with vehicles with internal-combustion engines, which were also in the initial stages of development.

The golden age of electric cars was from 1896 to 1912. The range of electric vehicles on a single battery charge was around 100 km. To increase the range, vehicles were developed in which a gasoline engine via an alternator charged the battery, which powered the electric motor – i.e., hybrid electric vehicles.
After 1912 the market share of electric vehicles dropped off dramatically. The

Figure 1: Variants of electrified drives for motor vehicles
HV High voltage.

reasons for this were the much greater range of vehicles with internal-combustion engines, the cheap fuel gasoline, the now comfortable process of starting the internal-combustion engine with the starter, but also the problem with the traction batteries.

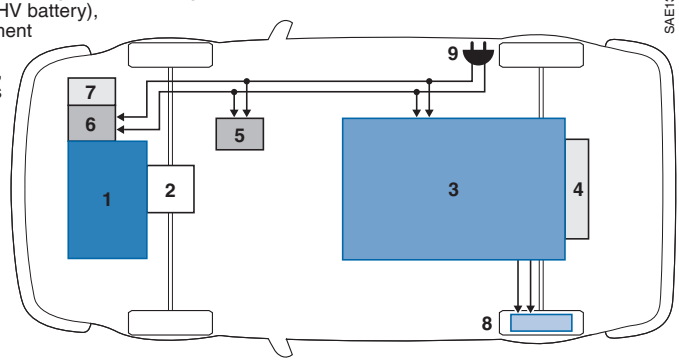
Rediscovery of the electrified drive
The electrification of the drive started to gather momentum only at the end of the 20th century with the demand for vehicles with lower exhaust-gas emissions and the demand for reduced fuel consumption. The high fuel consumption of internal-combustion engines results from the poor degree of efficiency of around 40 %. Electrical machines are at an advantage with an efficiency in excess of 90 %. However, the high-volume application of electric drives powered by one battery with a suitably large battery capacity initially failed due to the embryonic battery technology and the high costs. Because there was minimal take-up on electric vehicles owing to their limited range on one battery charge, vehicles with hybrid drives – i.e., a combination of electric drive and internal-combustion engine – were offered as a technology to bridge the gap.

Advances in battery development resulted in a significant increase in the range. In the meantime a series of electric vehicles is available on the market and a sharply growing market share of electric vehicles is anticipated in the future.

Variants of electrified drives for motor vehicles
The following variants of electrified drives can be found in motor vehicles (Figure 1):
– The mild hybrid with 48V battery assists the combustion engine (boosting) and offers the possibility of maneuvering the vehicle on electric power.
– The full hybrid with traction battery with a battery voltage of typically 400 V (HV, High Voltage) offers the possibility of driving limited distances by electric-only means with zero emissions locally.
– The external rechargeable hybrid can be recharged for example at the power socket in the garage (e.g., plug-in hybrid). The journey can thus be started with a fully charged battery; longer distances can by covered on electric-only power with a larger battery compared with the full hybrid.
– The electric drive with a traction battery (battery voltage typically 400 V or 800 V for powerful vehicles and commercial vehicles) propels the vehicle on electric-only power.
– A vehicle known as a “range extender” has an electric drive and also for example a small internal-combustion engine. It is designed as an electric drive for electric-only driving, with the corresponding performance of the electrical machine and traction battery. If the state of charge of the traction battery is no longer sufficient for propulsion, it is recharged by the combustion engine via a second electrical machine so that the vehicle can continue to be driven at reduced speed. In this operating mode this drive becomes a serial, externally rechargeable hybrid. Other concepts provide for the combustion engine to be mechanically connected directly to the drive (parallel hybrid). The combustion engine acts as a range extender.
– The electric drive with fuel cell produces the energy for propulsion continually from hydrogen and oxygen. A small back-up battery is used to intermediately store the generated energy. With a large battery this can be used for the drive; a small fuel cell charges the battery as required and thus acts as a range extender.

The electrical machine of the microhybrid set out in Figure 1 is not designed power-wise to make a contribution to the drive; this variant therefore is not a genuine hybrid.

Components of the electrified drive



Electric drive
An electric drive consists of the following components (Figure 2):
– electrical machine (e-machine),
– traction battery with battery-management system,
– power electronics for activating the electrical machine (inverter),
– electronic control (VCU, vehicle control unit),
– DC/DC converter,
– charging unit with charging socket, and
– transmission (single-stage reduction-gear unit or multi-speed transmission for higher power demand).

Consequently, the drivetrain of an electric vehicle consists of much fewer components compared with a conventional vehicle with combustion engine.

Interaction of the components
The traction battery (see Batteries for electric and hybrid vehicles) is the energy source for the battery-electric-powered electric vehicle; the energy is stored by charging the battery. In fuel-cell vehicles the current is generated continually (see Fuel cell). Both energy sources supply direct current. To operate the electrical machine the direct current must be converted into a three-phase alternating current (see Electrical machines for drives). This task is performed by an inverter, which activates the electrical machine in line with demand by targeted switching of the direct current (see Inverter). A reduction-gear unit adapts the high rotational speed of the electrical machine to the wheel speed. A single-stage reduction is sufficient depending on requirements; where necessary, transmissions with two or more switchable reductions are used. The torque requested by the driver for propulsion via the accelerator pedal is sensed and processed by the vehicle control unit (VCU) (see Control of an electric drive). The VCU activates the inverter in accordance with the driver's request. The 12V vehicle electrical system also required for electric vehicles (or 24V electrical system for commercial vehicles) is supplied via a DC/DC converter by the HV electrical system (high voltage) (see DC/DC converter).

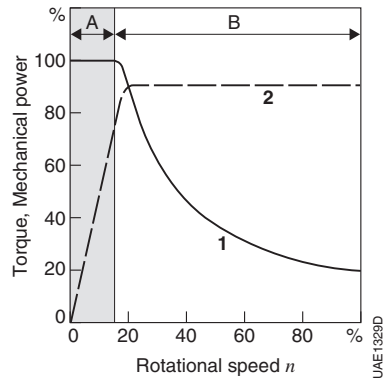
Regenerative braking system
The electric drive also incorporates a regenerative braking system in order to convert into heat during deceleration operations as little kinetic energy as possible via the service brake (friction brake, brake pad on brake disk). The aim with an electric drive is to keep the electrical machine in generator mode for deceleration operations and to store the power generated in the process in the battery (recuperation). The vehicle is decelerated in the process. The service brake is only then activated if the electrical machine's braking power

Figure 2: Components of an electric drive (schematic representation)
1 Electrical machine (e-machine),
2 Reduction-gear unit (single- or multi-stage),
3 Traction battery (HV battery),
4 Battery-management system,
5 DC/DC converter,
6 Power electronics (inverter),
7 Vehicle control unit,
8 Regenerative braking system,
9 Charging socket.

is not sufficient for the desired deceleration (see Regenerative braking system). The service brake is thus simultaneously protected. The stored energy can be used for propulsion.

Hybrid drive

Hybrid drives combine drives with combustion engine and electrical machine with suitably greater component outlay compared with a drive with combustion engine. There are different solutions, depending on the degree of electrification (see Figure 1).



Because power is additionally made available by the electrical machine, the combustion engine can be designed with smaller dimensions (downsizing) to obtain the same overall power.

Outlay can also be reduced in the transmission. The power take-up element can be dispensed with when the electrical machine is used for starting. Reversing (backing up) can be effected electrically so that the reverse gear can be dispensed with in the transmission (see Transmission with integrated electrical machine).

The dimensioning of the components for the electric drive in the network of a hybrid drive – electrical machine, battery, and inverter – depends on the degree of electrification. In particular the costs of the battery with a voltage of up to 400 V in a full hybrid are substantially higher than the costs of a 48V battery in a mild hybrid.

Figure 3: Basic torque and power curves of an electrical machine

1 Torque,
2 Mechanical power,
A Base-speed range,
B Field-weakening range.

Advantages of an electric drive in an electric vehicle

Torque curve of electrical machine

Unlike the combustion engine an electrical machine already outputs its maximum torque from a rotational speed of zero (Figure 3, see also Electrical machines for drives). The rotational speed when driving is so high that it must be adapted to the required wheel speed via a reduction-gear unit. The torque transmitted to the wheels increases in the same proportion.

Transmission

The high torque available over a wide rotational-speed range enables the vehicle to be driven over a wide driving-speed range with only one transmission reduction. Single-stage transmissions are primarily used for passenger cars. Two-speed or multi-speed transmissions are also used for sports cars which reach higher speeds and for commercial vehicles. A reverse gear is not required in the electric drive's transmission because the electrical machine changes the direction of rotation when activated accordingly. Consequently, the transmission for an electric drive is much simpler and compact in terms of design than the transmission of a drive system with combustion engine.

Efficiency

For a combustion engine the maximum efficiency is around 40 % in the low speed range at high load. A conventional route profile however requires part load in the event of poorer efficiency.

Electric drives operate independently of the operating point, i.e., even with a low load request, with an efficiency of over 90 %.

Energy consumption

Because the efficiency of an electrical machine is significantly better than that of a combustion engine, energy consumption is lower for electric drives in an electric vehicle.

Zero local emissions
The electric drive has zero local emissions. The charging current required to charge the battery does however, depending on how the current is generated, cause emissions at the point of origin. CO_2 emissions are created if the current is produced in gas- or coal-fired power plants. Only if current from regenerative sources is used (e.g., via solar cells or wind turbines) is the electric drive free from CO_2 emissions.

Operating noises
The operating noises of an electrical machine are low such that an electric vehicle is very quiet at low speeds where the other driving noises (rolling noise of the tires, aerodynamic noises caused by the air stream) are not yet pronounced.

Vibrations
Due to the rotational movement of the electrical machine, hardly any vibrations are generated in the drive in an electric vehicle.

Component outlay
The combustion engine with its extensive peripherals (e.g., air-intake system, exhaust system) requires a lot of installation space. The components of an electric drive – with the exception of the traction battery – require much less space.

Advantages of a hybrid drive
The electrical machine in a hybrid vehicle improves the utilization of the combustion engine compared with a drive solely with a combustion engine thanks to the following operating modes.
– Recuperative braking: The braking effect and thus the recuperated brake energy depend however on the electrical machine's power.
– Boosting: The electrical machine can assist the combustion engine in the hybrid vehicle.
– The combustion engine can be operated at a higher load point with greater efficiency (load-point shift), the energy required for propulsion is stored via the electrical machine in the battery and can be utilized later for propulsion. This improves fuel consumption. The amount of fuel that can be saved depends on the degree of hybridization.
– The combustion engine can be switched off when the vehicle is stationary (start/stop system).
– At low speeds and with only a small power demand (e.g., in urban traffic) a full-hybrid vehicle with electric drive and switched-off combustion engine can drive in parts with zero emissions. The average fuel consumption of the combustion engine is lower in combination with the electric drive; as a result the CO_2 emissions are also reduced.
– Starting operations can be performed with the electric drive; the combustion engine can be cut in from a specific speed while the vehicle is rolling. This delivers a quiet, low-emission starting operation.

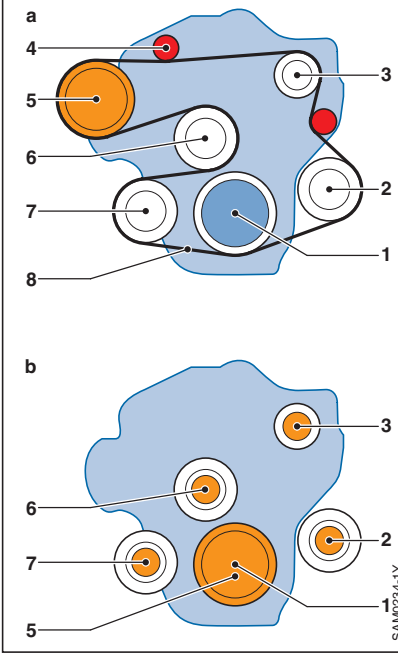
Compared with an electric vehicle the hybrid vehicle has the advantage of high range, comparable with that of a conventional vehicle with a combustion engine.

Electrified ancillary systems

The mechanical power dissipation of a drive system with internal-combustion engine includes, as well as the engine friction losses, the outlay on driving the accessories. These include, for example, the coolant pump, the engine-oil pump, the alternator, the high-pressure pump for fuel injection, the brake vacuum pump, the air-conditioning compressor, and the power-steering pump for the hydraulic power-assisted steering system. These accessories are typically driven for the most part by the internal-combustion engine via V-belts or toothed belts (Figure 4a). The internal-combustion engine must cater for the power demand of these accessories and also overcome the losses in the drive belt. This entails additional fuel consumption.

Demand control of the accessories

The power consumption of the driven accessories can be reduced by demand-oriented control. One example of this is intelligent alternator regulation. By specifying the control voltage it is possible to specifically control the power consumption. The alternator is still however driven via the lossy belt drive.



Electrically driven accessories

The accessories are driven even when they are not required. One example of this is the power-steering pump. When driving straight-ahead on expressways/freeways steering assistance is only needed on rare occasions, but the power-steering pump is permanently driven and causes losses. Electric power-assisted steering, which only cuts in when steering assistance is required, has in the meantime gained acceptance for use in passenger-car steering systems. The motivation behind these systems was however the possibility of realizing automated parking maneuvers.

Electrical driven accessories are no longer driven by the internal-combustion engine (Figure 4b) and can thus be operated in terms of their speed independently of the engine speed. The speed and thus the power consumption of the accessories are adapted to the demand. As the speed reduces, so too do the friction losses in the accessories. Coolant and lubricant flows can thus be adapted to the load and speed of the internal-combustion engine, which also impacts positively on the pollutant emissions.

Another advantage of electrified accessories is that they can even be operated while the engine is at a standstill if their operation is required during the standstill phase.

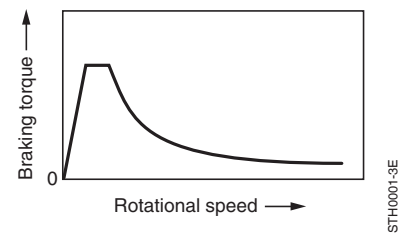
Regenerative braking system

In the case of regenerative braking (also known as recuperation), the vehicle's kinetic energy during deceleration is converted by the electrical machine, which is operated as a generator for this purpose, into electrical energy. In this way, some of the energy which is normally lost as frictional heat during braking is fed in the form of electrical energy to the battery and then utilized.

Drag-torque simulation
A simple way of realizing regenerative braking is drag-torque simulation. Here the electrical machine is operated as a generator as soon as the driver releases the accelerator. The driver does not need to press the brake pedal for this purpose. In the case of a full hybrid, the internal-combustion engine is decoupled and the electrical machine exerts a generator torque of the magnitude of the engine's drag torque.

If the engine cannot be decoupled (as in the case of a mild hybrid), alternatively a lower generator torque can be exerted on the drivetrain in addition to the engine drag torque (drag-torque increase). The vehicle behavior changes only slightly compared with a non-hybrid vehicle.



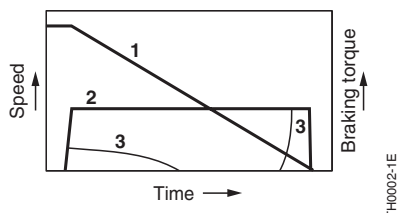
Simple regenerative braking system
During braking the electrical machine can exert an additional generator torque as well as drag-torque simulation and increase. The vehicle decelerates with the brake pedal in the same position faster than a comparable conventional vehicle. The available generator torque depends on the driving speed, the selected gear, and the state of battery charge. Therefore the vehicle can be subject to different levels of braking response, even with the brake pedal in the same position. This difference in braking response is perceived by the driver to be all the more disruptive, the greater the generator torque is part of the vehicle deceleration. For this reason, only small power levels can be recuperated with this simple regenerative braking system.

Cooperatively regenerative braking system
The service-brake system must be modified in the case of higher decelerations in order to further exploit the kinetic energy. To this end all or some of the service-brake friction torque must be replaced with a generator braking torque without the vehicle deceleration changing when the brake-pedal position and brake-pedal force are kept constant. This is realized in a cooperatively regenerative braking system, where the vehicle control and the braking system interact in such a way that constantly as much friction braking torque is recovered as generator braking torque can be replaced by the electrical machine.

During a braking operation the maximum generator torque that can be achieved by the electrical machine changes continuously over a wide speed range (Figure 5). This is due to the fact that the electrical-machine power (i.e., torque times speed) is constant in this range at high rotational speed. Only at low speeds is there a range of constant maximum electrical-machine torque. If the speed continues to drop, the regenerative braking torque that can be achieved again drops to zero.

A constant torque is required at the wheels for a constant deceleration of the vehicle. If the electrical machine operated as a generator is exploited to its limit torque, the friction braking torque must be continuously reduced with decreasing

Figure 5: Maximum torque path for electric-machine generator mode



driving speed (and thus decreasing electrical-machine speed) because the generator torque increases. Figure 6 shows by way of example a braking operation of a power-split hybrid. At the start of the braking operation the generator torque is increased until it reaches its maximum level. If this corresponds to the demanded total braking torque, the friction braking torque can be reduced to zero. Towards the end of the braking operation the generator torque is reduced and replaced completely by a friction braking torque because the electrical machine can no longer deliver a generator torque at very low rotational speeds (Figure 5). During the braking operation from high driving speed to a standstill, therefore, the distribution between friction braking torque and regenerative braking torque is continuously adapted with constant pedal actuation.

ESC-based regenerative braking system

For the technically simplest implementation of a cooperatively regenerative braking system essentially the hardware of a conventional ESC system (Electronic Stability Control, electronic stability program) is used (Figure 7) and the operating strategy is enhanced by the recuperation functionality.

Basically, such a system can be operated both with an electromechanical and with a vacuum brake booster where the combination with an electromechanical brake booster offers additional advantages with regard to recuperation efficiency and redundancy for highly automated driving. The back pressure of the low-pressure reservoir can be reduced to further increase the recuperation efficiency. The exact relationship is described in more detail in the following.

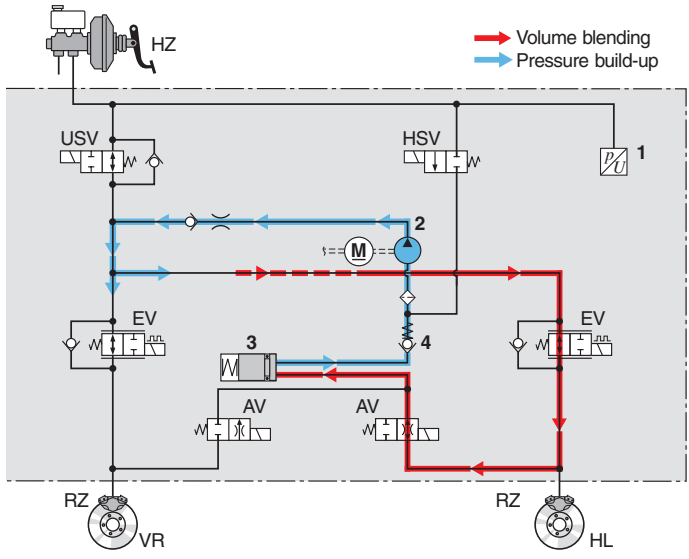
Figure 6: Cooperative braking operation for a power-split hybrid
1 Driving speed,
2 Total braking torque,
3 Friction braking torque.

Operating principle

A pedal-travel sensor is additionally required to detect the driver's braking request. This sensor either is automatically made available in combination with an electromechanical brake booster or must be integrated in the system in combination with a vacuum brake booster by way of an additional external pedal-travel sensor.

The driver's braking request must be detected via the pedal-travel sensor because the hydraulic pressure built up in the braking system during recuperation generally cannot be clearly assigned to a specific pedal position.

The requested braking torque is initially made available by the electrical machine operating as a generator. If the generator torque is not sufficient, additional hydraulic pressure and hence a friction braking torque are built up at the basic brake. This process is called torque blending. When the pedal is pressed, the same amount of brake fluid as used in a purely hydraulic braking operation is displaced in the braking system. To achieve a reduced pressure or no pressure in the brake calipers, the excess brake fluid is intermediately stored in the low-pressure reservoir; this is called volume blending. The brake fluid is displaced via the inlet or outlet valves on the rear or front axle into the low-pressure reservoir (Figure 7). Through this, during the entire braking operation the back pressure of the reservoir chambers is applied at the respective wheel brake and results in the case of purely recuperative braking operations in an unwanted residual pressure and consequently also in a possible residual slip torque at the brake disks. Through a reduction of the back pressure and a high selected wheel-brake response pressure these systems can, despite the residual pressure, achieve recuperation efficiency of up to 100 % (recuperated energy com-



pared with the energy made available by the generator). If additional pressure is requested during the braking operation, brake fluid is taken from the low-pressure reservoir by means of the return pump and displaced into the wheel brakes (Figure 7).

During recuperation the hydraulic pressure in the braking system is as a rule below the expected pressure of a purely hydraulic braking operation. If the brake booster has not yet exceeded the point at which the brake pedal is hydraulically coupled with the braking system, the pressure reduction is not yet detected at the brake pedal. However, as soon as this point is overcome, the original pressure must in the case of a vacuum brake booster be built up at least on one axle in order to ensure an unchanged pedal force and a consistent pedal feel. On the other hand, when an electromechanical brake booster is used, the missing pressure can be compensated for by reducing the electromechanical assisting force so as not to experience any limitation in recuperation or any reduction in recuperation efficiency. The compensation of the missing system for an unchanged pedal feel is also called force blending.

Highly automated driving

The integration of regenerative braking systems suggests itself particularly for vehicles with highly automated driving functions because these vehicles are as a rule electrically chargeable hybrids or even purely electrically powered vehicles. In the case of highly automated driving functions (level > 2) the combination with an electromechanical brake booster additionally provides the required redundancy

in order to safely brake the vehicle fully automatically to a standstill in the event of the total failure of a component.

Braking-force distribution
As with the design of conventional brake systems, so too with the design of a regenerative brake system the braking-force distribution between front and rear axles is of crucial importance to the vehicle's directional stability. As deceleration increases, the normal force on the front wheels increases while the normal force on the rear wheels decreases. If the electrical machine is connected to the front wheels, a greater wheel braking torque can also be transmitted with increasing deceleration and thus increasing normal force on the front axle. On a rear-wheel-driven vehicle or a vehicle with an electrified rear axle (i.e., internal-combustion engine on the front axle and electrical machine on the rear axle) the transmittable regenerative torque decreases with increasing deceleration.

The electric power of the battery also has a major influence on the utilization of recuperation since it is the limiting element for absorbing electrical energy from the vehicle movement. The maximum possible purely recuperative deceleration increases with increasing energy-accumulator power. For directional-stability reasons, however, a large generator braking torque can only be transmitted on the front axle.

Influence on driving-dynamics control
Since the regenerative brake system influences braking stability, the driving-dynamics control must be adapted to the changed physics of driving. It is expedient to suppress the regenerative component of braking when unstable driving states or excessively high brake slip are detected and to realize deceleration and stabilization interventions solely by means of the friction-braking system. Otherwise instabilities and drivetrain vibrations could disrupt optimum wheel-slip control.

In relation to partial-braking operations interventions by the vehicle stabilization system are so rare that the suppression of recuperative braking in these situations has no noticeable impact on the average energy consumption for an electrified vehicle.

Thermal management for electric vehicles

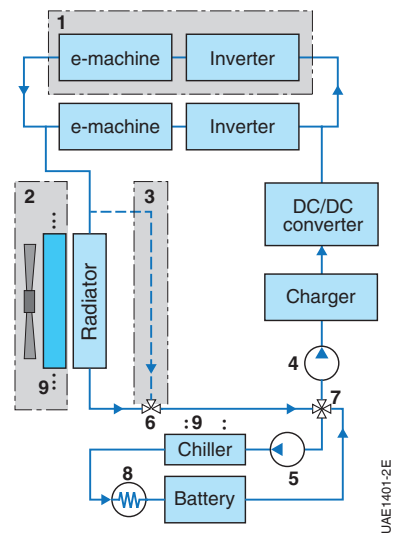
Thermal management refers to the control of heat flows in a vehicle. The function of thermal management is to protect components against overheating, operate these components in their optimal temperature ranges, and generate pleasant temperatures for the occupants in the passenger compartment. The thermal-management system switches into the appropriate operating modes in response to the heating or cooling demand of the components or the passenger compartment. The outside temperature is taken into consideration in the process. The correct configuration of thermal management is becoming ever more important and provides for increased range and comfort in electric vehicles.

Intelligent thermal management results in

– increased range for electric vehicles,
– full air-conditioning comfort through the targeted use of heat and cold,
– rapid charging by efficient battery cooling – even at high temperatures,
– longer battery service life due to lower thermal load.

Operating principle

A thermal-management system in an electric vehicle is generally more complex than in conventional vehicles with internal-Internal-combustion engines. Thus the e-axle (integration of electrical machine, power electronics, and transmission, see Electric final-drive unit) is constantly cooled while the battery must be either cooled or heated depending on the situation (Figure 8). Furthermore, the waste heat from an internal-combustion engine is no longer available to heat the passenger compartment, and consequently energy-efficient measures, e.g., a heat pump, are used for this purpose.



The refrigerant circuit and cooling circuit must come together in optimal interaction to transfer the heat in the vehicle and to make available the necessary temperatures. The routing of the two circuits changes depending on the heating or cooling demand. This gives rise to different operating modes.

Cooling circuit

In the cooling circuit coolant is circulated by an electric coolant pump to deliver a coolant flow in line with demand. The coolant transfers heat from where it is generated to the point in the vehicle where it is needed. Coolant switching valves direct the coolant flow in the secondary cooling circuits of the drivetrain and in the heating circuits of the passenger compartment for this purpose. Thanks to the high specific heat capacity the coolant can absorb a lot of heat in a very small space, which is necessary for example to cool the e-axle or the battery effectively.

Likewise, heat can be distributed very flexibly in the vehicle with the coolant. When coolant absorbs heat, its temperature increases and it must be cooled in a heat exchanger.

4 Coolant pump,
5 Coolant pump,
6 Switching valve,
7 Switching valve,
8 Battery heater,
9 Connection to refrigerant circuit.

Refrigerant circuit
In the refrigerant circuit a refrigerant, which can be both liquid and gaseous, circulates. When the refrigerant evaporates (transition from liquid to gaseous) a refrigerating capacity is generated which facilitates cooling even below the ambient temperature. This established principle of air-conditioning the passenger compartment in the summer is also used to cool the battery at very high outside temperatures. The heat released during condensation (transition from gaseous to liquid) can furthermore be used in the winter to heat the passenger compartment. The refrigerant circuit is driven by an electric air-conditioning compressor, which compresses the refrigerant to the desired pressure so that evaporation and condensation take place at the desired temperature in each case.

Driving in the winter
At low outside temperatures both the passenger compartment and the battery must be heated in order to ensure full drive power at all times. The passenger compartment is heated by the refrigerant circuit by way of a heat pump. The battery is heated by an electric flow-type heater and is additionally supported with waste heat from the e-axle.

The use of a heat pump improves the efficiency of the passenger-compartment heating, which has a positive effect on the range. The use of waste heat from the e-axle to heat the battery both improves efficiency and ensures that the battery is fully available at all times.

Driving in the spring and fall
At moderate outside temperatures the battery and e-axle can be jointly cooled via a coolant circuit, whereby the waste heat is dissipated via the radiator to atmosphere. As a result, the energy consumption for thermal management is reduced to a minimum, which impacts positively on efficiency and range. At the same time the battery and e-axle can be set to optimal temperature levels which enable the drive to operate at optimal efficiency.

Driving in the summer
At high outside temperatures the battery must be cooled via the “chiller” (heat exchanger between the cooling and refrigerant circuits) by the refrigerant circuit in order to guarantee the maximum permissible temperature in the battery and thereby ensure a long battery service life.

The refrigerant circuit is likewise responsible for air-conditioning the passenger compartment. The e-axle is cooled separately from the battery via the radiator, facilitating unlimited, energy-efficient cooling of the e-axle.

Charging
As a rule limited charging capacity with alternating voltage is available at home or at the workplace for charging the battery. The charger, which is responsible for converting the alternating voltage into direct voltage, and the battery are jointly cooled via a cooling circuit and the radiator. In this way the charging losses can be kept as low as possible, which has a positive impact on the battery-charging time.

During rapid charging at high outside temperatures the temperature in the battery increases very quickly. So as not to exceed the maximum permissible temperature and to enable the heat to dissipate in a short time, the battery is cooled via the “chiller” by the refrigerant circuit. This ensures a rapid charging process at all times.

Charging infrastructure for electrified vehicles

Facts
Electrical energy today is very widely used, very reliably available, and in every home and business at that. It seems reasonable to charge electric vehicles from the already existing mains-supply network as well.

Because the amounts of energy and in part also the desired charging capacities are a matter of some significance, an electric vehicle cannot be considered as an electrical domestic or industrial appliance. Charging sockets for vehicles therefore very often have special designs.

The sockets for the consumers make available worldwide alternating current (AC) in all major mains-supply networks. In some cases this may be three-phase alternating current. All batteries require direct current (DC) for charging. Consequently, charging vehicle batteries necessitates a battery charger that has two functions:
– converting from alternating to direct current and
– at the same time the charger must, depending on the current state of the battery, be able to adjust current and voltage individually.

Charging types
The charger can be accommodated in the vehicle ("on-board charger"). In this case the process involves alternating-current charging (AC charging) because the vehicle is supplied with alternating current (see On-board charger).

Alternatively the charger can also be accommodated in the infrastructure, for example in the charging post. In this case the process involves direct-current charging (DC charging) because the vehicle is supplied with direct current. It must still be borne in mind that vehicles cannot be connected to any direct-current sources because the charger is not just a rectifier.

Both charging types have their justifications. The charger carried in the vehicle can be connected virtually anywhere to existing alternating-current networks, but is generally limited in its charging capacity by installation space, weight, and costs. Furthermore, large capacities are only sensible to a limited extent in that larger capacities cannot be drawn from the mains-supply network everywhere.

When the charger is integrated in the infrastructure, this opens up the possibility of very high charging capacities because as a rule weight and installation space are less critical than in the vehicle itself. Sometimes the increased costs can be apportioned to a number of vehicles which use this charger one after the other. But the costs do not grow linearly with the capacity of the charger because upstream components of the mains-supply network must "grow alongside". Apportioning the additional costs for high charging capacities will accordingly always mean an increased price per energy (kWh), which must ultimately be billed.

A further additional expense associated with direct-current charging is appropriate signal transmission in that only the vehicle knows the battery condition precisely and consequently must control the charger in the infrastructure. Despite the expense, direct-current charging is today the method of choice for realizing very high charging capacities.

Orders of magnitude
To convey the orders of magnitude of the electrical engineering of vehicles, there follow some figures which are compared with households (in Germany).

Vehicle
As at 2020 figures of 13 kWh through 27 kWh per 100 km (with outliers up to over 40 kWh) are given for the energy demand per distance traveled for passenger cars. This is naturally also usage-dependent (dependent on the driving style) and additionally – in contrast

to internal-combustion engines – clearly weather-dependent. Heating (in the winter) and cooling (in the summer) mean a marked increased demand with regard to electric vehicles. 20 kWh per 100 km can be envisaged as an average. The other way round, this means: the driver can drive 5 km on 1 kWh of electrical energy. This figure may change somewhat over the years because the current trend is towards designing economical vehicles because economy with restricted battery capacity means increased range.

In the future larger and more cost-effective batteries as well as more luxurious vehicles can presumably be envisaged. Assuming that an average passenger car covers 10,000 km per year (naturally this value is subject to significant spread), a vehicle with the above-mentioned average value estimated over a year requires approximately 2,000 kWh.

Household

By way of comparison, the average annual consumption for households is in the order of 3,500 kWh per year – here too there is a very wide spread of around 500 kWh through 25,000 kWh per year – this would be similar to the spread of the annual mileage of passenger cars. In other words, in terms of energy a passenger car is to be considered as a small household.

Charging capacity

The sizes of the batteries used in vehicles cover a considerable range. The cause is a certain dilemma in the vehicle design because the weight and costs of the batteries are very high and can also make up a significant proportion of the weight and costs of the complete vehicle. In battery-powered electric vehicles battery capacities of 16 kWh (for a subcompact-size car) to over 100 kWh (for a luxury-class vehicle) may be given by way of example. The amount of energy that is charged to the vehicle in a single charging process is smaller. How much smaller depends very much on the user because the battery can be recharged for any partial states of charge and is not necessarily fully charged. Which charging capacity is required to recharge the mentioned energy also depends on the desired charging time.

Plug connectors

There are very many different socket-outlets used in public mains-supply networks. This is not only due to national-market variants, but also due to their purpose and power capacity. The difference between domestic socket-outlet (“Schuko” grounding-type) and industrial socket-outlet as per IEC 60309 [2] (“Cekon”) is mentioned by way of example. Continuous power of approximately 2.3 kW and short-time power of 3.7 kW can be drawn from a domestic socket-outlet. The figures can be lower due to other power consumers which are operated at the same time. Continuous power of 3.7 kW to over 100 kW can be drawn from an industrial socket-outlet (depending on the size). The types for 11 kW or 22 kW are very common.

To charge vehicles, a purely mechanical adaptation (as familiar from “travel plugs”) is conceivable but not sensible because the charging capacity would have to be designed for the weakest adaptable socket-outlet. However, there is often the wish to utilize the available current source or use the maximum capacity of the charger in the vehicle.

For this reason specific plug connectors have been introduced for electric vehicles which contain, in addition to the contacts for the charging current, signal contacts which communicate to the vehicle the load capability of the current charging source.

Control of electric drives

Drivetrain of an electric vehicle

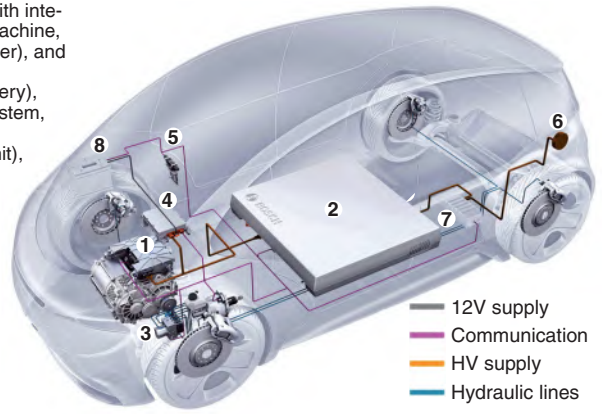
In an electric vehicle propulsion is provided by an electrical machine (e-machine). The electrical energy required for this is stored in battery-powered vehicles in the traction battery; in fuel-cell vehicles the energy is continually generated in the fuel cell. Direct current is available in both cases. However, a three-phase alternating current is required to operate the e-machine. Direct current is converted to alternating current in the inverter.

These components must be activated in a coordinated fashion in order to convert the torque request input by the driver via the accelerator pedal into an e-machine torque. The torque then provides the drive or decelerates the vehicle. All these operations are controlled in an electronic control unit called the VCU (Vehicle Control Unit).

Figure 1 provides an overview of the components in the drivetrain of a battery-powered vehicle.

Vehicle control unit for electric vehicles

Function



The electronic control of electric vehicles (vehicle control unit, VCU) is responsible for converting the driver command into propulsion. The drive torque required for this is relayed to the inverter control unit to implement e-machine drive power. Furthermore, the subsystems of the HV vehicle electrical system (HV, High Voltage) and the components for heating and cooling the cooling circuits in the vehicle are coordinated.

Electrical system overview

Figure 2 describes the ECUs and subcomponents in the drivetrain of an electric vehicle. Aside from the VCU as the central processor there is among others the battery control unit, which is responsible for opening and closing the contactors in the traction battery. The charging control unit is responsible for coordinating the charging process, firstly for charging with alternating current and secondly for rapid charging with direct current at charging posts. The inverter control unit regulates the current through the e-machine. The HV consumers for heating and cooling (electric continuous-flow heater and

8 12V battery.

air-conditioning compressor) are likewise featured and are activated and deactivated by the VCU. The DC/DC converter supplies the LV vehicle electrical system (Low Voltage,12 V for passenger cars and 24 V for commercial vehicles) with electrical energy. This vehicle electrical system contains the consumers such as for example the infotainment and further ECUs in the vehicle.

Functional system overview

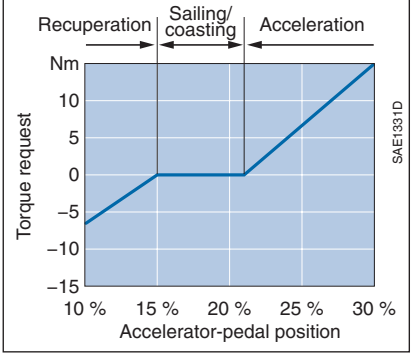
A VCU has many other subtasks aside from the primary tasks of implementing the driver command, coordinating the subsystems of the HV vehicle electrical system, and controlling the cooling circuits in the vehicle.

Torque Demand subsystem

The driver issues a concrete driver command through the accelerator-pedal position. The accelerator-pedal position is converted into a setpoint value for the drive or deceleration torque.

If the accelerator-pedal position is in a low range (e.g., 0 to 15 %), a negative torque request is made (Figure 3). The e-machine is in this case used to decelerate the vehicle and the electrical energy generated by recuperation is returned to the traction battery. A medium accelerator-pedal posi-

Figure 3: Torque request with one-pedal control



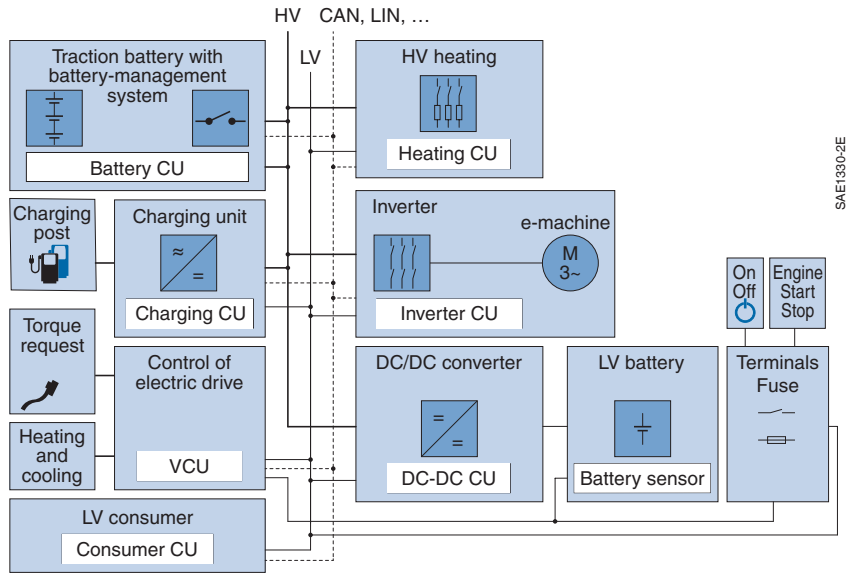


Figure 2: Electrical system diagram for an electric vehicle

HV High Voltage, LV Low Voltage (12 V for passenger cars, 24 V for commercial vehicles), AC Alternating Current, DC Direct Current, ECU Electronic Control Unit.

tion (e.g., from 15 to 21 %) is interpreted in such a way that driving at constant speed is desired. The ehicle behavior here is similar to the sailing (coasting) mode of a vehicle with an internal-combustion engine. A high accelerator-pedal position (e.g., greater than 21 %) requests a pedal-position-dependent acceleration. Acceleration and braking with the accelerator pedal can be controlled by means of this one-pedal control.

The vehicle's driveability is influenced by selecting a driving profile – Normal, Eco or Sport. In the Eco driving program a lower drive torque is requested with the same accelerator-pedal position (Figure 4). More drive torque is requested when the Sport driving program is selected.

In addition, there is an interface through which the driver can adjust the recuperation level (e.g., selector-lever position “B” or an additional switch). The higher the recuperation level, the higher the requested recuperation torque. Figure 5 describes the torque requests for recuperative braking at different recuperation levels.

As well as selector-lever position “B”, by means of which the recuperation mode is activated, there are usually still further selector-level positions known by vehicles with automatic transmissions:

– P (Park): the vehicle is parked and secured against rolling away.
– N (Neutral): the drivetrain has no frictional connection. The vehicle is not secured against rolling away.
– D (Drive): the vehicle is in the driving mode in the forward direction.
– R (Reverse): the vehicle is in the driving mode in the reverse/backing-up direction.

Aside from the direct torque input the driver can make an indirect torque input via the cruise control (vehicle-speed controller) (Figure 6). A setpoint drive torque is calculated, depending on the current driving condition. A speed limiter restricts the maximum speed to the value set by the driver. The creeping function is activated at low speeds when the vehicle is in the driving mode and the accelerator pedal is not pressed. The vehicle then moves at a low speed (e.g., 5 km/h). This simplifies vehicle handling in certain situations, for example when parking.

Unlike vehicles with internal-combustion engines, there is no idle speed in electric vehicles when the accelerator pedal is not pressed and the vehicle is stationary.

Figure 4: Torque request with one-pedal control for different driving programs
(Sailing/coasting range shown applies to Eco driving program.)

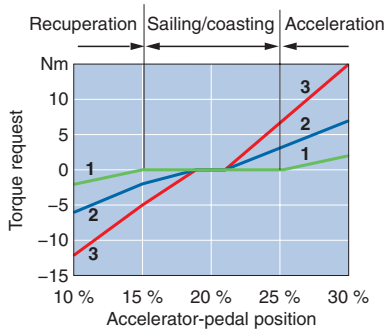
2 Normal driving program,
3 Sport driving program.



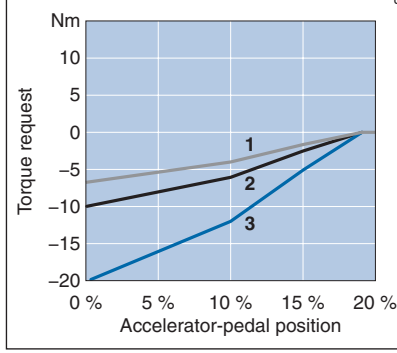


Figure 5: Torque request for recuperative braking for different recuperation levels
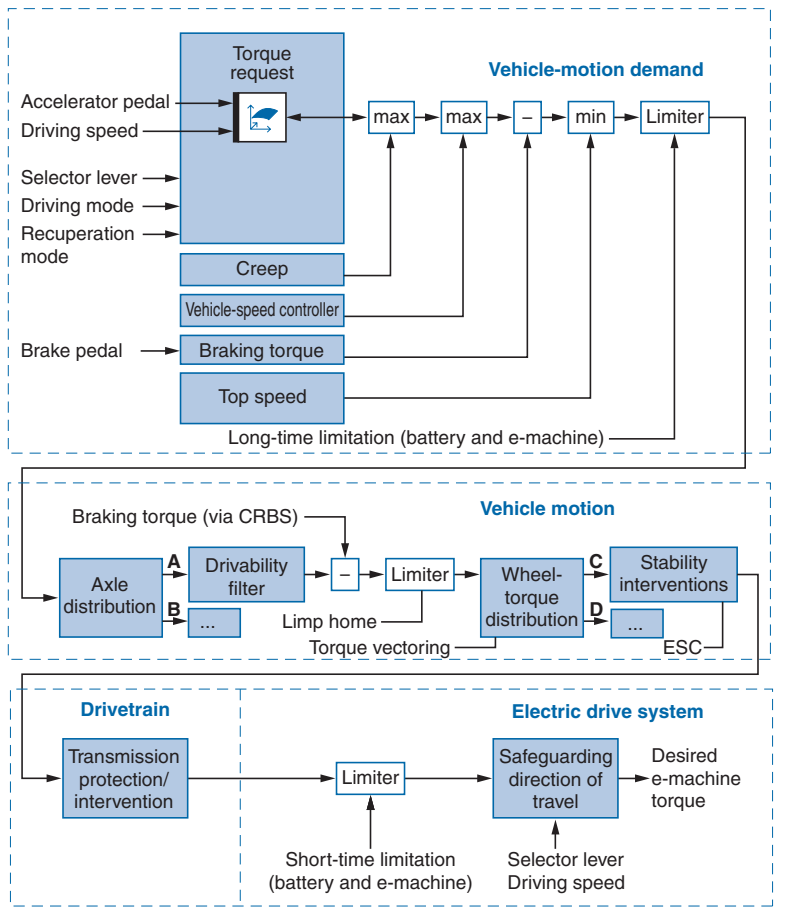
1 Recuperation level 1,
2 Recuperation level 2,
3 Recuperation level 3.



In vehicles of some manufacturers one-pedal control is used to bring about deceleration via the e-machine but also activation of the mechanical friction brake. In some countries there are standards which provide for an activation of the stop lamps from a certain deceleration. Despite the possibility of activating the mechanical friction brake via one-pedal control there is however still a brake pedal, which facilitates safe and direct activation of the friction brake.

Torque Structure subsystem

The ECU for driving-dynamics control (ESC, Electronic Stability Control) spe-

ESC Electronic Stability Control (electronic stability program),
CRBS Cooperative Regenerative Brake System,
Torque Vectoring: Wheel-individual drive-torque distribution.

cifically initiates brake interventions in order to guarantee vehicle stability. In the Torque Structure subsystem the individual torque requests from the Torque Demand subsystem, the brake intervention by the ESC, and the request for purely generative deceleration by the regenerative braking system are coordinated. The functionality contains a filter for smoothing the torque request and thus for improving driveability and avoiding load reversals. The torque calculation takes into account the position of the selector lever and thus it is ensured that the vehicle moves in the forward direction in the "Drive" position and in the reverse direction in the "Reverse" position. No electrical torque is generated in the "Neutral" and "Park" selector-lever positions (Figure 6).

Electrical Supply System subsystem
A further task of the VCU is to coordinate the components of the HV vehicle electrical system. When the driver requests a vehicle drive-ready state (e.g., via the start button), the VCU sends a request via the CAN bus to the battery control unit to close the contactors in the traction battery. Once the HV vehicle electrical system has been successfully activated, the VCU sends a further request to the ECU of the DC/DC converter so that the latter starts with the voltage conversion from the high-voltage side to the low-voltage side (12V side for passenger cars or 24V side for commercial vehicles). This ensures that the low-voltage supply is redundant.

Furthermore, HV consumers (e.g., the PTC booster heater or the HV air conditioner) can be deactivated by the energy management where necessary.

Electric vehicles also have a 12V or 24V battery because this is needed during the first starting operation to check the HV system.

Thermal Management subsystem
In the Thermal Management subsystem the VCU controls the components for heating and cooling the cooling circuits in the vehicle. Typically there is a cooling circuit for the drive, in which the e-machine, the inverter, the DC/DC converter, and the charger are located. Depending on the temperatures of these components the VCU activates the coolant pump in the cooling circuit and this pump cools the specified components accordingly. The heat transferred to the coolant is dissipated via the radiator to atmosphere. In the event of a higher cooling demand the radiator fan is additionally activated. The aim is to protect the components against overheating.

The radiator fan can, depending on the installation location of the traction battery, also be used to cool the battery. In the case of a separate cooling circuit for the battery the VCU controls a second coolant pump for this cooling circuit. If the battery temperature is very low (e.g., below 10 °C), the VCU activates the PTC booster heater in the battery circuit so that the traction battery is heated up. At very high outside temperatures (e.g., above 40 °C) it activates the air-conditioning compressor, which can lower the coolant temperature and with it also the battery temperature. This is necessary especially on hot days, at high loads during driving or when rapid charging because overheating the battery could shorten its service life.

Vehicle Functions subsystem
The VCU computes the remaining range that the vehicle can cover on the current battery charge. The computation is made on the basis of the available energy in the traction battery and the energy consumption in the vehicle. The remaining range is sent on the CAN bus to the display ECU so that the value can be seen by the driver in the display.

Further applications of the VCU for electric vehicles

Battery-electric buses and commercial vehicles

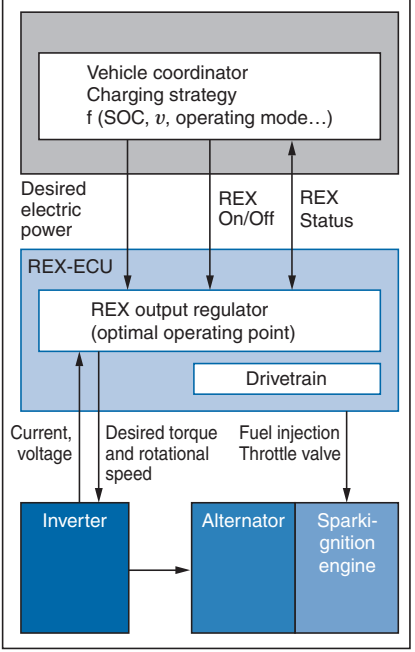
Battery-electric buses and commercial vehicles can be used for passenger transportation and goods deliveries in urban environments. The operating principle of the VCU in these applications is very similar to those for passenger cars.

Range-extender operation

There are electric vehicles which are equipped with an internal-combustion engine that operates as a range extender. An additional e-machine is operated by the combustion engine and generates electrical energy in generator mode. The power figures of the combustion engine and the additional e-machine are much smaller than the power of the electric driving motor. Because the combustion engine is mechanically independent of the drivetrain, it can operate in at an optimal operating point. The electric power generated in this way is stored in the traction battery or made available to the electric drive. As a result, the range of the electric vehicle is increased when compared with pure battery mode.

A fuel cell may also be used as a range extender instead of an internal-combustion engine. The operating principle of the VCU is in this case very similar.

Coordination of the range extender with the VCU



When the state of charge of the traction battery is low, the VCU issues a power request to the range extender's engine control unit (REX-ECU). The vehicle coordinator implemented in the VCU for range-extender operation determines the desired electric power (Figure 7) depending on the

– charging strategy,
– operating mode,
– power limitations of the battery,
– start/stop requests.

The engine control unit activates the range-extender internal-combustion engine by inputting variables for fuel injection and throttle-valve position and requests a torque via the additional inverter, which activates the e-machine operating in generator mode. The output regulator in the engine control unit computes the desired e-machine speed and the desired torque. The inverter coordinates the operating mode and sets the desired values (torque, speed, limitations). The requested electric power can thus be made available.

Hybrid drives

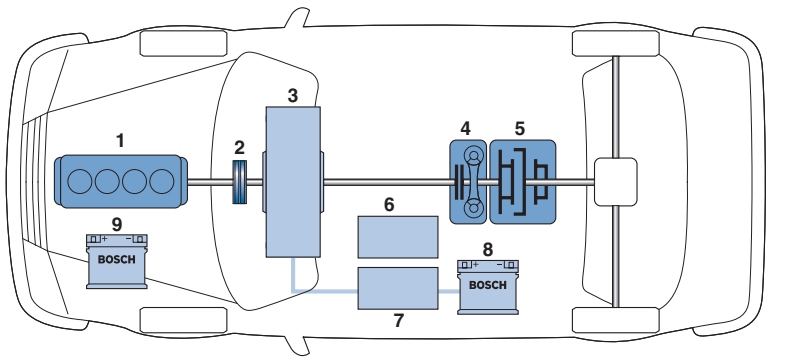
Motivation

A hybrid electric vehicle (HEV), also called a hybrid vehicle, has two or more energy storage devices with their associated energy converters which drive the vehicle jointly or separately (EU Directive 2007/46/EC, [1]). In most hybrid vehicles one or more electrical machines operate as well as the internal-combustion engine. The energy for driving is drawn from a fuel tank and a traction battery (Figure 1). The traction battery is based for the most part on lithium-ion technology with voltage levels of 48 to 800 V.

Essentially three objectives are pursued with the use of electric hybrid drives, where a vehicle driven purely by an internal-combustion engine serves as the reference:

– reduced fuel consumption and thus CO_2 emissions,
– reduced exhaust emissions (including zero emissions by electric driving), and
– increased torque and power output to improve operative dynamics.

Features



Hybrid vehicles combine many benefits of both types of drive in the drivetrain. The extended ranges of an internal-combustion engine and rapid refueling are combined with the high efficiency of an electrical machine also in urban environments at low driving speeds and with many stops at traffic lights.

The internal-combustion engine and the electrical machine can appear in the drivetrain in a variety of drive structures. Here vehicle transmissions (if necessary with one or more integrated electrical machines) also play a role, mostly to provide the internal-combustion engine with variable gear ratios for power conversion or to drive or decelerate the vehicle electrically.

The electrical machine offers high torques at low engine speeds. It thus complements the internal-combustion engine, whose torque only starts to increase at medium engine speeds. The electrical machine and the internal-combustion engine contribute to vehicle motion to varying degrees, depending on the drive power demanded.

Reducing the electrical losses in the 12 V vehicle electrical system

The electrical power demand in passenger cars is rising continuously and will continue to increase in the next few years due to the use of an increasing number of powerful electrical comfort components (Figure 2a). The electrical energy required to supply the electrical loads/consumers in the 12 V vehicle electrical system is currently generated in conventional vehicles by an alternator which is connected via a belt to the internal-combustion engine's crankshaft. The load on the internal-combustion engine for generating current increases the fuel consumption. For a mid-size vehicle the fuel consumption and hence the CO_2 emissions at an electrical-system load of 500 W increases typically by approximately 0.5 *l* per 100 km; the CO_2 emissions increase accordingly (Figure 2c).

A reduction in the CO_2 emissions can be achieved by lowering the electrical losses in spite of increasing electrical-system load. This can be achieved by increasing the voltage in the vehicle electrical system to for example 48 V. Increasing the voltage enables the current to be reduced with the same power output and thereby reduce the ohmic losses (Figure 2b). This becomes apparent particularly in high-power consumers such as an electric air-conditioner compressor; most consumers (e.g., ECUs) are operated in the 12 V vehicle electrical system.

Figure 2: Development of electrical-system demand and its influence on CO_2 emissions [2]

1 New European Driving Cycle (NEDC, previous driving cycle),
2 Worldwide Light-duty Test Cycles (WLTC, driving cycle to be applied since 09/2018 for newly registered passenger cars, since 09/2019 for newly registered light commercial vehicles),
3 Excluding combustion-engine drag losses (engine is disconnected via a clutch from the electrical machine),
4 Including combustion-engine drag losses (engine is connected to the electrical machine).

Functionalities of hybrid drives

The way in which internal-combustion engine, electrical machine and energy storage device (battery) interact determines the possible hybrid functionalities. Hybrid-drive systems can be classified on the basis of the implemented functions and the proportion of electric power that goes towards the entire drive (Table 1).

Start/stop function

The average fuel consumption and thus the CO_2 emissions can be reduced by switching off the internal-combustion engine when this is not required for propulsion of the vehicle. The electrical energy required to supply the vehicle electrical system during this time is delivered by the battery.

The start/stop function switches the internal-combustion engine off temporarily without the driver having to turn off the ignition switch ("the ignition"). The engine is typically switched off when the vehicle is stationary or during constant driving if no energy is required. It is then restarted automatically as soon as the driver is ready to drive off, accelerate or brake.

This functionality is achieved in many vehicles already with the existing 12 V vehicle electrical system with manageable technical outlay.

Recuperation

One measure for reducing fuel consumption is aimed at converting the vehicle's kinetic energy into electrical energy (recuperation). With an electrical machine power output of approximately 12 kW already a large proportion (roughly 80 %, see Figure 2d) of the available kinetic energy can be recuperated and stored in the battery. Depending on the electrical-system load and the vehicle, even more energy can be recuperated than is needed for the electrical-system supply. In this case it is expedient to export this energy in the form of kinetic energy back to the crankshaft.

In the case of recuperation the electrical machine is used to convert kinetic energy into electrical energy. Braking operations are effected where possible not – or at least not only – by the friction torque of the service brake, but by a generative braking torque of the electrical machine (regenerative braking). The electrical energy is transferred to and stored in the battery (Figure 3).

Hybrid driving

Hybrid driving refers to those states in which the internal-combustion engine and the electrical machine are in opera-

tion together. The assistance provided by the electrical machine makes it possible to operate the internal-combustion engine by means of operating-point optimization predominantly in the range of its best efficiency or in operating ranges in which only low pollutant emissions occur. Hybrid driving can be subdivided into generator and motor modes of the electrical machine.

Generator mode
In generator mode the internal-combustion engine is operated in such a way that it delivers a higher power output than is needed for the desired propulsion of the vehicle (Figure 4). The excess mechanical power is supplied to the electrical machine and converted into electrical energy, which is used to charge the battery.

Motor mode
In motor mode, also called boosting, the electrical machine supports the internal-combustion engine in providing the desired drive power. The battery is discharged in this operating state (Figure 5).

Two different objectives are pursued with boosting: Vehicle performance can be increased compared with a purely engine-powered drivetrain. The second possibility is to maintain the existing overall drive power and use a smaller, more efficient internal-combustion engine (power-neutral downsizing).

Purely electric driving
In the case of purely electric driving the vehicle is driven solely via the electrical machine. For this operating mode the internal-combustion engine is disengaged from the vehicle drive and switched off. With the electric drive the vehicle drives quietly, without local emissions and fuel-efficiently on the energy from the battery (Figure 6).

Classification of hybrid drives

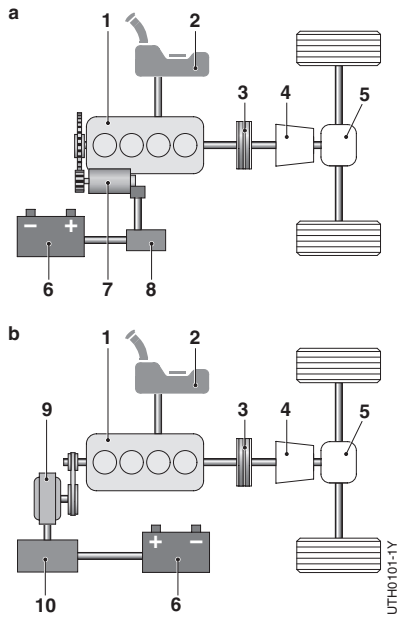
Depending on the operating state and required drive power, the internal-combustion engine and the electric drive contribute to propelling the vehicle to different extents. Hybrid drives can be classified according to the amount of power the electric drive contributes to the overall power of the vehicle and the possible functionalities (see Table 1). Vehicles can be classified according to the following features:
– start/stop system (microhybrid),
– mild hybrid,
– full hybrid,
– externally chargeable hybrid.

Start/stop system

Features

A start/stop system, also called a micro-hybrid, essentially equates to a conventional drive with internal-combustion engine, alternator as electrical machine, starter, and starter battery. The power of the electrical machine is at approximately 3 kW not high enough to make a contribution to propulsion. Therefore it is not in the proper sense a hybrid drive.

This system implements the start/stop (see Start/stop functionality) and recuperation functions. During recuperation the alternator increases at increased regulator voltage its power in the vehicle's overrun mode (with zero fuel consumption) to convert as much kinetic energy as possible into electrical energy and store it in the starter battery (12 V). During vehicle accelerations and at high load the alternator decreases its power depending on the battery charge state as far as possible by reducing the regulator voltage. In this way the load on the internal-combustion engine caused by the alternator and the fuel consumption are reduced. The alternator supplies less electrical energy in this phase; the consumers draw the electrical energy from the battery.



This start/stop system requires battery management with a charge-state sensor system (battery sensor). The amount of energy that can be recuperated is however limited in the 12 V vehicle electrical system.

Classic starter

The start/stop functionality can be achieved with a classic starter (Figure 7a). The engine-management system switches the engine off when the vehicle comes to a stop. The engine restarts automatically when the brake is released (automatic transmissions) or the clutch is operated (manually shifted transmissions). Starters which are designed for a higher number of starting operations are used for this application. The battery must also be designed for this operation, exhibiting increased cycle stability.

This system offers a simple way of reducing fuel consumption with limited outlay. These system with start/stop functionality and recuperation can therefore now be found in many vehicle models.

10 Power electronics.

Starter generator
Starter generators combine the starter and the alternator (generator) in a single component. It is permanently connected to the internal-combustion engine for the generator function. When the engine starts this electrical machine drives the internal-combustion engine. The starter generator can, depending on the installed power, also support (boost) the internal-combustion engine.

Belt-driven starter generator
The belt-driven starter generator is connected via a belt drive to the internal-combustion engine (Figure 7b). The layout is the same as that of a conventional alternator; this topology can also be found in a mild hybrid with 48 V vehicle electrical system. It can be easily integrated, with no changes to the drivetrain needed. Because, depending on the operating state, there is a slack strand or taut strand in the belt drive, mechanical adjustments are however required in the belt-drive tensioning system. In the case of a belt-driven starter generator the power transmittable by the belt determines the upper limit for the system power.

Starter generators which are connected via belts to the internal-combustion engine were used in series production for the first time in 2004.

Integrated starter generator
The integrated starter generator, also known as the crankshaft starter generator, is seated between the internal-combustion engine and the transmission on the crankshaft. In the case of an integrated starter generator the transmittable power is limited by the starter generator's performance and its power electronics.

The coaxial mounting of the starter generator on the crankshaft necessitates a lengthening of the drivetrain. Thus, integrating such a system in an existing vehicle concept entails an outlay on mechanical adjustments.

The crankshaft starter generator can demonstrate its advantages particularly with voltages of 42 V and upwards. A 42 V vehicle electrical system had been discussed for some time, but was not then introduced. Hence the crankshaft starter generator could not make the breakthrough in the 12 V vehicle electrical system in parallel to the belt-driven starter generator. This concept is first implemented with the mild hybrids and the 48 V vehicle electrical system.

Advantages of a starter generator over a classic starter
Starting operation
A classic starter accelerates the internal-combustion engine to around 250 rpm. At this speed fuel is injected in such a way that the engine automatically reaches idle speed. This operation, because of the starter pinion's meshing process and its rotation in the engine's flywheel, is accompanied by noises and vibrations. Because the starter generator is permanently connected to the crankshaft, these side-effects occur much less frequently. The starter generator can also accelerate to higher rotational speeds; the first injection can thus take place at higher rotational speeds (high-speed start). This results in a quieter and faster starting operation.

Start/stop system
Because of the meshing process, a classic starter can only initiate the starting operation while the engine is stopped. This reduces the effectiveness of a start/stop system because the engine can only be restarted at zero speed. Therefore, with these start/stop systems, the engine can only be switched off when the vehicle is stationary. With a starter generator, on the other hand, the engine can already be switched off while it is coasting, which thanks to the longer engine-standstill phases impacts positively on fuel consumption. A renewed starting operation can if necessary be initiated again even when the engine is turning.

Mild hybrid

Features

With a mild-hybrid system the hybrid-driving function can be implemented in addition to the functions of a start/stop system. An electrical machine assists the internal-combustion engine here. As well as the 12 V battery, the mild hybrid contains a traction battery with a higher voltage level (e.g., 48 V) from which the electrical machine draws its energy. Purely electric driving is not possible because the electrical machine and the internal-combustion engine are permanently connected. These systems are therefore called mild hybrid (mild hybridization).

Integration in the drivetrain

There are different ways of connecting the electrical machine in the drivetrain and to the engine. Figure 8 shows the connection of the electrical machine to the internal-combustion engine via a belt drive. The electrical machine can be used in this hybrid vehicle instead of the alternator from the 12 V vehicle electrical system.

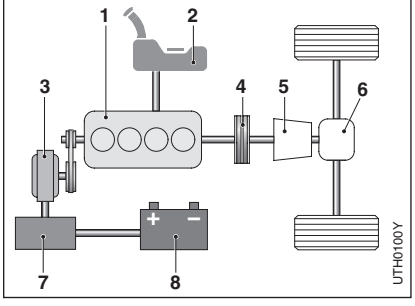
The other widespread integration option is to arrange the electrical machine on the crankshaft between the internal-combustion engine and the clutch or transmission. This arrangement facilitates the transmission-ratio-free connection of the electrical machine to the internal-combustion engine. However, the additional component increases the length of the drivetrain.

Depending on the hybrid-vehicle power requirement, there are further integration options for one or if necessary more electrical machines (see Drive structures).

Full hybrid

Features

A full-hybrid system can, in addition to the functions of a mild-hybrid system, drive over shorter distances with the electrical machine alone. The internal-combustion engine is disengaged during purely electric driving from the drivetrain by the power take-up element or an interrupting clutch and switched off.



The traction battery can store energy during recuperation and with excess combustion-engine power in the case of operating-point shifts. The voltage level of the traction batteries in a full hybrid are typically up to 400 V and for high power requirements up to 800 V. However, the capacities of the traction batteries used are not sufficient to facilitate purely electric driving over longer distances. But the electric drive in a full hybrid can increase the efficiency of the internal-combustion engine.

Because the battery in the case considered here is not rechargeable from an external source, full-hybrid vehicles are from the electric-storage perspective “autarkic”. The full hybrid is therefore assigned to the group of autarkic hybrid systems (see Table 1).

The Toyota Prius was the first full-hybrid vehicle to be a volume-production model in 1997. Since then further vehicle models have been brought onto the market as full hybrids.

Figure 8: Installation position of belt-driven electrical machine

1 IC engine, 2 Fuel tank,
3 Electrical machine, 4 Clutch,
5 Transmission, 6 Final-drive unit,
7 Pulse-controlled inverter, 8 Battery.

Integration in the drivetrain
A full-hybrid vehicle uses both an internal-combustion engine and at least one electrical machine as the means of propulsion. There are in this respect a multitude of drive structures which partly pursue different optimization objectives and which utilize to differing extents electrical energy to drive the vehicle (see Drive structures).

Electrical machine
Permanent-field synchronous machines (PSM), asynchronous machines (ASM), and electrically excited synchronous machines (ESM) are used for full hybrids (see Electrical machines for motor-vehicle propulsion, types of electrical machines).

Traction battery
Battery voltages of typically 200 to 400 V are required for use in full hybrids with the given power requirements relating to the electrical machine. The system voltage can be increased by a step-up converter to up to 800 V. The battery voltage for hybrid applications in commercial vehicles, in plug-in hybrids and in pure electric vehicles can be up to 800 V. The storage capacity of the traction battery depends on the requested range that can be covered by purely electric means. Typical storage capacities of the traction batteries used in full hybrids are up to 2 kWh. Thus, purely electric driving is possible over shorter distances (typically around 2 to 3 km) with full-hybrid vehicles.

Vehicle electrical systems
Full hybrids have an HV (high-voltage) vehicle electrical system in line with the battery voltage. The low-voltage vehicle electrical system also required in full hybrids (12 V in the passenger-car and 24 V in the commercial-vehicle sector) with a battery is connected via a DC/DC converter to the HV vehicle electrical system. The battery in the low-voltage electrical system is charged via the DC/DC converter; the alternator in the conventional vehicle electrical system is not required here.

Inverter
The inverter generates from the HV battery voltage the three-phase alternating current (see Inverter) for operating the electrical machine.

Advantages
The combination of electric and combustion-engine drives in the full hybrid has the following advantages over a conventional drivetrain:
– The electric drive offers constantly high torques at low rotational speeds. In this way, it ideally supplements the internal-combustion engine, whose torque only starts to increase at mid-range rotational speeds.
– The electric drive and internal-combustion engine together are thus able to deliver a high dynamic response from every driving situation.
– The assistance provided by the electric drive makes it possible to operate the internal-combustion engine with a higher-geared transmission with identical mileages predominantly in the range of its best efficiency or in ranges in which only low pollutant emissions occur. Operating-point optimization occurs.
– The combination with an electric drive often facilitates the use of a smaller internal-combustion engine while retaining the same overall power output (power-neutral downsizing).
– Through generator operation of the electrical machine, it is possible when braking as compared to a mild hybrid to convert a much greater part of the vehicle's kinetic energy into electrical energy (recuperation). The electrical energy is stored in the energy storage device and can be used at a later stage to drive the vehicle.
– The electric drive can be use for purely electric driving. Here the internal-combustion engine is switched off and the vehicle is locally operated with zero emissions.

Externally chargeable hybrids
Plug-in hybrid
Features
An extension of the full-hybrid system is the plug-in hybrid, whose traction battery can be charged not only internally but also from the mains-supply network – i.e., externally. As a result, the journey can be started with a fully charged traction battery.

Electrical machine
The electrical machine in a plug-in hybrid is the same as the in a full hybrid.

Traction battery
The traction battery for plug-in hybrids as a rule has a larger capacity (e.g., 16 kWh) than that for full hybrids. This enables plug-in hybrids to be driven longer distances of typically up to 70 km (increasing trend) without the internal-combustion engine cut in. The decisive factor here is that a plug-in hybrid with a fully charged traction battery can be started and driven purely electrically over predominantly short distances.

Range extender
Features
The range of an electrical vehicle on one battery charge is currently still much lower than that of a vehicle with an internal-combustion engine. An added complication is that the charging process is very time-consuming, making it difficult to use an electric vehicle for longer distances. Range extenders denote additional assemblies in an electric vehicle which extend the range limited by the restricted battery capacity. Internal-combustion engines with limited power for example are used for this purpose. These vehicles are designed as electric vehicles; the power of the electrical machine and the capacity of the traction battery correspond to those of an electric vehicle. The traction battery is charged from the public mains-supply network, e.g., at a charging post. The range extender enables the vehicle to continue to be driven with a flat battery to the next charging facility.

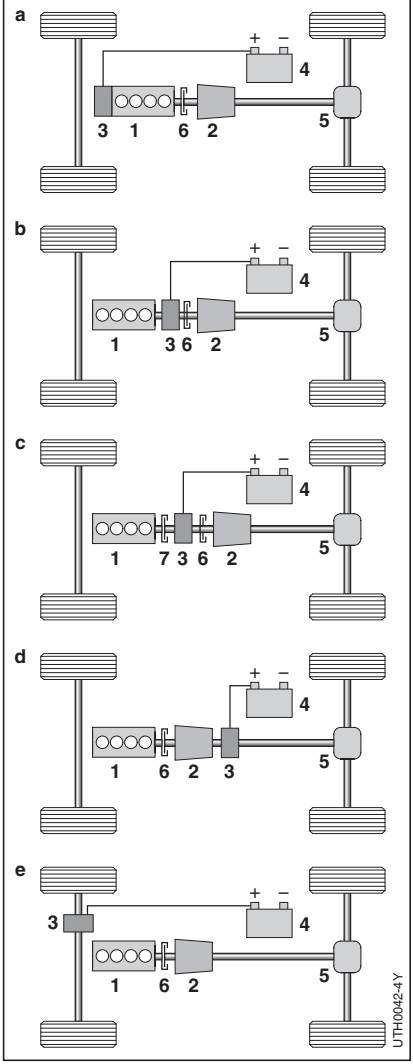
Classification based on drive structure

The different hybrid drives can be classified on the basis of how the electrical machine is integrated in the drivetrain. The requirements which are imposed on an electrical machine depend not least on the installation location and consequently on the drivetrain topology. There are different ways of configuring the internal-combustion engine, transmission and electrical machines in hybrid vehicles. The different drive structures can be divided using possible energy flows into three categories:
– parallel hybrid drive,
– series hybrid drive,
– power-split hybrid drive.

Parallel hybrid
Topologies
In a parallel hybrid drive both the internal-combustion engine and the electrical machine influence the vehicle drive simultaneously (parallel). The electrical machine of the parallel hybrid drive can basically be positioned at different points in the drivetrain, which brings with it specific advantages and disadvantages. A nomenclature originally defined by Daimler AG has gained acceptance for designation purposes; this system designates the parallel-hybrid drivetrain based on the position of the electrical machine in the drivetrain as P0 through P4. The P here stands for the parallel architecture, while the number denotes the installation location of the electrical machine in the drivetrain.

Figure 9 shows the layout of the electrical machine for the different topologies using the example of a standard drive. An external charging socket can be installed but is not pictured here. This also applies to the front-transverse drive.

Essentially, the electrical machine can be installed in the drivetrain in a number of different positions:



– on the internal-combustion engine with belt connection to the crankshaft (P0 topology),
– between internal-combustion engine and clutch or power take-up element, directly connected to the internal-combustion engine (P1 topology),
– between internal-combustion engine and transmission input, can be disconnected via a clutch from the internal-combustion engine (P2 topology),
– on the transmission input (P3 topology),
– connected to the final-drive unit or integrated in the wheel (P4 topology).

Features of the parallel hybrid
In parallel hybrid drives the internal-combustion engine and one or more electrical machines independently of each other or jointly contribute to propelling the vehicle (full hybrid) or to boosting the internal-combustion engine (mild hybrid). The two energy flows from the internal-combustion engine and the battery therefore run parallel to each other, the two individual components of power adding up to a total drive power. Parallel hybrid drives come in a mild-hybrid variant (with start/stop functionality, regenerative braking, and hybrid driving) or in a full-hybrid variant (additionally with electric driving).

Advantages of the parallel hybrid
A fundamental advantage of the parallel hybrid is the possibility of maintaining the conventional drivetrain in wide ranges. For the hybrid versions of the respective vehicle no new transmission has to be developed. A modular construction kit can be used to realize both conventional transmissions (dual-clutch or automatic planetary transmissions, but also continuously variable transmissions) in conjunction with internal-combustion engine and transmissions specially developed for hybrid drives with integrated electrical machines with different power stages.

The extent of development and installation work for parallel drive structures is lower when compared with series and power-split structures, in that for the most part only one electrical machine with lower electric power is required and the adaptations necessary in converting a conventional drivetrain are fewer.

3 Electrical machine, 4 Traction battery,
5 Final-drive differential,
6 Power take-up element (clutch or converter),
7 Interrupting clutch.

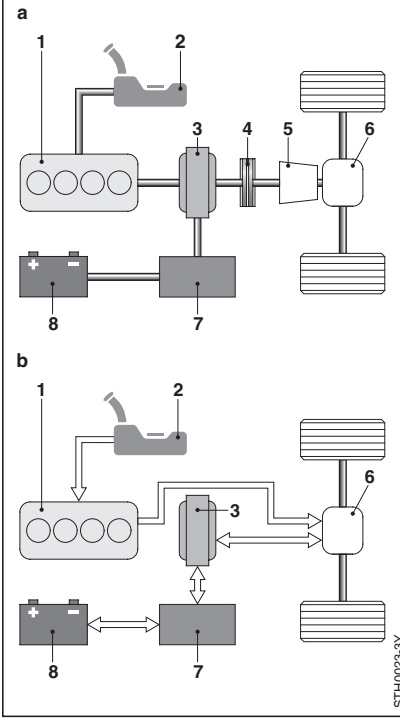
P0 topology
The electrical machine is permanently connected via a belt drive to the internal-combustion engine (see Figure 8). It replaces in this topology the conventional alternator (see also Start/stop system).

The electrical machine can with this topology perform the conventional alternator function even when the vehicle is at a standstill and thereby reliably supply the vehicle electrical system. On the proviso that the electrical machine has a suitably compact design and no additional water cooling is required, mounting the electrical machine in the original alternator position entails only minimal additional integration outlay, since the alternator installation space can be utilized. However, the belt tensioner must be adapted to the different operating states in which taut strand or slack strand occurs.

Because the electrical machine is connected to the internal-combustion engine, the engaged internal-combustion engine reduces the energy to be recuperated when decelerating.

The power output of the electrical machine connected via a belt drive to the internal-combustion engine is typically approximately 10 kW. Consequently, only a mild hybrid can be realized with the P0 topology. The CO_2 savings potential is thus also limited due to the electrical machine's restricted power output.

At an operating voltage < 60 V there is no need for the costly measures to comply with the contact-protection stipulations.



P1 topology
In the P1 topology (Figure 10) the electrical machine is again connected directly to the internal-combustion engine. The electrical machine can be connected via a belt as in the P0 topology, making it possible to realize the functions of a mild hybrid.

When the electrical machine is seated, as shown in Figure 10, directly on the crankshaft (typically a permanent-field synchronous machine), the loss-affected belt drive is omitted, consequently increasing the mechanical efficiency. Furthermore, when compared with a belt-driven electrical machine, a more powerful electrical machine can be used because the power transmittable via the belt is lower.

In contrast to series and power-split drive structures, the speed of the internal-combustion engine is permanently coupled to the speed of the electrical machine. In vehicle deceleration phases the internal-combustion engine cannot be decoupled from the electrical machine and is therefore always engaged. In the process the drag torque of the internal-combustion engine reduces the energy to be recuperated during deceleration. The CO_2 savings potential is thereby limited.

Purely electric driving is not possible with this drive structure. The electric drive can be used to assist the internal-combustion engine and thereby improve dy-

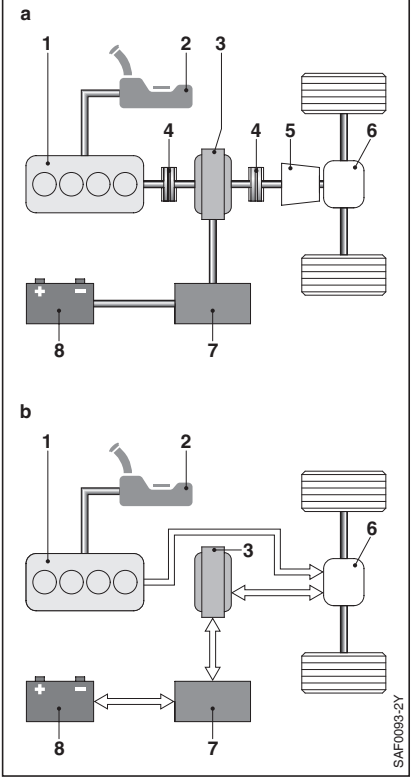
Figure 10: P1-topology parallel hybrid with one clutch
a) Drive structure,
b) Energy flow.
1 IC engine, 2 Fuel tank,
3 Electrical machine, 4 Clutch,
5 Transmission, 6 Final-drive unit,
7 Pulse-controlled inverter, 8 Battery.

namic performance. The P1 topology is therefore only suitable for a mild hybrid.

The power output of the electrical machine connected via a belt drive to the internal-combustion engine is typically approximately 10 kW. Values of around 20 kW are typical for an electrical machine integrated on the crankshaft.

The outlay on integrating the electrical machine in the drivetrain is higher here than for the P0 topology with belt drive. The P1 topology is possible with all transmission variants.

P2 topology



If a clutch is installed between the internal-combustion engine and the electrical machine which allows the engine to be cut in and out and thus decoupled from the electrical machine (Figure 11), purely electric driving with a full hybrid is made possible. The internal-combustion engine can also be decoupled in deceleration phases. Firstly, this increases the energy to be recuperated during acceleration. Secondly, it permits sailing operation, whereby the vehicle rolls freely and is slowed down only by aerodynamic drag and rolling friction. However, engine starting can only take place with the clutch closed, which hampers the transition from electric driving to driving with the internal-combustion engine, above all without a clutch between the electrical machine and the transmission.

To make this drive structure acceptable, it is very important to enable the internal-combustion engine to be started from electric driving without compromising comfort. There are two different ways of achieving this. In the first option the internal-combustion engine is started when the interrupting clutch is open by a separate starter and there is no unwanted effect on vehicle motion. This however calls for a separate starter, which can actually be dispensed with in a hybrid vehicle. Another option is to activate the internal-combustion engine, the electric drive and the clutch in such a way that the effect on vehicle motion is compensated for during engine starting. To this end an intelligent control system requires access to measured values from the internal-combustion engine, the electric drive, and the clutch located in between. The clutch must be able to adapt automatically to the changing conditions in ongoing operation and to follow the control-system inputs.

The additional moment of inertia acting via the transmission input shaft must be taken into account in the design of the synchronizer rings. Reliable generator operation via the internal-combustion engine is interrupted when the clutch is open.

The integration outlay for this topology is high since significant changes to the

Figure 11: P2-topology parallel hybrid with two clutches
a) Drive structure,
b) Energy flow.
1 IC engine, 2 Fuel tank,
3 Electrical machine,
4 Clutch or converter (optional),
5 Transmission, 6 Final-drive unit,
7 Pulse-controlled inverter, 8 Battery.

transmission housing are required. Installation space is additionally required for the electrical machine and the clutch. The P2 topology is possible with all transmission variants.

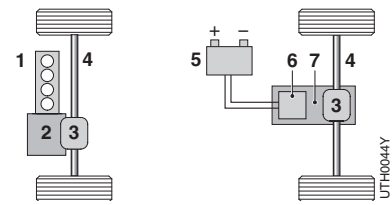
P3 topology
Connecting the electrical machine to the transmission outlet is also feasible. This topology is possible with all transmission types.

However, in this topology the rotational-speed spread of the drive axle must be transmitted to the machine shaft. Electric driving can only be achieved by choosing a suitable conversion ratio between the electrical machine and the drive shaft. If, at higher driving speeds, this results in the upper rotational-speed limit of the electrical machine being exceeded. the electrical machine must be automatic disengaged.

In principle, this topology offers the greatest efficiency during recuperation since the lowest mechanical transmission losses occur here. But this only applies provided the electrical-machine power output does not decrease substantially with the speed. Otherwise the maximum possible recuperation or boost power would drop prematurely with the driving speed. If the electrical machine has be to disengaged due to its rotational-speed limit at higher driving speeds, energy cannot be recuperated in these high rotational-speed ranges.

The internal-combustion engine cannot be started from a vehicle standstill. As well as the additionally required conventional alternator for reliable electrical-system supply this topology must have a conventional start/stop-capable starter or a 12 V- or 48 V-based starter generator.

The integration outlay for the electrical machine must here too be gaged as very high. Furthermore, installing the additional clutch between the internal-combustion engine and the electrical machine in this P3 topology entails increasing the length of the drivetrain and thus necessitating a larger installation space.



P4 topology
A further parallel drive structure is obtained by electrifying a separate axle (axle-split parallel hybrid, Figure 9e for standard drive, Figure 12 for front-transverse drive). Here, a conventional drivetrain comprising internal-combustion engine and transmission on a powered axle is combined with an electrically powered axle. A semi-automatic transmission and a start/stop system for the internal-combustion engine are required for this purpose. One or more interrupting clutches can be installed.

This drive structure is classed as a parallel hybrid drive because the individual components of power from the engine and the electric drive add up. This concept delivers a four-wheel-drive functionality limited by the power of the electrical machine and battery charge. Distribution of the drive torques can be adjusted by specific activation of the electric drive within wide limits.

The traction battery is recharged by regenerative braking or externally via a charging socket. The traction battery can only be recharged externally when the vehicle is stationary.

The transmission for the internal-combustion engine is the same as that of a vehicle without axle hybrid, but must also be able to be operated over longer distances at high speed in neutral – i.e., open. Lu-

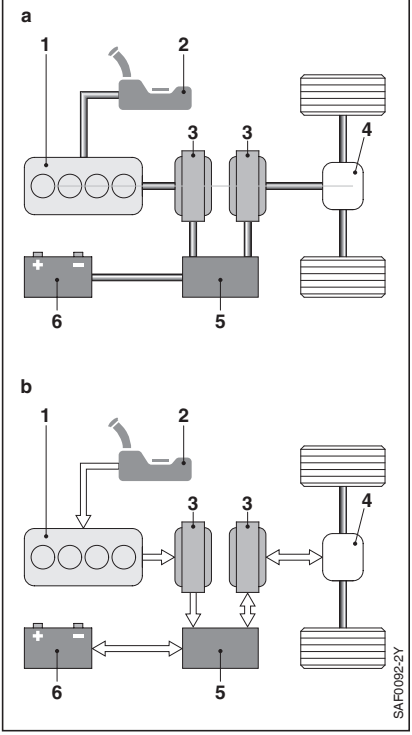
7 Step-up gear unit (fixed ratio).



brication of the transmission must be assured when both the input shaft and the output shaft are stationary.

Final drive via an axle
Particularly for front-transverse drives with very limited installation space it can be advantageous not to have to accommodate the electrical machine between the engine and the transmission. A P0 or P1 position by means of a belt drive is just as conceivable as a P4 position on the axle driven by the internal-combustion engine. The downside of this concept is that the electrical machine may not be able to utilize the different gears of the combustion-engine transmission and is subject to losses at high driving speeds as long as it cannot be disengaged from the final-drive differential and the wheels.

Series hybrid
In a series-hybrid drive there is no mechanical connection of the internal-combustion engine to the vehicle drive. The internal-combustion engine drives an electrical machine, which operates as an alternator (Figure 13). The electric power generated in this way is made available together with the battery power to a second electrical machine, which drives the vehicle. From the perspective of the energy flows, a series connection exists in this case.

Advantages of the series hybrid
In view of the fact that there is no mechanical connection between the internal-combustion engine and the powered wheels

Figure 13: Series hybrid drive
a) Drive structure,
b) Energy flow.
1 IC engine, 2 Fuel tank,
3 Electrical machines, 4 Final-drive unit,
5 Pulse-controlled inverter, 6 Battery.

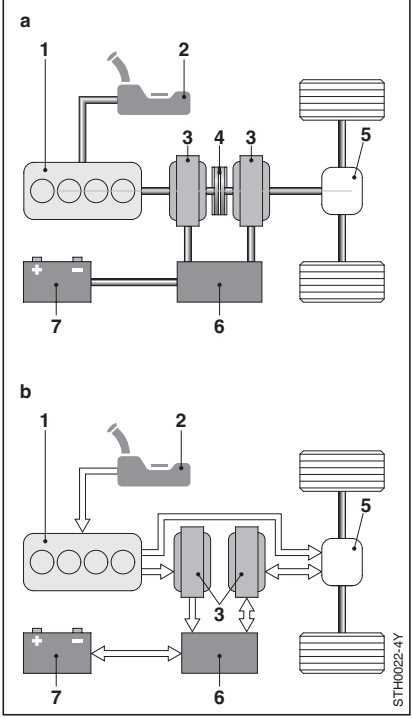
in the series hybrid, this drive structure offers some advantages. Thus, a conventional range transmission is not required in the drivetrain. This creates free space for arranging the overall drive ("packaging").

In addition, starting the internal-combustion engine from electric driving does not cause any unwanted effect on vehicle motion.

The chief advantage when driving is the ability to freely select the operating point of the engine. Excess mechanical energy produced by the internal-combustion engine at full load with high efficiency which is not required for vehicle propulsion can be stored in the battery and then utilized later when the combustion engine is turned off for the electric drive. This supports fuel-saving and low-emission operational management of the vehicle. The engine can also be optimized to a limited operating range.

With a larger battery capacity the electrical machine operated as an alternator and the internal-combustion engine can be designed with smaller dimensions. The combustion engine can be maintained at more favorable operating points; it only makes available the average energy required for vehicle propulsion for the base load. The missing power for acceleration processes for example is drawn from the battery.

As the combustion engine and alternator further decrease in size, this system devolves into a range extender.



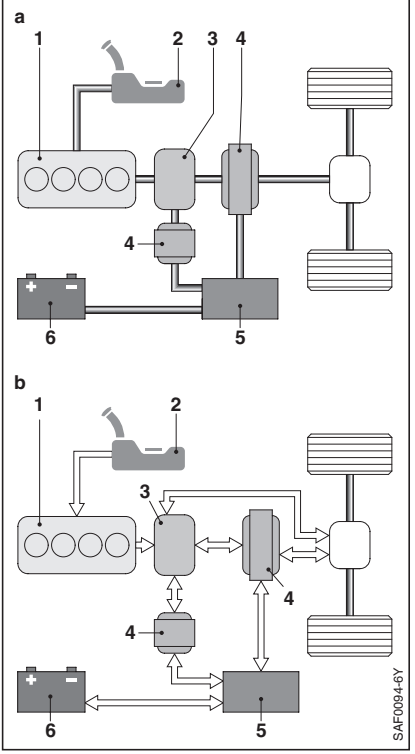
Disadvantages of the series hybrid

A downside of the series hybrid is that electrical energy has to be converted twice. The losses incurred through double energy conversion are higher than in the case of a purely mechanical transfer by a transmission. Furthermore, this principle lacks the possibility of adding the power of the internal-combustion engine to that of the electrical machine (boosting).

Standing against the high driving comfort provided by the electrical machine without ratio change and the possibility of operating the internal-combustion engine at its optimum consumption point is the high complexity in the form of two electrical machines. These, due to their very concept, have to be very powerful since the entire energy of the internal-combustion engine must be converted. This means greater weight and higher costs.

Due to the double energy conversion, the series hybrid is only fuel-efficient under certain operating conditions. At low and medium speeds a series hybrid, despite the higher losses, offers a fuel-consumption advantage because here the positives afforded by the ability to freely select the engine's operating point outweigh the negatives. The higher losses are predominant at higher speeds.

Figure 14: Series-parallel hybrid drive
a) Drive structure,
b) Energy flow.
1 IC engine, 2 Fuel tank,
3 Electrical machine, 4 Clutch,
5 Final-drive unit, 6 Pulse-controlled inverter,
7 Battery.



Series-parallel hybrid
A series hybrid is extended to become a series-parallel hybrid (Figure 14) by establishing a mechanical connection between the two electrical machines which is connected or separated by a clutch. The series-parallel hybrid can utilize the advantages of the series hybrid at low speeds and circumvent the disadvantages at higher speeds by closing the clutch. When the clutch is closed, the series-parallel hybrid behaves like a parallel hybrid. Since the double energy conversion is limited to the range of lower speeds and power outputs, smaller electrical machines are sufficient for the series-parallel hybrid than are required for the series hybrid.

Compared with the series hybrid, the advantage in "packaging" is lessened on account of the mechanical connection between the internal-combustion engine and the powered wheels. Compared with the parallel hybrid, two electrical machines are required for the same task.

Power-split hybrid
Features
A power-split hybrid drive generally has two electrical machines, which on the one hand function as electric variators and on the other hand perform "hybrid" functions such as boosting and recuperation. Power-split hybrid vehicles combine features of parallel and series hybrid vehicles with those of a power split (Figure 15). For the variator function of the two electrical machines some of the mechanical power (speed times torque) is supplied via the planetary gear to the first electrical machine, which now functions as a generator and converts the mechanical power into electric power (electrical path). The remaining power, together with the second electrical machine, drives the vehicle (mechanical path). The electric power is supplied via an inverter to the second electrical machine, which functions as a motor at a speed independent of both the generator and the internal-combustion engine and supplies its power to the drivetrain again in mechanical form.

Power split
The central element of power split (or power summation) is a planetary-gear set, which is connected via its three shafts to the internal-combustion engine and two electrical machines. For the input-power split the internal-combustion engine is connected to an element of the planetary-gear set (e.g., the planetary-gear carrier), the generator to a second element (e.g., the sun gear), and the second electrical machine to the third element (e.g., the ring gear) and the output. For the output-power split the internal-combustion engine and the generator engage an element of the planetary-gear set and

Figure 15: Power-split hybrid drive
a) Drive structure,
b) Energy flow.
1 IC engine, 2 Fuel tank,
3 Planetary gear, 4 Electrical machine,
5 Inverter, 6 Battery.

the second electrical machine engages a second element of the planetary-gear set, while the output is connected to the third element of the planetary-gear set. In both cases the electric component in the power-split hybrid can be varied by activation of the electrical machine. This provides for continuously variable starting and continuously variable ratio adjustment. The battery can be charged or discharged by varying the generated and supplied electrical energy of the two electrical machines.

Because of the kinematic boundary conditions at the planetary-gear set, the engine speed can be adjusted within certain limits independently of the driving speed. The internal-combustion engine can thus operate extensively in the optimal operating range. Following a continuously variable transmission (CVT), the terminology used here is an electric continuously variable transmission (ECVT).

Some of the engine power is transmitted by the planetary-gear set via the mechanical path to the powered wheels. The remainder of the power is transmitted via the electrical path with double energy conversion to the powered wheels. Similarly to the series hybrid, the electric transmission path can be used in the case of low power demands. For higher power demands, the mechanical transmission path is also available. However, it is not possible to switch arbitrarily between the mechanical and electrical transmission paths. Depending on the configuration of the planetary-gear set, the electrical machine and the internal-combustion engine, without an additional transmission only certain combinations between the mechanical and electrical transmission paths are ever possible. In this way, the power-split hybrid can achieve substantial fuel savings at low and medium speeds. No additional fuel savings can be achieved at high speeds.

The power-split hybrid can be expand by mechanical, fixed gears by using a second planetary-gear set. The mechanical complexity increases, while the electrical complexity decreases. Smaller electrical machines are then sufficient for a comparable concept. Furthermore, fuel consumption at medium and higher speeds can be improved.

Disadvantages

Standing against the high driving comfort of this concept is the high complexity in the form of two electrical machines, which due to their very concept have to be very powerful as they must convert a large proportion of the power. Their overall power is thus in the range of the installed combustion-engine power. There is no provision for modularity with an existing basic transmission without electrical machines.

Incorporating the transmission in the hybrid drive

Transmissions for P0 and P1 topologies

Hybrid drives come in the most varied forms. For P0 and P1 topologies, where the electrical machine is located between the internal-combustion engine and the clutch or converter, the classic drivetrain components can be used. The required changes in the drivetrain for the hybrid drive are minimal; no changes to the transmission itself are required. All transmission types can be used.

Adapted conventional transmissions

Conventional transmissions adapted to hybrid functionality are prevalent in vehicles with P2-topology hybrid drive. These vehicles are based on the variant of classic drive with internal-combustion engine; the classic drive components can be used for the most part. The function of the automatic transmission is the same as that of a conventional drive.

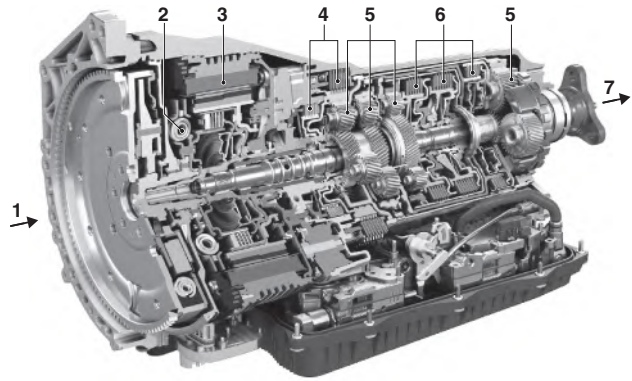


Figure 16 shows an automatic planetary transmission for the standard drive in whose housing an electrical machine is integrated at the drive end (IMG, integrate motor-generator, see Electrical machines for motor-vehicle propulsion). With these transmissions it is possible to achieve a modular, gradual electrification of the drivetrain ranging from the mild hybrid, through the full hybrid up to the plug-in hybrid. This transmission with integrated electrical machine is only slightly longer than a conventional transmission. The extended length even fits into the same outer transmission case on frequent occasions. This simplifies the vehicle platform.

Transmissions with integrated electrical machine

In some vehicles the installation space required for the P3 drive configuration is not available. This problem can be remedied by integrating the electrical machine in a dual-clutch transmission. The electrical machine is no longer connected to the crankshaft of the internal-combustion en-

Figure 16: Structural design of a P2 transmission with integrated electrical machine base on a conventional automatic planetary transmission for a standard drive

1 From driving engine, 2 Torsion damper, 3 Electrical machine, 4 Multi-disk brakes, 5 Planetary-gear sets, 6 Multi-disk clutches, 7 To final-drive unit.

gine, but is instead connected to a subunit of the dual-clutch transmission. This arrangement does not require an additional clutch between the internal-combustion engine and the electrical machine. Purely electric driving with the engine stopped is possible by opening the double clutch of the transmission. Depending on the gear selected in the transmission subunit, with the electrical machine a different transmission ratio is possible between the engine and the electrical machine. This produces an additional degree of freedom for the hybrid control, which can be used to further reduce fuel consumption.

Special transmissions for hybrid drives

Specially developed hybrid vehicles which are only offered as hybrid variants arrive on the market in high numbers. Here it is practical to adapt the entire drivetrain to the hybrid-drive possibilities and thereby optimize the complete system. One measure is to simplify the mechanical design of the transmission by omitting the components for the reverse gear. Instead, at least one electrical machine is integrated into the transmission to provide for reversing (backing up). The electrical machine is thus part of the transmission, whereby the connection to the transmission can be effected by various transmission shafts. The transmission can be further simplified by reducing the gears. Tight stepping of the gears as encountered in a classic drive is not necessary in a hybrid drive.

Transmissions specifically developed for a hybrid drive with one or more integrated electrical machines called dedicated hybrid transmissions (DHTs) [3]. They can be derived from all the possible transmission concepts – the dual-clutch transmission, the automatic planetary transmission, the continuously variable transmission (CVT) or the automated manual transmission. Power-split operating conditions can be created with planetary-gear sets additionally integrated in such transmissions.

Control of a hybrid drive

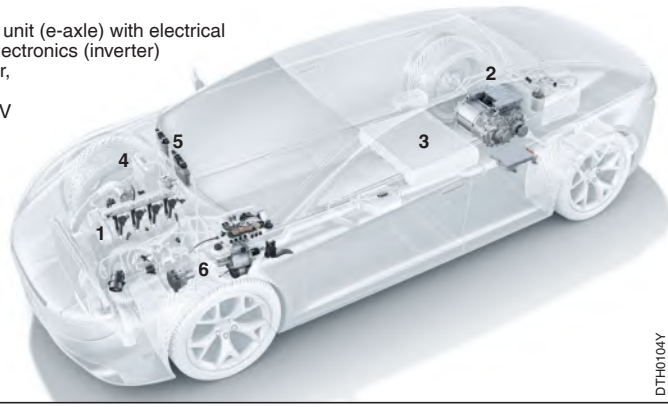
Hybrid vehicle

In a hybrid electric vehicle (HEV) propulsion is provided by an internal-combustion engine and one or more electrical machines (e-machines). Depending on the performance of the electrical machine there is mild hybridization with a mild hybrid (battery voltage typically 48 V) or strong hybridization with a full hybrid (also called a strong hybrid, battery voltage typically 200 to 400 V; HV High Voltage). The following components are required for the drive of a hybrid vehicle:

– internal-combustion engine,
– clutch to separate the electrical machine from the internal-combustion engine,
– transmission (e.g., automatic planetary transmission, dual-clutch transmission),
– electrical machine,
– power electronics (inverter),
– battery (e.g., 48V battery for mild hybrid, HV battery for full hybrid),
– DC/DC inverter for connecting the HV vehicle electrical system to the low-voltage electrical system,
– regenerative braking system for recuperative braking.

Figure 1 shows by way of example a vehicle with electric final-drive unit (e-axle).

Vehicle control unit for hybrid vehicles



Function

In a hybrid vehicle these components must be operated by open- and closed-loop control. The efficiency which can be achieved with the relevant hybrid drive is crucially dependent on the higher-level hybrid control. Figure 2 shows the electrical system overview of a hybrid drive with the networking of the individual components and ECUs in the drivetrain. The higher-level hybrid control (vehicle control unit, VCU) coordinates the entire system, the subsystems of which have their own control functions. These are battery management, engine management for the internal-combustion engine, management of the electric drive (including the electrical machine, the clutches, and the power electronics), transmission management, and management of the braking system.

In addition to pure control of the subsystems, the hybrid control also includes an operating strategy which optimizes the way in which the drivetrain is operated. The operating strategy brings influence to bear on the consumption- and emission-reducing functions of the hybrid vehicle; it must implement the different hybrid functions, such as regenerative braking and hybrid and electric driving, and start-

stop operation of the internal-combustion engine. The operating strategy determines how the drive power is shared between the engine and the electric drive. It decides the extent to which the potentials for fuel saving and for reducing the emissions of a vehicle are utilized.

Selection of and switching between the individual states is performed in accordance with numerous conditions relating to, for example, the accelerator-pedal position, the state of charge of the battery, and the vehicle's current speed. The components in the hybrid vehicle behave differently, depending on the optimization objective (e.g., fuel saving or emission reduction).

Drivetrain operating strategy for hybrid vehicles

Function

In a hybrid vehicle with internal-combustion engine and electrical machine the interaction of these two drives must be coordinated. This drivetrain operating strategy is part of the software in the VCU (vehicle control unit), which controls the degrees of freedom of the interaction of the drives in such a way as to minimize the overall drive-system losses over the route.

The overall wheel torque requested (or the wheel force or the mechanical power) is determined by a driver request (accelerator-pedal position, vehicle-speed controller). The purpose of the optimization strategy is to delivery this overall torque with the best possible distribution between the internal-combustion engine and one or more electrical machines. The strategy must furthermore decide whether it is more favorable to drive by hybrid or purely electric means if purely electric driving is possible for the given hybrid-vehicle topology.

Classification of operating strategy

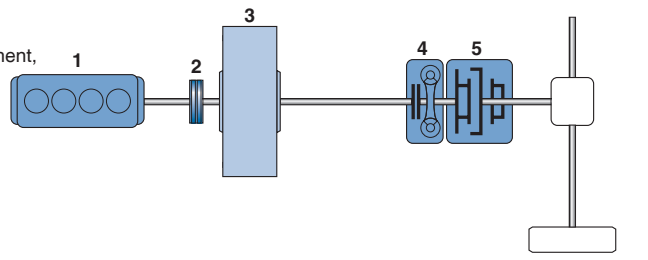
Generally, the operating-strategy solutions can be classified into three main categories: control-based, optimization-based, and learning strategies.

Control-based operating strategy

Control-based operating strategies comprise deterministic strategies and fuzzy-logic strategies. In the deterministic strategy events – particularly future events – are clearly defined by preconditions. In typical fuzzy-logic strategies the continuous data are classified into discrete value ranges. Both strategies have a series of predefined rules without the remaining route being known from the outset.

Optimization-based operating strategy

Optimization-based strategies can be either offline or online approaches. In the case of offline approaches optimization is performed offline; the results are then stored in the VCU for example in program maps. Dynamic programming (DP) is an established offline approach. This involves splitting the optimization problem into subproblems with the intermediate results being stored. The optimal solution of the overall problem is made up of the optimal solutions of the subproblems.



In the case of online optimization strategies, on the other hand, an algorithm for calculating the optimal operating points is calculated directly in the VCU. Examples of online optimization approaches are the equivalent consumption minimization strategy (ECMS) andmodel predictive control (MPC) [1]. MPC approaches predict a trajectory of vehicle motion, calculate a cost function for each step in the trajectory, and select the nearest element ahead of the vehicle for present optimization [2]. Online approaches can react better to different driving conditions.

Learning strategies

Learning strategies demonstrate that promising advances are as a rule possible with approaches based on neural networks [3].

Figure 3: Topology of a P2 parallel hybrid

1 IC engine,
2 Interrupting clutch,
3 Electrical machine,
4 Power take-up element,
5 Transmission.

Influences on operating strategy

The description of a drivetrain operating strategy applies here generally to all hybrid topologies. The concept of an operating strategy is explained with reference to a P2 parallel hybrid (Figure 3). The P2 topology features a interrupting clutch between the internal-combustion engine (ICE) and the electrical machine, which in turn is connected via a transmission to the wheels. The arrangement of the drives facilitates both purely electric and hybrid driving. In the hybrid driving mode the operating strategy determines the optimal torque distribution or the optimal power distribution. The operating strategy also decides between operation in the hybrid driving mode and the electric driving mode whereby the total losses during optimal power distribution in the hybrid driving mode are compared with the total losses in the electric driving mode. It is important to bear in mind that the operating strategy must find an optimum for each instant taking account of the overall distance traveled and not just for an instantaneous optimization. This is required because the battery state of charge (SOC) is a long-term aspect of the system. Discharge of the battery resulting from electric driving for example can only be evaluated if the system takes into account how much electrical energy is returned to the battery (e.g., by load-point increase, operation of the internal-combustion engine with excess power for generator operation of the electrical machine).

Figures 4 and 5 show representative speed/torque program maps of an internal-combustion engine and an electrical machine. It becomes clear that electrical machines operate efficiently in a wide speed and torque range, i.e., with high efficiency. The internal-combustion engine on the other hand is much less efficient and has only certain speed/torque ranges with higher efficiency which are marked in Figure 4 as the optimal operating curve. Values with the same specific fuel consumption (values in g/kWh) form the characteristic curves shown in the diagram. The program map is also called a graph diagram. Optimization of the operating point of internal-combustion engine (Figure 4), electrical machine (Figure 5), and battery and taking into account the relevance of the instantaneous driver-command torque in relation to the energy requirement for the entire journey give rise to a complex optimization problem.

Figure 4: Example of the efficiency of a gasoline internal-combustion engine depending on speed and torque

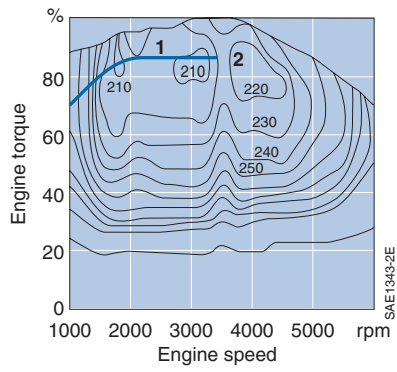

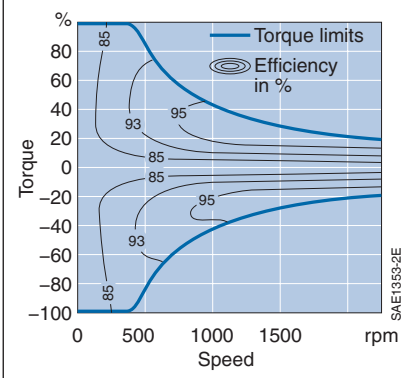

Figure 5: Example of the efficiency of an electrical machine depending on speed and torque within their physical limits [5]

Torque > 0: motor mode,
Torque < 0: generator mode.

Equivalent consumption minimization strategy

A method for solving the previously explained problem is an equivalent consumption minimization strategy (ECMS). The term "equivalent consumption" comes about as a result of the ECMS attempting to make consumption of electrical energy from the battery comparable with fuel consumption. This strategy optimizes the torque distribution or the power distribution between an electrical machine and an internal-combustion engine by attempting to store and utilize electrical energy in the battery with the highest possible global efficiency (overall efficiency of all the system elements involved). The ECMS achieves this by taking account of losses of the internal-combustion engine, the electrical machine (including inverter), and the battery.

The idea behind the ECMS is to find a way to compare the power delivered by the internal-combustion engine with the power of the electric system. This is achieved by using an equivalence factor s comprising several aspects for optimizing the torque distribution between engines. The equivalence factor will be described in detail later.

The power requested by the driver P_D is the sum total of the mechanical power of the internal-combustion engine P_{ICE} and that of the electrical machine P_{EM}.

$$P_D = P_{ICE} + P_{EM} . \quad (1)$$

The ECMS is based on a cost function (equation (2)) in which the equivalence powers P_{Eq} are considered as costs. This cost function must then be minimized:

$$P_{Eq} = P_F + s\, P_B . \quad (2)$$

P_F and P_B are the power figures that the system must deliver to achieve the desired power [6], s is the equivalence factor. P_F is the power obtained from the fuel for the internal-combustion engine; it is obtained from the sum total of the engine power P_{ICE} and the engine losses P_{ICEL}. P_B is the power drawn from the battery; it is obtained from the sum total of the mechanical power of the electrical machine P_{EM} and the losses in the machine P_{EL}.

Consequently:

$$P_{Eq} = P_{ICE} + P_{ICEL} + s\,(P_{EM} + P_{EL}) . \quad (3)$$

The desired optimum from equation (3) is the point at which the overall system losses are minimized.

The losses P_{ICEL} and P_{EL} are generally determined empirically by way of program maps depending on the speed and the torque of the internal-combustion engine and the electrical machine, as shown in Figures 4 and 5. The values of P_{ICE} and P_{EM} for the operating points at which the losses are minimized are determined by an optimization algorithm which evaluates a multitude of P_{ICE} and P_{EM} combinations and stores the combination for which P_{Eq} assumes the lowest value.

Figure 6 shows some results by way of example of an ECMS optimization. The minimum equivalence power constitutes here the optimal torque distribution based on the cost function. Figure 6a shows the equivalence power for the hybrid drive in kW (y-axis) plotted against the torque of the electrical machine in Nm (x-axis) at an internal-combustion-engine and electrical-machine speed of 1500 rpm and a total torque demand of 120 Nm. The shift towards a negative electrical-machine torque (i.e., generator operation and charging of the battery) with a lower SOC becomes clear in Figure 6a. The equivalence power for electric driving at which the driver's overall torque request is effected via the electrical machine and the internal-combustion engine is isolated and switched off is also shown in Figure 6a for two SOC values. At the higher SOC value for this combination of driver-requested torque and drivetrain speed the equivalence power for electric driving is lower than the best possible torque distribution for hybrid driving.

Figure 6b shows for two SOC values the equivalence-power levels for hybrid drive and electrical-machine torque at an internal-combustion-engine and electrical-machine torque of 3000 rpm and a total torque demand of 400 Nm.

Equivalence factor

The equivalence factor s plays a key role in the ECMS by providing a comparison

between the power from the battery and the fuel. The equivalence factor is typically subdivided into two parts: a constant s_0 and an SOC-based correction. The s_0 component depends on the future speed and the load profile of the vehicle. Because this information can only be estimated, a correction of s_0 is made based on the deviation between the desired and the actual SOC of the battery. This also serves to maintain the SOC in a range so that charging or discharging is always possible where required. Figure 7 shows a potential realization of the behavior [3].

One drawback of the ECMS is that to calculate the optimal power distribution in the hybrid driving mode equation (3) generally cannot be mathematically solved for the minimum. The equivalence power must therefore be calculated several times in order to find the optimal solution. This results in a high computing-capacity requirement [7].

Selection of the optimal operating mode
As already mentioned, the strategy must select which operating mode – hybrid or purely electric driving – is optimal. To find the best solution, the equivalence power with the best power distribution in the hybrid driving mode is compared with the equivalence power in the electric driving mode. The prerequisite for this is that the driver request can be completely fulfilled by the electrical machine and the internal-combustion engine has no losses because it is isolated and switched off. The mode in which the lowest equivalent overall power can be achieved is then selected as the optimal energy mode.

Figure 7: Possible behavior curve of the dependence of equivalence factor s as a function of state of charge (SOC)
1 Example of the SOC end value for a driving cycle.

1 Hybrid driving, state of charge SOC = 30 %,
2 Hybrid driving, state of charge SOC = 80 %.
A Cost minimum for hybrid driving with SOC = 30 %,
B Costs of electric driving with SOC = 30 %,
C Costs of electric driving with SOC = 80 %,
D Cost minimum for hybrid driving with SOC = 30 %,
E Cost minimum for hybrid driving with SOC = 80 %.

Map-based strategies
A common type of control-based strategy is a map-based strategy. In this approach, the optimal torque distribution for example from program maps can be determined on the basis of driving conditions. The program maps which are to be selected to determine the torque distribution are determined on the basis of a set of rules which are dependent on system properties such as for example SOC classification (high, medium, low).

Map-based strategies offer the following advantages and disadvantages compared with an optimization-based operating strategy, for example an ECMS approach.

Advantages of a map-based strategy compared with the ECMS
– Freedom from calibration offers the implementer when calibrating the data (e.g., program maps) more possibilities to determine the behavior of the drivetrain in certain driving situations (e.g., combination of SOC, driver request, gear selection).
– Less computing time in real time is required because the decision as to which program maps are to be used and calling up the desired value from the program maps take place only once per optimization time step.
– In the solution it is less probable that the optimal torque distribution will exhibit great leaps with minimal changes to the driving conditions.

Disadvantages of a map-based strategy compared with the ECMS
– Major demands are made of data storage, some series solutions have more than 100 calibration curves and maps to cover all the combinations of relevant input parameters adequately.
– It is not possible to transfer the calibration from one vehicle model to another because the calibration of the individual curves and maps is based not on the physical properties of the individual components but on the combined effects of all the components in the system. In comparison, an ECMS calibration typically consist primarily of program maps that show the loss characteristics of the internal-combustion engine, the electrical machine and the battery individually.
– There is no capacity to react to changes in the environmental conditions. Depending on the implementation an ECMS can adapt online if the equivalence factor changes on account of a long-term deviation between the desired and the actual battery SOC.

On the basis of these advantages and disadvantages both equivalent consumption minimization strategies (ECMS, i.e., optimization-based strategies) and map-based strategies are used by a number of vehicle manufacturers.

Outlook – Artificial intelligence and neural networks
Neural networks (NNs) simulate the workings of the brain, permit a kind of biological information processing, and are a technical concept for solving different types of problems, including pattern recognition, prediction, planning, etc. [8]. Neural networks are the usual modules of artificial intelligence. A neural network consists of a combination of
– neurons which are interconnected (Figure 8),
– weights which define the interactions between inputs to the neural network and the neurons and interactions between neurons.

A neural network is adapted by a training process in which a lot of data are used with combinations of inputs to the neural network and resulting “correct” outputs. The training process adapts the weights in the neural network to be able to depict all the training data in the best possible way (see for example [8]).

Furthermore, progress is being made in the field of neural networks and their use in recognizing situations and trends and in solving optimization with appropriate accuracy. Generally speaking, data-based processes like neural networks have the reputation of imposing high demands on computing capacity and data storage. Interestingly, studies have shown that an efficiently designed neural network can deliver virtually optimal results for an

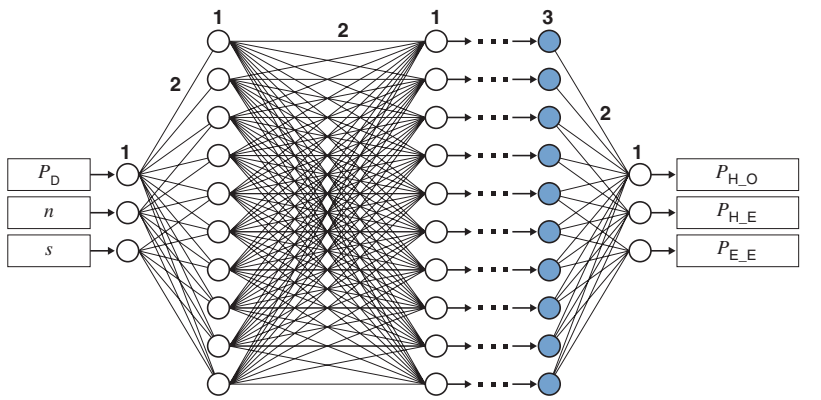
operating strategy for hybrid drives with fewer online computing resources and data-storage requirements than an ECMS method [3].

General design of a neural network for a hybrid operating strategy

As already mentioned, the P2 topology facilitates two driving modes, namely hybrid driving and purely electric driving. Therefore the solution of the neural network must not only determined the optimal mechanical power of the electrical machine in the hybrid driving mode but also provide information to facilitate the decision as to whether the electric or hybrid driving mode is better from the point of view of energy optimization. A neural network with three outputs for example could be selected to solve this optimization problem (Figure 8):

– The mechanical power of the electrical machine equating to the best solution in the hybrid driving mode (P_{H_O}),
– the equivalent overall power with the best power or torque distribution in the hybrid driving mode (P_{H_E}), and
– the equivalent overall power in the electric driving mode assuming that the driver's torque request is completely fulfilled by the electrical machine (P_{E_E}).

The decision as to which driving mode (hybrid or electric driving) is to be selected can then be made in the software outside the neural network, where for example the energy required for the transition of the driving mode and for driver-acceptance reasons the permissible time between the transitions are taken into consideration (the driver is informed of the mode change typically via a display).



As shown in Figure 8, the network inputs are the power requested by the driver (P_D), the speed n of the internal-combustion engine and the electrical machine, and the equivalence factor s.

Application

To obtain data for the training, data records, i.e., combinations of values for P_D, n and s, were generated on the basis of a general test plan (design of experiments, DOE), with which the entire solution space

Figure 8: Concept of a neural network for a drivetrain operating strategy of a hybrid drive

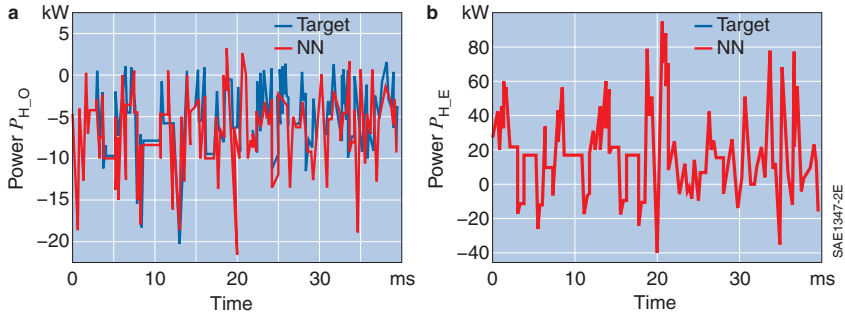
P_{E_E} Equivalent overall power with optimization of the costs of purely electric driving.

is depicted by combinations of P_D, n and s. The resulting data records were then fed into an ECMS model which was already calibrated for the target vehicle in order to supply the "correct" answers for training the neural network. In addition, test cases were created for the neural network using international driving cycles in order to represent real driving situations.

Use of plasticity in an NN-based HEV operating strategy

Networks with the ability to remember and to learn from experienced have garnered a lot of attention in the last few years. A promising form of network was published in [9]. The authors introduced a neural network with plastic weights, i.e., weights that follow Hebb's rule from biology and mean that the connections between neurons (synapses) change depending on the intensity of their interaction [10]. By applying plasticity to artificial networks it is possible to learn even after the first training and thereby facilitate adaptation to actual situations. Compared with LSTM networks (Long Short-Time Memory) the architecture of plastic neural networks is much less complex and requires less memory capacity, which makes them ideal for use in an electronic control unit for a vehicle.



The shaded neurons in Figure 8 are affected by the expansion to a plastic neural network [3].

The results are shown in Figure 9. Figure 9a shows the direct comparison of the resulting optimal mechanical power of the electrical machine over time. Figure 9b shows the results when the mechanical NN power is converted into an equivalent power and compared with the equivalence power from the basic ECMS result. There is no discernible difference here between the NN result and the ECMS. Figure 9b shows that – although the NN results for the optimal mechanical power of the electrical machine deviate from those of the ECMS result – the deviation with regard to energy consumption makes no difference. This is useful because under certain conditions a large difference in the power or torque distribution can only have a very small influence on the overall energy consumption.

The neural network was able to deliver results comparable with an ECMS approach with regard to global efficiency while is demonstrated much fewer computation steps than the ECMS and much fewer data-storage requirements than a map-based strategy. The addition of the plasticity terms also reduced the overall system error while the advantages with regard to storage capacity and computing time were retained [3].

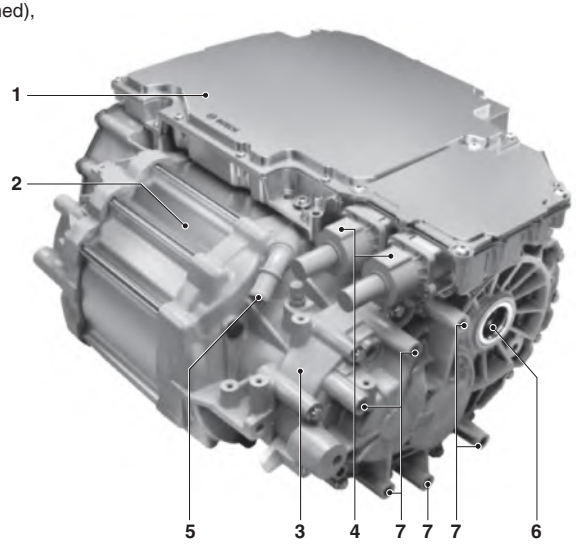
Electric final-drive unit

The electric final-drive unit (e-axle, known by Bosch as eAxle) is a compact electric drive solution for battery-electric vehicles and for fuel-cell and hybrid vehicles. The three relevant components of an electric drive – the power electronics (inverter), the electrical machine (motor), and the transmission – are combined in a functional unit (Figure 1).

Thanks to the functional integration of power electronics, electrical machine and transmission, the complexity can be significantly reduced in contrast to three separate components.

Functional component integration



Functions of components

The power electronics, also known as an inverter, is required to generate from the direct voltage of the vehicle's traction battery via the resulting direct current (DC) a frequency-variable alternating voltage or a 3-phase alternating current (AC) for the electrical machine. A rotating field and with it a torque is generated in the electrical machine with the aid of this 3-phase alternating current.

The mounted transmission serves to transmit the torque for the vehicle drive. A two-stage spur-gear drive is usually used. The transmission has a fixed step-down ratio between 8 and 13 and a differential for compensating different wheel speeds, e.g., when cornering. Multi-speed solutions may also be used as an alternative to the solution with a fixed step-down ratio. Continuously variable transmissions (CVTs) are also possible.

Figure 1: Design of the electric final-drive unit (e-axle) from Bosch

2 Electrical machine,
3 Transmission,
4 HV-connection to traction battery (HV: High Voltage),
5 Connection to cooling circuit,
6 Differential output (connection of side shafts),
7 Mechanical connecting points.

Manual transmissions with up to four gears are also used in the commercial-vehicle sector with the aim of providing a high starting torque for the acceleration process and an operating point with optimum efficiency at constant speed.

By converting the electrical energy, the power electronics also regulates the entire electric drive to the required setpoint torque and monitors the components for safe operation, e.g., by measuring the critical component temperatures and further system limit values.

The design and the function of the power electronics and the electrical machine are described in detail elsewhere (see Inverters, electrical machines for propulsion).

Construction

The electrical machine and the transmission are permanently joined to each other at the housing end via a common end plate (end-face housing component). To transmit the torque the electrical machine's rotor shaft is connected with the transmission input shaft, usually via a spline.

Alternatively, the rotor and the transmission can also be connected with each other via a common uninterrupted shaft, this arrangement often being used in smaller performance classes (< 100 kW) or oil-cooled electrical machines.

The end face pointing towards the transmission is also called the A-bearing side and the face pointing away from the transmission the B-bearing side.

The power electronics is integrated in the unit comprising electrical machine and transmission. The electrical connection between the power electronics and the electrical machine is established at the end pointing away from the transmission (B-bearing side) via three conductor bars (in the case of a 3-phase electrical machine). The conductor bars have flexible elements that guarantee the compensation of tolerances during installation and operation. The conductor bars are usually connected via screwed-crimped or welded joints, where for reasons of easy exchangeability and maintenance of the components detachable connections are preferred. The modularity in the e-axle design thereby achieved also enables the three components to be freely combined and configured, thus allowing the drive system to be individually adapted to the vehicle requirements.

Thermal layout

Thanks to the integration of the three components in a single drive system the e-axle's cooling system can be specifically matched and optimized to the system requirements. The e-axle is connected to the vehicle cooling circuit.

The coolant is as a rule routed through the e-axle serially (Figure 2). If flows through first the power electronics, then the electrical machine (in the case of a coolant-cooled electrical machine), and finally the transmission (if a heat exchanger is installed). Alternatively, several cooling circuits can be deployed in parallel, e.g., if the power electronics and the transmission are in each case connected separately to the vehicle's cooling system.

Aside from the described cooling concepts, there are also special solutions such as for example pure passive cooling via the surroundings or air specifically flowing round or through the components.

Cooling of the power electronics

The power electronics is usually cooled by the coolant used in the vehicle (e.g., glycol/water mixture). To this end the coolant is routed through a cooler (e.g., pin-fin cooler with pin-shaped heat sink) inside the power electronics, which is connected with the loss-affected components (as a rule power modules and link capacitor). Consequently the heat loss from these components is dissipated in the best possible way.

Cooling of the electrical machine

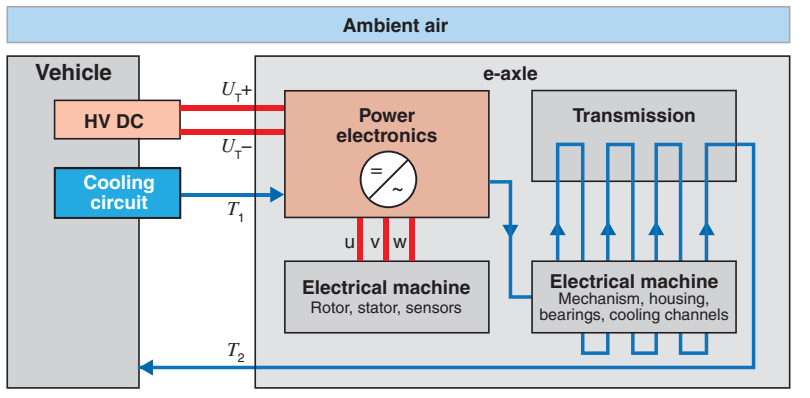
The electrical machine can be cooled by the coolant in a water jacket or directly by the transmission oil by means of heat exchanger. When coolant is used, this is directed through channels in the housing jacket (e.g., helix- or meander-shaped). This solution is therefore also known as water-jacket cooling.

As an alternative to water-jacket cooling the oil from the transmission that is used to lubricate and cool the components

there may also be used. In this case, the electrical machine and the transmission share a common oil circuit with the oil routed directly into the inside of the machine and consequently also reaching the winding. Because the oil use is electrically non-conductive, it can be routed specifically to the electrical machine's heat sources. As a result, despite having a generally poorer cooling effect and higher viscosity, it delivers the necessary heat dissipation. The oil is supplied to the rotor via the rotor shaft and to the stator via grooves and channels. In this case, the arrangement is called a wet-running electrical machine. The key advantage of a wet-running electrical machine is the cooling of the winding overhang for greater performance.

Because of the direct heat dissipation, generally higher continuous outputs can be achieved with this solution with minimal design and engineering effort. In addition, with the omission of the water jacket, the electrical-machine housing can have a simpler and more compact design. It is, however, essential to ensure the chemical resistance of the materials wetted with oil, particularly the copper conductors and the insulation materials. In addition, the oils used for cooling can as a rule only be used up to a maximum temperature of approx. 150 to 180 °C. This must be taken into account for the permissible stator temperature. Because the stator in a water-cooled machine with maximum short-time performance can also reach temperatures of over 200 °C, the short-time performance may in contrast have to be reduced in an oil-cooled machine.

Both cooling media can furthermore be used in combination, e.g., cooling the jacket with coolant and cooling the rotor with oil. But, in view of the increased sealing effort involved, this combination is not very widely used.



Cooling of the transmission

The oil used for lubrication in the transmission absorbs the heat loss from tooth-flank contacts. The oil must be cooled as a result. A heat exchanger, in which the heat if the oil is dissipated to the coolant, is usually used for this purpose.

Here too different cooling concepts are used to suit the performance class. In low performance classes (< 100 to 150 kW) the transmission oil is often cooled purely by passive cooling via the transmission housing with the aid of fins. In mid and high performance classes solutions integrated into the housing, e.g., channels and pin structures, can be used to dissipate the heat of the transmission oil to the

coolant. Oil-to-coolant heat exchangers integrated into the oil sump are also used.

Alternative topologies
Aside from the described design, which is also referred to as axially parallel because the output shaft or the differential output is arranged parallel to the electrical machine's rotor shaft, there are further e-axle topologies.

Coaxial e-axle topology
In the coaxial e-axle topology the differential output is positioned coaxially to the electrical machine's rotor shaft. The torque at the end facing away from the transmission (B-bearing side) is provided by an additional intermediate shaft, which is guided by the hollow rotor shaft. The transmission can in this topology take the form of a two-stage spur-gear drive with countershaft or a single- or multi-stage planetary gear. The advantages of the coaxial topology are the compact design and consequently small installation-space requirement. The disadvantages are the increased costs owing to the mechanical complexity.

Arrangement of the power electronics
Aside from the axial arrangement, the topology of the e-axle is determined by the position of the power electronics. A distinction is made here between jacket-side and end-face installation.

In the case of jacket-side installation, the power electronics is positioned on the electrical machine's jacket surface. Here the power electronics can be vertically or horizontally aligned (see figure 1). Crucial to optimum alignment are, aside from the vehicle architecture, the desired accessibility in the installed state and the connection of the HV (high-voltage) conductor bars and the signal cables.

In the case of end-face installation, the power electronics is located on the end face of the electrical machine pointing away from the transmission (B-bearing side). This position known primarily from small three-phase AC drives in vehicles (e.g., radiator fans, transmission oil pumps, electric air-conditioning compressors) is also used in e-axles of smaller performance classes (< 100 kW).

T-shaped topology
Another topology that is being increasingly used is T-shaped topology. Here the transmission forms the central unit in the middle of the e-axle and accommodates the other two components. The electrical machine and the power electronics are mounted at the transmission end and the opposite end respectively. The HV conductor bars and the signal cables are routed past but very close to or even through the transmission. The advantage of this topology is that it uses side shafts of equal length without the need for an intermediate shaft. The drawbacks are the large installation-space requirement and the thermal effects of the transmission on the power electronics.

Special solutions
As well as the widely used e-axle topologies described here there are numerous special solutions, but these will not be considered any further here.

Vehicle integration and interfaces

The e-axle can be installed in the vehicle both on the front axle and on the rear axle. All-wheel applications are also possible accordingly. When it comes to the positioning of the e-axle a distinction is made between two arrangements, with the position of the electrical machine being the critical factor. This can be positioned either facing the center of the vehicle (or the traction battery) or facing away from it (Figure 3).

Arrangement of the e-axle in the vehicle

Arrangement facing the center of the vehicle

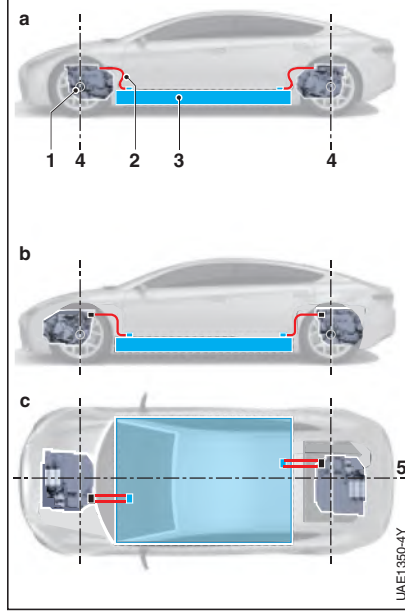
Characteristic of the arrangement facing the center of the vehicle is the position of the electrical machine between the two vehicle axles, i.e., within the wheelbase along similar lines to a mid-engine arrangement (Figure 3a).

The differential output of the e-axle usually lies in the cross-sectional plane of the vehicle axis. This position can however also be varied slightly according to the approach angles of the side shafts that can be achieved by the shaft joints, for example to create more space for the traction battery.

The key benefit of the arrangement facing the center of the vehicle is the small installation-space requirement of the e-axle in the area in front of the front axle and thus in the crash zone. In addition, further components can be arranged in front of the e-axle on the front axle, e.g., the steering box or the air-conditioning compressor. The drawback is the large installation-space requirement between the axles, which is usually used for the battery.

Arrangement facing away from the center of the vehicle

In the arrangement facing away from the center of the vehicle the electrical machine is situated in the area in front of the front axle, the upshot of which is that more space can be made available between the axles for the battery.



Choice of arrangement in practice

There is essentially no preferred solution when it comes to choosing the e-axle arrangement. This is very much dependent on the vehicle architecture. Both arrangements are therefore employed in virtually equal measure.

In each case the crash safety of the HV components must be taken into consideration. If the power electronics is installed upright on the jacket side, it is important to ensure that it is positioned facing the center of the vehicle and therefore does not impinge on the crash zone in the area in front of the front axle. This applies to all the arrangements described because

5 Center line of cross-sectional plane.

damaged cables must be exchanged completely in the event of an accident.

Interfaces
The following interfaces are featured between the e-axle and the vehicle: Electrical interfaces for high voltages (HV, >60 V) and low voltages (LV, 12 V for passenger cars, 24 V for commercial vehicles), signal / communication interfaces, and hydraulic and mechanical interfaces.

Electrical interfaces
The electrical HV connection to the traction battery is usually achieved with cables. The connection to the e-axle can be made by connectors or screw contacts. For safety reasons it is important when laying the cables to ensure that these have sufficient leeway to enable the e-axle to move particularly in the event of a crash and prevent them from ripping off and leaving open contacts. Reference is made in the cable routing to an S-bend (S-shaped cable routing) (see Figure 3).

The electrical connection to the e-axle power supply from the LV vehicle electrical system (e.g., for the electronics) and the communication interface to the vehicle (e.g., via CAN) are usually bundled in a connector with several pins. Often also featured are further vehicle-individual signal or power supplies (e.g., crash signal, HV interlock for monitoring correct connection of the plug-in connections in the HV circuit). The ground connection is established by a conducting connection from the e-axle housing to the vehicle's body structure.

Hydraulic interfaces
The hydraulic connection to the vehicle cooling system is achieved by hoses and hose clamps or by special quick-release locks.

Mechanical interfaces
The mechanical interfaces include the connection of the side shafts to transmit the torque to the wheels and the mounting of the e-axle in the vehicle body. The vehicle-side joints of the side shafts are inserted with splines into the two differential outputs. Alternatively, other joints may also be used, e.g., bolted flanges.

The e-axle is usually mounted in the vehicle body by means of bolted rubber mounts. The rubber mounts reduce the forces on the vehicle structure generated by the dynamic torque support of the e-axle and isolate the e-axle acoustically from the vehicle structure. Consequently, the structure-borne noise emitted by the e-axle can only be transmitted to a small extent to the vehicle structure.

Depending on the vehicle architecture, an auxiliary frame can also be used which contains the connection of the e-axle and the chassis. This auxiliary frame is in most cases also connected via bolted rubber mounts with the vehicle body, which brings about a double acoustic isolation of the drive from the vehicle body.

The compatibility of the e-axle with different vehicle-individual connection points is achieved through a number of bolting points on the e-axle (see Figure 1), which form by way of additional bolted brackets (support elements) the connection to the vehicle body. Furthermore, thanks to the modularity of the e-axle, the housing parts to be joined can also be fashioned individually for each vehicle and the e-axle can thus be connected directly with the vehicle body without the use of brackets.

Performance classes and performance characteristic

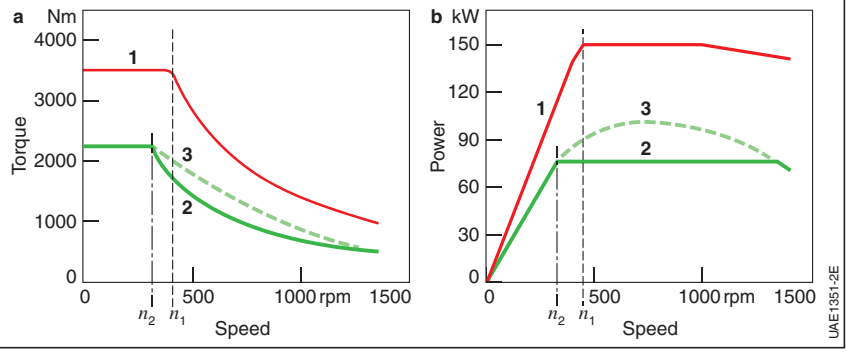
Performance classes

The e-axle can be individually adapted by means of scaling and the efficient combination of components to the vehicle segment and usage scenario. Based on current market requirements there is a performance spectrum of 50 to 300 kW, with the following performance classes having been established within this spectrum:

– ≤ 110 kW
– 120 to 150 kW
– 180 to 200 kW
– ≥ 250 kW

The largest shares are currently in the performance classes up to 150 kW, which are primarily used in the vehicle segments A (subcompact cars) through C (mid-size cars).

Performance characteristic



The provision of power to the e-axle is determined by the performance characteristic of the three components, where the respective limitations of the components overlap (by superposition) and in their totality define the performance characteristic of the e-axle. Added to this are possible limitations of the connecting parts, e.g., the AC conductor bars or the DC connection of the traction battery and the EMC filter components (electromagnetic compatibility).

The performance characteristic of the e-axle is derived from the design (installation space and layout) and the thermal interactions of the components used. Integrating the components in the e-axle offers advantages, but the thermal interactions must be taken into account.

In the provision of power a distinction is basically drawn between short-time performance (provision of power / maximum torque, as a rule between 10 s and 30 s operating duration) and continuous performance (usually 30 min operating duration) (Figure 4). The exact definition of short-time and continuous performance including the boundary conditions can vary from manufacturer to manufacturer.

Crucial to the short-time provision of the maximum torque particularly in the base-speed range (approx. between standstill and specific speed n_1, n_2 in Figure 4) is the provision of the maximum current by the power electronics. It must also be ensured during the short period of 10 s that the heat loss generated due to the switching losses and the ohmic losses – particularly in the power modules and in the link capacitor, but also in the other current-carrying com-

ponents – can be dissipated and an overheating of the components is prevented. The maximum current provided by the power electronics leads in the electrical machine to the requested torque, where further component-specific boundary conditions must be observed, e.g., maximum permissible current in the electric conductors and dissipated of the heat loss arising here to the housing or the cooling medium. The maximum torque provided is crucial to the design of the transmission and other mechanical components (e.g., rotor shaft and splines).

Owing to the compact function integration in the e-axle a sufficient heat-loss dissipation within the permissible driving-function areas poses a particular challenge. In this connection, local overheating, which leads to aging and damage mechanisms within the power electronics, electrical-machine and transmission subassemblies, must be effectively prevented under different driving and operating conditions. To ensure this, various temperature sensors whose signals provide the necessary input variables for installed software component-protection models are placed inside the e-axle. These installed models help to provide comprehensive component protection inside the e-axle which depending on the different driving and operating conditions automatically ensures a thermal overload regardless of driver intervention.

The heat loss arising in the electrical machine must be dissipated in the best way possible by the cooling medium. This gives rise to the theoretical continuous performance of the electrical machine. Furthermore, the transmission's cooling concept is designed for a defined continuous output to prevent the permissible oil temperature from being exceeded. The real continuous performance of the e-axle is obtained with these boundary conditions (Figure 4). Compared with the theoretical continuous performance it is reduced above the specific speed, on the one hand for component-protection reasons and on the other hand to be able to represent a uniform output over a larger speed range. Continuous performance can be further increased by effective cooling concepts and measures, where however always the relevant application must be taken into consideration and it is necessary to weigh which continuous output is required in the respective application.

The dominant performance characteristic depends on usage. If the e-axle operates as the main drive, continuous performance is more relevant. In the event that it acts as an auxiliary drive on the axle not driven by the main drive (e.g., all-wheel drive, boost mode), short-time performance depending on the repetition rate is more relevant.

Efficiency

As well as the targeted adaptation of the performance characteristic to the respective application, another development objective is to reduce the losses of the three components and thus to increase system efficiency. To determine system efficiency, it is necessary to multiply the efficiency maps of the components by each other. Through the targeted optimization of the individual components in the system context, it is thus possible to achieve an efficiency of up to 96 % at selected operating points in the e-axle.

Furthermore, reducing the losses has a positive effect on the performance characteristic, particularly continuous performance. When the power dissipation of a component is reduced, that component is heated less with the result that with constant cooling power the limit for continuous performance is increased or cooling power can be reduced.

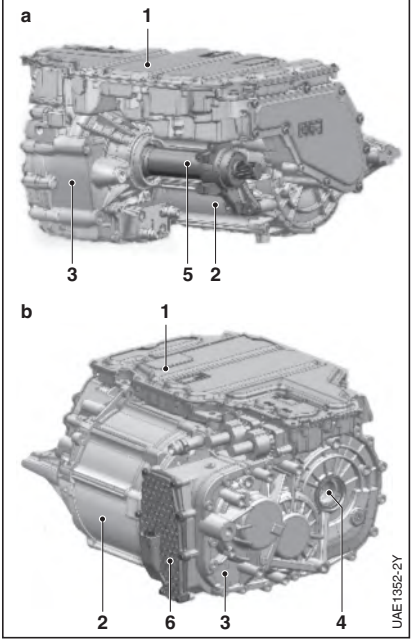
Scalability

Through scaling and the efficient combination of the components, the torque and output of the e-axle can be matched to the specific requirements with discrete stages in the combination of the components having been established along similar lines to the discrete performance classes listed at the outset. A certain degree of continuous scaling is possible within these stages.

The output or the maximum current made available in the power electronics is defined here primarily via the chip surface area of the power modules. The peripheral components of the power electronics (e.g., link capacitor and conductor bars) are also adapted accordingly.

The achievable electrical-machine torque can be scaled by means of the machine's diameter or length. The greater the diameter or the length, the greater the torque for the same current and same number of turns of the electrical machine. Furthermore, the torque and output of the electrical machine can varied by varying the number of turns (see Electrical machines for motor-vehicle propulsion).

It is possible by varying the step-down ration to vary between the maximum torque and the maximum rotational speed. The higher the step-down ratio, the higher (for the same electrical machine) the torque and the lower the maximum rotational speed. Varying the step-down ratio does not affect the maximum output.



Adaptation for application

Additional optional elements can furthermore be integrated in the e-axle. These are described in brief in the following.

Intermediate shaft
Because the e-axle output shafts are not situated centrally in the vehicle in relation to the installation position, an intermediate shaft (Figure 5a) can be used to obtain side shafts of equal length and a higher number of common parts for the vehicle manufacturer. Beyond the pure cost advantage, this is also a prerequisite for symmetrical driving dynamics.

Parking lock
The parking lock (Figure 5b) is a positive mechanical lock which prevents the vehicle

Figure 5: Additional e-axle components
a) View with intermediate shaft,
b) View with parking lock.
1 Power electronics, 2 Electrical machine,
3 Transmission, 4 Differential output (connection of side shafts), 5 Intermediate shaft,
6 Parking lock (as option).

from accidentally moving (cf. position P on automatic or dual-clutch transmissions).

The parking lock is preferably actuated electrically in the e-axle. Hydraulic and pneumatic actuations are also possible, but this is only useful if the appropriate peripherals are provided, for example in the case of a two-speed solution. The parking lock can also be actuated via a mechanical cable.

The translatory and rotatory vehicle masses are mechanically locked by means of a parking-lock gear (permanently connected with a transmission shaft) and a parking-lock pawl (housing-affixed). This ensures that the driver leaves the vehicle in a safe state.

To prevent the vehicle from coming to an uncontrolled or an unwanted abrupt stop, the parking lock can no longer be engaged above a so-called ratchet or pawl speed (approx. walking speed). This is usually implemented by a mechanical rejection of the pawl at the parking-lock gear.

The customary parking brake used to date in vehicles with manually shifted transmissions generates, in contrast to the parking lock, a frictionally engaged prevention operation which cannot prevent the vehicle from rolling further in unfavorable conditions (e.g., laden vehicle with trailer on a hill). But frictionally engaged parking brakes are also used in electric vehicles.

Disconnect or disengagement unit

The electrical machine can be disconnected from the vehicle's side shafts with the aid of a disconnect unit in order to eliminate the drag losses of the electrical machine and also those of the transmission when the vehicle is rolling. This offers, in particular in the case of a permanent-magnet synchronous machine (PSM), the advantage that this does not rotate and consequently no voltage is induced and no kinetic energy of rotation is converted. This makes coasting possible, whereby the vehicle rolls without its own propulsion power.

Furthermore, it can also be beneficial in all-wheel or hybrid applications to disengage the auxiliary drive and thereby minimize the losses. During the disengagement process, the electrical machine is synchronized without torque in the disengagement unit, rotationally disconnected, and brought to a controlled standstill. During the reconnect process, the electrical machine is synchronized accordingly without load to the current rotation speed of the rotating transmission or side shaft and then connected. Positive clutches have become established here.

The disengagement unit can essentially be implemented on each of the rotating shafts inside the e-axle or also on the side shafts. In this way it is possible to disengage the rotatory masses including their friction points and thus also eliminate the transmission's drag losses.

When a PSM is used, it is also possible to tow the vehicle rolling on its wheels without inducing a voltage which otherwise is normally reduced for example by an active short circuit. As a result, the mechanical and thermal system loads are reduced and towing is made easier or made possible at all.

With multi-speed transmissions it is also possible to disconnect via the clutch provided anyway.

Connecting the air-conditioning compressor

As described already, the e-axle is isolated from the vehicle structure, as a result of which the emitted structure-borne noise is reduced. This property, together with short mechanical power-transmission paths, offers the possibility of mounting the air-conditioning compressor directly on the e-axle. The e-axle's high-voltage distributor is used for the electrical power supply. Unlike an internal-combustion engine, there is the additional benefit of lower thermal load by the electric drive because the latter produces no waste combustion heat.

Electric drives with fuel cell

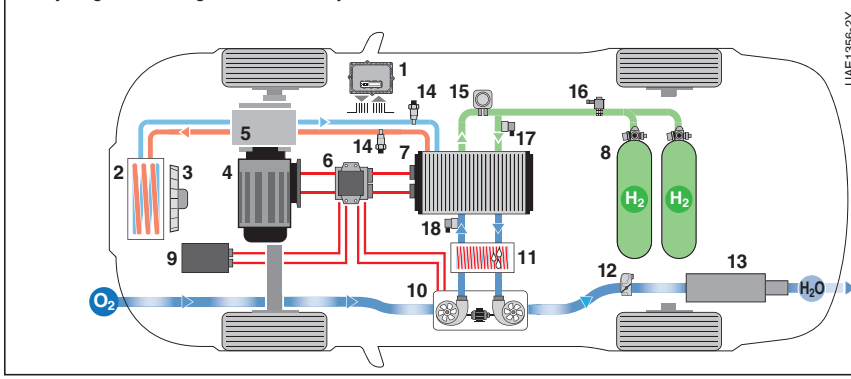
Features

Fuel-cell electric vehicles (FCEVs) are electric vehicles. They enable the climate-neutral carriage of persons and goods by using regeneratively produced hydrogen. The fuel-cell electric drive (Figure 1) consists of the electric drive, as is known from the battery-electric drive, and the fuel-cell system. At the heart of the fuel-cell system is the fuel-cell stack, which consists of individual fuel cells.

Fuel cells are electrochemical converters which convert the chemical energy of the fuel directly into electrical energy. There is a large number of different fuel-cell types that use different fuels and components. For motor-vehicle applications currently the low-temperature proton-exchange membrane fuel cell (LT-PEMFC; temperature < 100 °C), which is run on hydrogen (H_2) and oxygen (O_2), is the most interesting. In such a fuel cell the hydrogen reacts with oxygen to create water, releasing electrical energy in the process.

Advantages of fuel cells

Within the field of electromobility fuel-cell drives have the advantage of permitting the accustomed convenience of conventional vehicles such as short refueling time and long range with existing H_2 infrastructure. As in an internal-combustion engine energy storage and conversion are separated, which makes increased range possible by tank expansion. In particular, fuel-cell drives therefore have an advantage when it comes to vehicles which call for high availability, useful load, and range. Examples include trucks, city and intercity buses, trains and ships, as well as commercially used vehicles such as taxis and company cars.



Fuel cells do not produce any greenhouse gases or air pollutants locally during operation.

Expansion of the fuel-cell system with a battery

Fuel-cell vehicles are electric vehicles in which the energy for the electric drive is made available by the fuel-cell system. For several reasons, it is sensible to expand the drivetrain to include a traction battery:

Figure 1: Drivetrain of a fuel-cell electric passenger car

1 Fuel-cell ECU, 2 Radiator, 3 Radiator fan, 4 e-machine, 5 Transmission, 6 Power electronics, 7 Fuel-cell stack, 8 Hydrogen tank, 9 HV battery, 10 Air compressor, 11 Humidifier, 12 Pressure-control valve, 13 Muffler, 14 Temperature-pressure sensor, 15 Anode recirculation fan, 16 Tank shutoff valve, 17 Hydrogen-metering valve, 18 Safety valve.

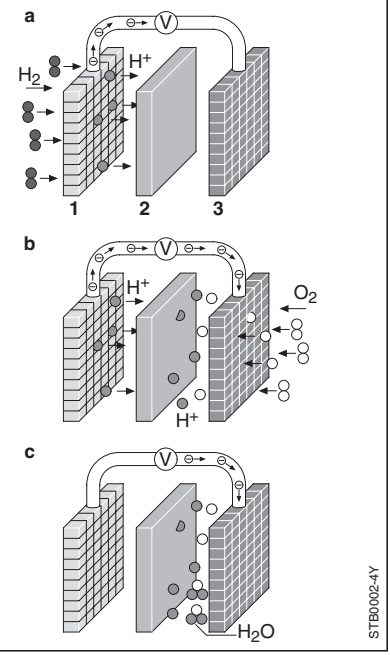
– the energy gained through recuperative braking can be temporarily stored,
– the dynamic response of the drivetrain can be further increased,
– the efficiency of the drivetrain can be further increased by shifting the load point of the fuel-cell system.

The ratio of battery power and total power varies for different applications. Typically, fuel-cell systems are used as the primary energy source in the drivetrain. Such vehicles are characterized as strong fuel-cell electric vehicles.

Alternatively, the battery can have a much greater power rating and energy content, and be recharged by a smaller fuel-cell system where necessary. This drive concept is called fuel-cell range extender because it allows the range of battery electric vehicles (BEVs) to be increased.

Fuel-cell system power ratings of up to 100 kW are usual in today's FCEVs in the passenger-car segment. Batteries have a power rating of up to 40 kW with an energy content of 1 to 2 kWh. In the commercial-vehicle sector either the higher fuel-cell power demand (200 to 400 kW) is realized by modular approaches (combination of several lower-power modules) or the fuel-cell system is directly configured for the higher power rating.

The system power is often also called net power to distinguish it from the stack power (gross power). The net power, i.e., the system power, is actually utilizable Fahrzeugaufbau for a concrete application. The stack power required for this is approximately 15 % higher because the internal assemblies of the system (particularly the air compressor) must be supplied.



Design and operating principle of the fuel cell

Operating principle

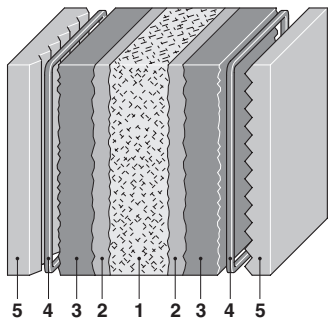
The LT-PEMFC consists of two electrodes (anode and cathode) which are electrically insulated by a polymer-electrolyte membrane (Figure 2). When the anode is supplied with hydrogen (H_2) and the cathode with oxygen (O_2, normally from the air), H_2 and O_2 react with each other even though they are not in direct contact with each other. The reaction is mediated by the membrane and the electric circuit (electron transport, e^-). The following reactions take place:

Anode: $H_2 \rightarrow 2\,H^+ + 2\,e^-$.
Cathode: $O_2 + 4\,H^+ + 4\,e^- \rightarrow 2\,H_2O$.
Overall reaction: $2\,H_2 + O_2 \rightarrow 2\,H_2O$.

Figure 2: Operating principle of the PEM fuel cell
a) Hydrogen oxidation at the anode,
b) Oxygen reduction at the cathode,
c) Water production.
1 Anode, 2 Membrane, 3 Cathode.

In the overall reaction hydrogen reacts with oxygen to produce water, in the course of which electrical energy and heat are generated. The electrical energy can be converted in the circuit to mechanical energy. The waste heat is dissipated via coolant channels.

Figure 3 shows the schematic design of a so-called "cell". Cells have a height of < 1 mm and an area of 200 to 400 cm^2.



Catalyst layers

The most important components of the fuel cell are the catalyst layers. This is where the chemical reactions which generate the current take place. All the components (including the catalyst layer itself) serve to make available to the catalyst particles within the catalyst layer

– the gaseous reactants (H_2, O_2) in sufficient quantity,
– protons (H^+) from the polymer-electrolyte phase fast enough,
– to offer a conductivity path to electrons,
– to carry off liquid and gaseous product water (H_2O).

Figure 3: Design of the PEM fuel cell

1 Membrane (electrolyte layer),
2 Electrodes (catalyst layer),
3 Gas-diffusion layers,
4 Gaskets,
5 Bipolar plates.

The gas flow begins in the bipolar plates (BPP, metallic or graphitic), which incorporate the channel structures. The gas diffuses via the channels into the gas-diffusion layers (GDL) and from there to the catalyst layer, where it can react (Figure 3).

The electrons flow from the catalyst layer into the gas-diffusion layers, then into the bipolar plates, and from there into the outer circuit (or into the neighboring cell). The protons (H^+) move from the anode through the membrane to the cathode. The product water must be transported from the catalyst layer via the gas-diffusion layers to the channels in the bipolar plate and from there outwards.

Transport mechanisms

Three transport mechanisms occur in the same volume in different phases:

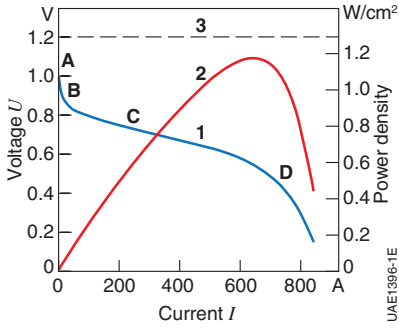
– H^+ through the aqueous component in the polymer-electrolyte membrane,
– gases and H_2O through pores, and
– e^- through a solid-body path.

Making possible all three paths with low resistances places great demands on the material and system design because even the scale at which transport must be guaranteed varies by several orders of magnitude:

– catalyst particles < 15 nm,
– catalyst layer < 30 µm,
– membrane thickness < 30 µm,
– gas-diffusion layer thickness < 300 µm,
– bipolar-plate thickness < 1 mm,
– cell area 200 to 400 cm^2,
– stack height < 1 m.

Electrical properties of the fuel cell

Shape of the polarization curve



The electrical property of a fuel cell is depicted by the so-called polarization curve (also known as the current-voltage characteristic or U-I characteristic). It generally has the shape depicted in Figure 4.

The voltage of the cell is a direct indicator of its electrical efficiency, where 1.23 V is 100 %. As current and power increase the electrical efficiency of the fuel cell decreases because different losses come into play.

Range A
In the de-energized state (the corresponding voltage is called OCV, open circuit voltage) the theoretical voltage of an H_2-O_2-LT-PEM fuel cell is 1.23 V, which is not achieved however in reality on account of losses (above all H_2 gas-passage losses). These losses cause a low current flow on the inside of the catalyst layer (above all the anode) which cannot be measured towards the outside, which is why the OCV is for the most part in the range of 0.9 to 1 V.

Range B
At low currents the voltage drops quickly first. Here losses which arise due to the chemical reaction of the reactants on the catalyst surface dominate. These losses increase rapidly with small electric currents, but hardly change at high currents (for details on the description of the reaction kinetics as per Butler-Volmer, see [1]). It is to be noted that range A is also actually reduced by this reaction kinetics of the leakage current.

Figure 4: Ranges of the polarization curve (current-voltage characteristic of a cell)
1 Cell voltage,
2 Power density,
3 Theoretical maximum voltage.
A…D Ranges.

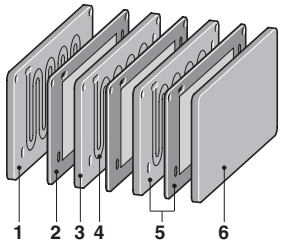
Range C
The comparatively linear section is called the ohmic range because the ohmic resistance of the fuel cell is dominant here for the gradient of the curve. The ohmic resistance is made up of the H^+ conductivity of the polymer-electrolyte membrane and the electrical bulk and contact resistances of the fuel-cell layers.

Range D
The inflection of the curve towards 0 V can be called the mass-transport range. The transport of reactants to the catalyst particles is the limiting factor here.

It is to be noted that the losses in the four ranges are always a combination of the losses described above and never is only one loss type (except for OCV) present.

Influences on the polarization curve
The shape of the polarization curve is dependent on the material property of the fuel cell, e.g., on the
– catalyst activity,
– catalyst load,
– membrane thickness,
– ionomer-exchange capacity,
– porosity of the gas-diffusion layers,
– hydrophobicity of the gas-diffusion layers,
– conductivity of the bipolar plates.

Even the operating method has a decisive influence on the shape of the polarization curve, e.g.,
– gas pressures,
– temperature,
– moisture,
– volumetric flow and stoichiometry.



The parameter set under which the polarization curve was plotted is decisive (above all the pressure) and should be observed without fail in a comparison of different fuel-cell types.

Fuel-cell stack
In order to achieve the high voltages required for a technical application, individual cells are electrically connected in series to form a stack (Figure 5). Each cell must be supplied separately with H_2, air, and coolant.

These fuel-cells consist, depending on the requirement, of up to 450 or more cells so that the maximum operating voltages can be up to 450 V.

Typically stacks in the power range up to 120 kW are used for passenger-car drives. High electric currents are achieved either by large membrane surfaces or improved fuel-cell materials (e.g., higher catalyst activities, better mass transport). Currents up to 450 A flow at full load automotive applications.

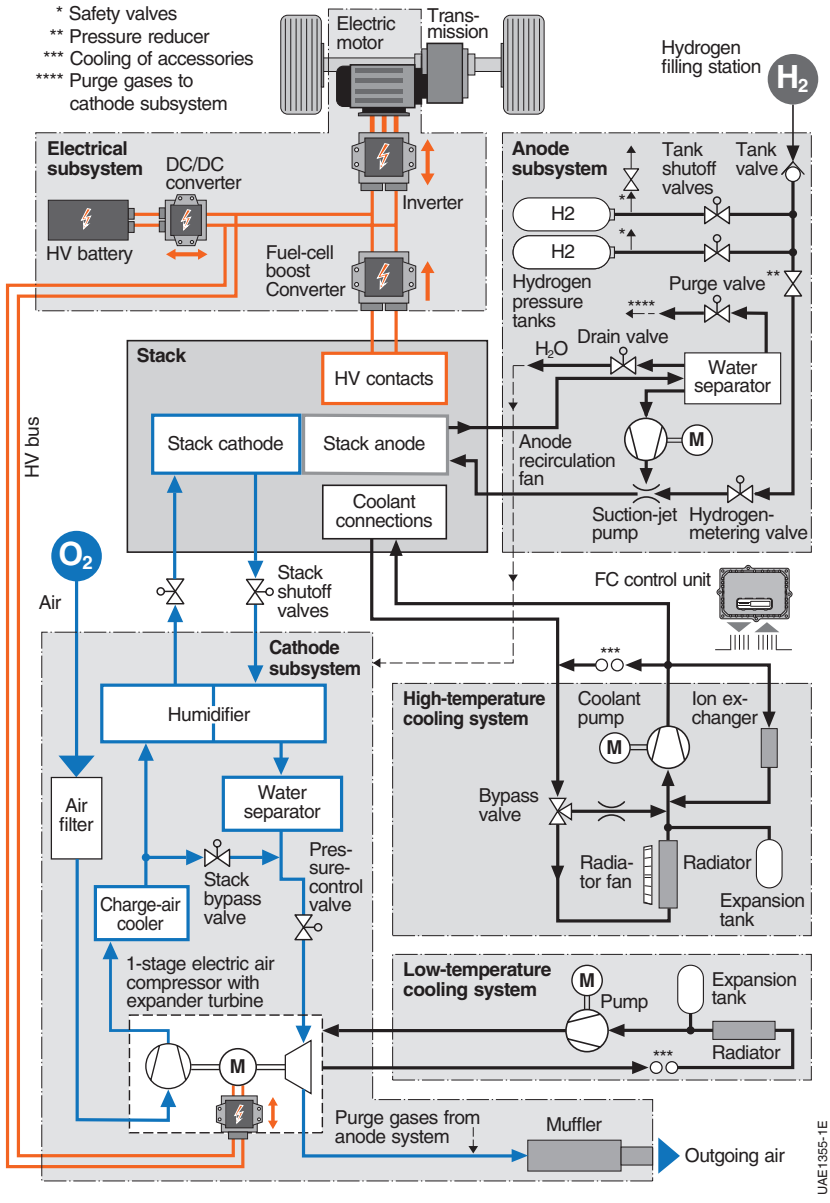
Functioning principle of the fuel-cell system

At the heart of the fuel-cell system is the fuel-cell stack. Subsystems for oxygen and hydrogen supply and for temperature control (Figure 6) are required to operate the stack. There are, in principle, different ways of realizing these subsystems. The one described here shows only one possible variant with an exemplary fuel-cell system power rating of 100 kW net.

Hydrogen supply
The hydrogen is stored in one or more high-pressure tanks at a pressure of around 700 bar. According to the state of the art, type-IV composite tanks with carbon-fiber casing and HDPE lining (high-density polyethylene) are used as an H_2 diffusion barrier. The hydrogen is initially relaxed via a pressure reducer to a mean pressure (approximately 15 bar) and supplied via a hydrogen-metering valve to the anode at low pressure (up to 3 bar).



The hydrogen-metering valve is an electrically actuated valve used to set the pressure of the hydrogen on the anode side. In contrast to fuel injectors in internal-combustion engines, the metering valve should set continuous mass flows. The metering valve can also be operated in clocked mode for small pressure and mass-flow pulses, for example when using a suction-jet pump.

A typical throughflow value for 100 kW system power is approximately 1.9 g/s hydrogen.

In order to supply the stack over the entire active surface area with sufficiently high hydrogen concentration, the anode is operated under leaner than stoichiometric conditions (i.e., with H_2 surfeit). To increase system efficiency, the unconsumed hydrogen is returned from the anode output to the input.

Recirculation is effected by a suction-jet pump or a recirculation fan or by a combination of both components. The suction-jet pump, which operates passively, is effective at high power and thus connected with high H_2 mass flow by the hydrogen-metering valve driving the suction-jet pump. The actively actuated recir-

Figure 6: Fuel-cell system with drive

culation fan, however, facilitates recirculation even if no or only minimal power is requested by the system.

Recirculation creates a closed system in which disruptive foreign gases (nitrogen, water vapor) are enriched over time and diffuse from the cathode side to the anode. These foreign gases are regularly discharged via an electrically actuated valve, the purge valve. This valve is mounted on the anode side on the stack outlet.

A water separator permanently removes liquid water from the anode circuit. The water collected in it is regularly drained via a valve. A combination of purge and drain valves in one component is possible.

The hydrogen inevitably dissipated during draining and purging is either strongly diluted with air (when the discharged anode gas is metered into the exhaust pipe) or catalytically converted to water (when metered into the air flow ahead of the cathode). Because this involves only small amounts of H_2 which are not used in the fuel cell to produce electrical energy, the overall efficiency is only slightly reduced.

Oxygen supply

The oxygen required for the electrochemical reaction is taken from the ambient air. The air mass of up to 120 g/s requested for 100 kW system power is inducted by an air compressor, compressed to max. 3 bar, and fed to the cathode side of the fuel cell. The pressure in the fuel cell is adjusted by a dynamic-pressure control valve in the exhaust-gas path downstream of the fuel cell.

To prevent the fuel-cell stack from drying out on the inlet side, the air can be pre-humidified, e.g., via a membrane humidifier, which removes some of the water vapor from the fuel-cell waste air and transfers it to the dry supply air.

In the variant shown the air is diverted via an exhaust-gas turbine seated on the shaft of the electric air compressor. The advantage of this is that using the enthalpy of the waste air relieves the load on the compressor drive motor and increases system efficiency. On the downside, an additional water separator is needed to protect the exhaust-gas turbine against impingement.

Thermal management

Fuel cells have an electrical efficiency in the range of around 50 % (at full load) to 70 % (at part load). This means that a large proportion of heat is released during the conversion of chemical energy to electrical energy which must be dissipated. In normal operation PEM fuel cells typically operate at an operating temperature of 60 °C to approximately 80 °C and thus at a much lower temperature level than internal-combustion engines. The radiator and radiator fan must therefore be designed to be bigger in fuel-cell systems in the vehicle drive in spite of the higher efficiency.

Because the coolant used is in direct contact with the fuel cells, it must not be electrically conducting as otherwise internal short circuit would result. The coolant based on a deionized water-glycol mixture is constantly deonized in the vehicle by an ion exchanger. The setpoint value for coolant conductivity is less than 5 µS/cm.

The electric coolant pump directs a flow of coolant through all the incorporated components. For 100 kW system power the coolant delivery rate can be up to 220 *l*/min. A coolant control valve splits the flow of coolant between the radiator and the radiator bypass.

Sensor systems

Operation of the fuel-cell systems currently requires numerous sensors in the anode path, in the air path, and in the cooling circuit of the system. The pressure sensors familiar from the internal-combustion engine must be adapted to the heightened requirements in the fuel-cell system. This concerns above all robustness against hydrogen and high moisture.

Sensors are furthermore required at numerous points to determine the hydrogen concentration. For fuel-cell systems specifically hydrogen-concentration sensors (see Hydrogen sensors) and coolant-conductivity sensors are required. Furthermore, sensors in the hydrogen and air paths are subject to a heightened requirement with regard to hydrogen resistance and resistance to deionized water.

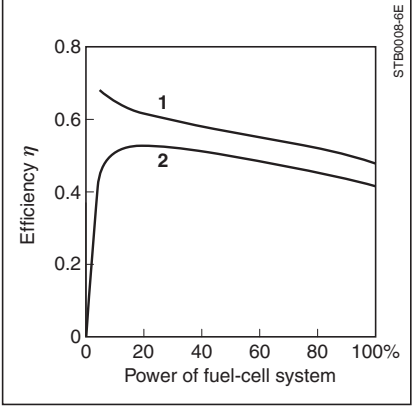
Safety

H_2-specific dangers

H_2-specific dangers result from the wide combustibility range of hydrogen-air mixtures and the high energy content that is chemically stored in hydrogen. Depending on how the hydrogen is stored, even the high pressure or the low temperature can constitute a danger. The 700 bar compressed-gas tank has established itself as the standard for “on-road fuel tanks” and the associated infrastructure.

The handling of hydrogen in motor vehicles is governed by statutory provisions such as for example UNECE R134 [2], EU406/2010 [3], UNECE GTR13 [4], and applicable standards such as ISO 12619 [5] or ANSI HGV 3.1 [6]. Here the primary focus of the statutory provisions is on sealing the hydrogen-carrying parts, particularly the tank.

With regard to use in vehicles, it is essential to prevent the uncontrolled release and accumulation of hydrogen in closed or partly closed rooms. In addition, a design goal is in place to prevent ignition sources in the immediate vicinity of hydrogen-carrying parts. Measures for detecting unwanted leakages are either system-internal diagnostics or gas sensors installed in suitable positions.



Efficiency of the fuel-cell system

In addition to quickly providing the requested power to the stack under the best possible operating conditions, it is important to design the system for primarily operating at high efficiency.

In Figure 7, the efficiency of a fuel-cell stack is compared by way of example with that of a fuel-cell system. The secondary loads/consumers (e.g., air compressor, coolant pump) take up some of the electric power and thereby reduce the overall efficiency of the system. Fuel-cell systems demonstrate substantially higher efficiency than an internal-combustion engine, particularly in the frequently used part-load range.

Figure 7: Efficiency of fuel-cell stack and fuel-cell system

1 Efficiency of fuel-cell stack,
2 Efficiency of fuel-cell system.

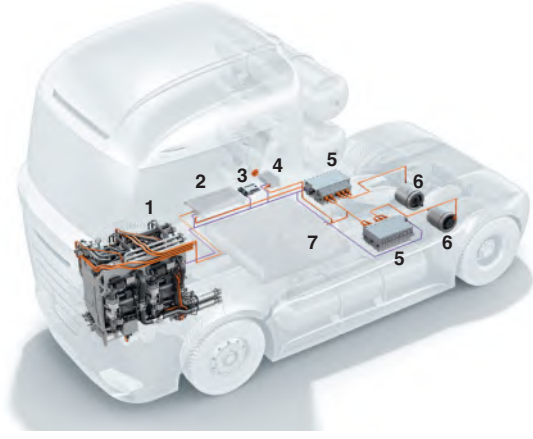
Fuel cell in the drivetrain

Figure 8 depicts the drivetrain of a truck with a fuel cell.

Electrical-system typologies
One or more DC/DC converters (at least one DC/DC converter is required) spread the power between the fuel-cell system, the traction battery, and the electric drive. In the case of a topology with two DC/DC converters – one for the fuel-cell stack and one for the traction battery – an optimized voltage can be set independently of both. The latter offers advantages for the design of the HV system components (high voltage) such as the compressor.

For safety reasons, the traction electrical system is isolated from the vehicle ground.

Components of the drivetrain
Electric drive
The electric drive consists of power electronics (an inverter) and a synchronous or asynchronous machine that is energized by the inverter to generate the required engine torque (see Electrical machines for motor-vehicle propulsion). Because the electric drive has a high power rating (approximately 150 kW), it is operated at voltages of up to 450 V. A voltage of up to 800 V can be selected for powerful vehicle classes and trucks.



The direct voltage of the traction electrical system is converted in the inverter into a multi-phase alternating current (see Inverter) where the amplitude is regulated as a function of the desired drive torque.

During braking the electric machine is switched to generator mode. In this process the vehicle's kinetic energy is converted into electrical energy and fed back to the traction battery.

Traction battery
Depending on the application, high-capacity or high-energy batteries are used with voltages of between 150 V and 400 V (see Batteries for electric and hybrid drives). Nickel-metal-hydride or lithium-ion batteries are used in high-capacity applications, while only lithium-ion batteries are used in high-energy applications. A battery-management system monitors the state of charge and the capacity of the battery.

DC/DC converter for the traction battery
A DC/DC converter regulates the traction battery's charge and discharge currents, where maximum currents of up to 300 A flow through the battery. This converter may be omitted in certain system configurations.

Figure 8: Electrically powered truck with fuel cell
1 Fuel-cell system,
2 Fuel-cell DC/DC converter,
3 Vehicle control unit (VCU),
4 Battery charging socket,
5 Inverter,
6 e-machines,
7 HV battery.

DC/DC converter for the fuel cell
Another DC/DC converter regulates the current from the fuel-cell stack, where maximum currents of up to 500 A flow through the stack. This converter too may be omitted in certain system configurations.

DC/DC converter for 12V vehicle electrical system
There is also – as in conventional vehicles – a 12V electrical system for the low-power electric loads/consumers. The 12V vehicle electrical system is supplied from the traction electrical system. A DC/DC converter is used between the two networks for this purpose. This converter is electrically isolated for safety reasons. It operates unidirectionally or bidirectionally with a power output of up to 3 kW to keep the currents in the 12V electrical system within the limits.

Outlook
Drives with fuel cells have already proven that they are suitable for everyday use. Estimates from 2015 by the Department of Energy ([7], [8]) start out from fuel-cell-system costs of 54 US$ per kW at 80 kW and 500,000 vehicles per year and additionally 488 US$ per kilogram of hydrogen for the tank.

System simplifications deliver both cost and reliability advantages. One approach is to develop new polymer membranes for fuel cells where it is not necessary to humidify the reaction gases and which at the same time allows the operating temperature to be increased.

Passenger-car models available on the market are the Hyundai Nexo, the Toyota Mirai, the Honda Clarity Fuel Cell, and the Mercedes-Benz GLC F-Cell (as at 2020). German automobile manufacturers are planning market launches in the coming years.

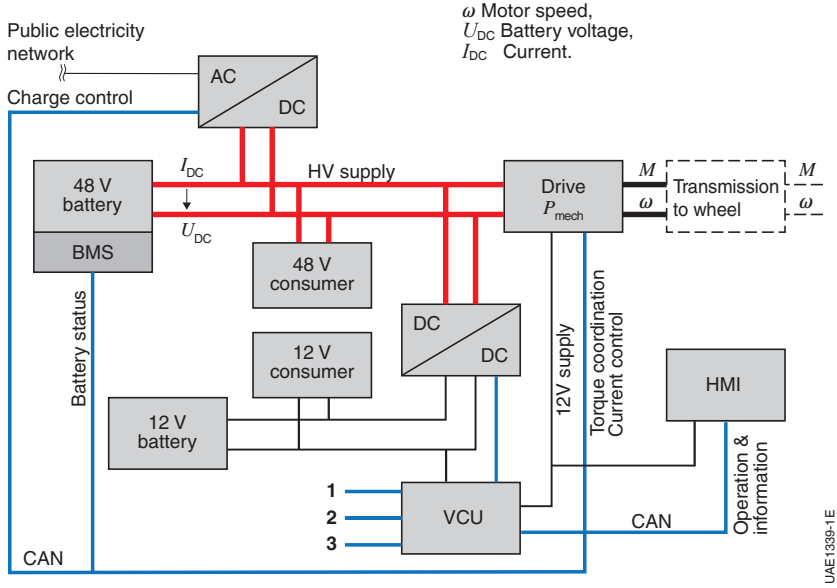
Electromobility for two-wheelers

Features

Definition and delimitation

Like electromobility in the four-wheel sector, mobility in the two-wheel sector is also following the trend of electrification. With the focus on purely electric vehicles, vehicles in this sector can be a PHEV (Plug-in Hybrid Electric Vehicle), an HEV (Hybrid Electric Vehicle) or a BEV (Battery Electric Vehicle). Only vehicles with a battery-electric drivetrain will be considered in more detail in the following.

EC168/2013



It is possible with reference to the classification of light vehicles in accordance with EC168/2013 [1] to categorize in particular two- and three-wheel vehicles into vehicle segments. The vehicle classes for four-wheel light vehicles will not be considered here. The segmentation applies to vehicles with internal-combustion engines and electrically powered vehicles.

Requirements

Two-wheel electric vehicles are characterized by the fact that they have, compared with passenger cars, energy accumulators with relatively low energy content (in kWh). There is here typically a P/E ratio (power to energy, see Batteries for electric and hybrid drives) of 0.5 to 5.0 kW/kWh for the segment of electrically powered two-wheel vehicles. Moreover, passive cooling methods (primarily air cooling) are used in such vehicles in the lower power range below 11 kW. Two-wheel vehicles are sometimes subject to statutory provisions for antilock braking systems (e.g., in the EU from 11 kW).

Figure 1: System architecture

AC Alternating Current, DC Direct Current,
HMI Human Machine Interface (operation and display), CAN Controller Area Network,
M Drive torque,
ω Motor speed,
U_{DC} Battery voltage,
I_{DC} Current.

System architecture

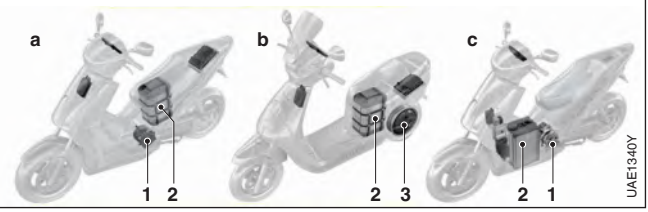
Aside from chassis, steering, suspension, and damping, the following main components are used in an electric two-wheeler (Figure 1): driving motor with power electronics, DC/DC converter, charger, battery, vehicle control unit (VCU), and display instrument. Figure 1 also shows the networking of the individual main components of the electric drivetrain (traction energy via 48 V electrical system, communication paths via CAN bus).

The transmission of electrical-mechanical energy from the electric machine to the wheel can be achieved by means of different technical solutions. The connection to the driving wheel can be established via a transmission, a toothed belt or a chain.

Figure 1 is also valid for operating voltages greater than 60 V, but some benefits of the 48 V technology are lost. These are on the one hand the omission of technical protection measures (shock protection); on the other hand, untrained employees (non-HV-technical specialists) are permitted to work on the vehicle. Significant cost savings are thus possible.

Motor arrangement
Two essentially different motor arrangements may be used within a system architecture. The central motor (Figure 2a) is characterized in conjunction with its power transmission by higher torques. The wheel-hub motor has the advantage of lower noise emissions (e.g., due to the absence of a chain).

Battery arrangement
Electric two-wheels can furthermore be distinguished on the basis of the installation position of the battery. The battery can be installed close to the steering column at the front of the vehicle, in the running-board area (Figure 2c) or in the former helmet compartment under the seat in the vehicle (Figure 2b).



In order to establish the installation position of the battery, it is necessary to define beforehand the use to which the vehicle will be put. The type of battery used depends on this intended use. This constitutes an important extra dimension in the definition of electric two-wheelers. A distinction is made here between permanently installed batteries, portable batteries with an additional plug-in process, and portable batteries without an additional plug-in process.

Charging methods
Likewise, different charging methods may be used for an electrified two-wheeler. Generally, the following different methods may be used:
– charging with a permanently installed charger,
– charging with a portable (mobile) charger or
– charging via swapping systems.

Here too the intended use of the vehicle is crucial in determining which charging method is the most expedient.

Emission-control legislation

Provided for information purposes only, no liability assumed for completeness!

Overview

California introduced the first emission-control legislation for gasoline engines in the mid-1960s. These regulations became progressively more stringent in the ensuing years. In the meantime, all industrialized countries have introduced emission-control laws which define limits for gasoline and diesel engines, as well as the test procedures employed to confirm compliance.

In many countries, regulations governing exhaust-gas emissions are supplemented by limits on evaporative losses from the fuel systems of vehicles with gasoline engines. Statutory OBD is addressed in the chapter "Diagnostics".

The most important legal restrictions on exhaust-gas emissions are listed below:
- CARB legislation (California Air Resources Board)
- EPA legislation (Environmental Protection Agency), USA
- EU legislation (European Union) and the corresponding UN/ECE regulations (United Nations/Economic Commission for Europe)
- Japanese legislation
- Chinese legislation

Classification
Countries with legal limits on motor-vehicle emissions divide vehicles into various classes:
- Passenger cars: Emission testing is conducted on a chassis dynamometer.
- Light commercial vehicles: Depending on national legislation, the top limit for gross vehicle weight (GVW) is 3.5 to 6.35 t. Emission testing is performed on a vehicle chassis dynamometer (as for passenger cars)
- Heavy commercial vehicles: Gross vehicle weight over 3.5 to 6.35 t (depending on national legislation). Emission testing is performed on an engine test bench.
- Non-road (e.g., construction, agricultural, and forestry vehicles): Emission testing is performed on an engine test bench, as for heavy commercial vehicles.

Furthermore, there are emission regulations for other two-, three-, and four-wheel vehicles (see section Emission legislation for motorcycles), for locomotives, for boats and ships, and for non-road mobile machinery.

Test procedures
Japan and the European Union have followed the lead of the United States by defining test procedures for certifying compliance with emission limits. These procedures have been adopted in modified or unrevised form by other countries.

Legal requirements prescribe any of three different tests, depending on vehicle class and test objective:
- Type approval (TA) to obtain General Certification,
- Random testing of vehicles from serial production conducted by the approval authorities (COP, Conformity of Production),
- In-field monitoring for checking the emission-reduction systems of privately owned production vehicles under real driving conditions.

Type approval
Type approvals are a precondition for granting General Certification for an engine or vehicle type. For this purpose, test cycles must be driven under specific operating conditions and emission limits must be complied with. The test cycles and emission limits are specified individually by each nation.

Dynamic test cycles are specified for passenger cars and light commercial vehicles. The country-specific differences between the two procedures are rooted in their respective origins (see Test cycles for passenger cars and light-duty trucks):
- Test cycles designed to mirror conditions recorded in actual highway operation, e.g., the FTP test cycle (Federal Test Procedure) in the USA or the UN ECE WLTC (World Light-duty Test Cycles),

– Synthetically generated test cycles consisting of phases at constant cruising speed and acceleration rates, e.g., the MNEDC (Modified New European Driving Cycle) of the European Union.

The mass of pollutant emissions from each vehicle is determined by operating it in conformity with speed cycles precisely defined for the test cycle. During the test cycle, the exhaust gases are collected for subsequent analysis to determine the pollutant mass emitted during the driving cycle (see Exhaust-gas measuring techniques).

For heavy-duty trucks and non-road applications, steady-state (e.g., 13-stage test) and dynamic test cycles (e.g., US HDDTC or ETC) are carried out on the engine test bench (see Test cycles for heavy commercial vehicles).

Serial testing (Conformity of Production)
Vehicle manufacturers normally perform serial testing themselves during production as part of quality control. The same test procedures and the same limits are generally applied as for type approval. The approval agency audits the serial testing and can request retests. The strictest requirements are applied in the USA where very nearly 100 % quality monitoring is required (EPA: "Compliance Assurance Program" CAP; CARB: "Production Vehicle Evaluation" PVE).

In-field monitoring
In-field monitoring involves the detection of type-specific defects (e.g., design or manufacturing defects, defective maintenance instructions) which result in dramatically increased pollutant emissions during the operation of vehicles under normal conditions of use. To this end, a check is carried out in the field on production vehicles to ascertain that they comply 100 % with the emission regulations. Privately owned production vehicles are randomly chosen for testing. The mileage and age of the vehicle must be within defined limits.

Emission-control legislation for passenger cars and light commercial vehicles

USA CARB legislation
The emission limits of CARB (California Air Resources Board) for passenger cars (PC) and light commercial vehicles (light-duty trucks; LDT) are specified in the emission-control standards LEV I, LEV II, and LEV III (LEV, Low Emission Vehicle, i.e., vehicles with low exhaust and evaporative emissions). Since model year 2004 the LEV II standard has applied to all new vehicles up to a gross vehicle weight of 14,000 lbs (lb: pound; 1 lb = 0.454 kg, 14,000 lb = 6.35 t). Model year 2015 marked the beginning of the incremental introduction of the new emission level LEV III to be completed by 2025 (or 2022 for evaporative emissions).

Originally the CARB legislation only applied in the US state of California, but has since been adopted in other states.

Vehicle classes
Figure 1 shows an overview of the categorization of vehicles into vehicle classes.

Emission limits
CARB legislation specifies limits for the carbon monoxide (CO), nitrogen oxides (NO_x), non-methane organic gases (NMOG), formaldehyde (HCHO), and particulate matter (diesel: LEV I to LEV III; gasoline: LEV III only) (Figure 2). On account of the very low emission limits, the LEV III legislation provides for an aggregate value of NMOG and NO_x.

Pollutant emissions are measured in the FTP 75 driving schedule (Federal Test Procedure). The emission limits are correlated with the route driven during the test and are expressed in grams per mile.

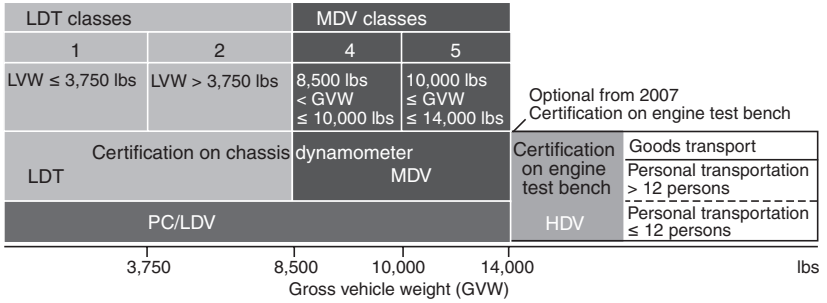
The SFTP (Supplemental Federal Test Procedure) standard, comprising two further test cycles (SC03 and US06 cycles) was introduced in 2001. There are also further limits that require compliance in addition to FTP emission limits.

Exhaust-gas categories
Automotive manufacturers are at liberty to deploy a variety of vehicle concepts within the permitted limits, providing they maintain a fleet average (see the section entitled “Fleet average”). The concepts are allocated to the following exhaust-gas categories, depending on their emission values for NMOG, CO, NO_x, and particulate emissions:
– LEV (Low-Emission Vehicle),
– ULEV (Ultra-Low-Emission Vehicle),
– SULEV (Super Ultra-Low-Emission Vehicle).

Since 2004 new vehicle registrations have been governed by the LEV II exhaust-emission standard. The CO and NMOG limits from LEV I remain unchanged, but the NO_x limit is substantially lower for LEV II.

LEV III provides for a total of six vehicle categories (Figure 2), one of which is below SULEV. In addition to the categories of the LEV emission-control standards, three categories of zero-emission or partial zero-emission vehicles are defined (see ZEV program).

Figure 1: Vehicle classes, CARB legislation
LDT Light Duty Truck, MDV Medium Duty Vehicle, HDV Heavy Duty Vehicle, PC Passenger Car, LDV Light Duty Vehicle, LVW Loaded Vehicle Weight (vehicle tare weight plus 300 lbs), GVW Gross Vehicle Weight.



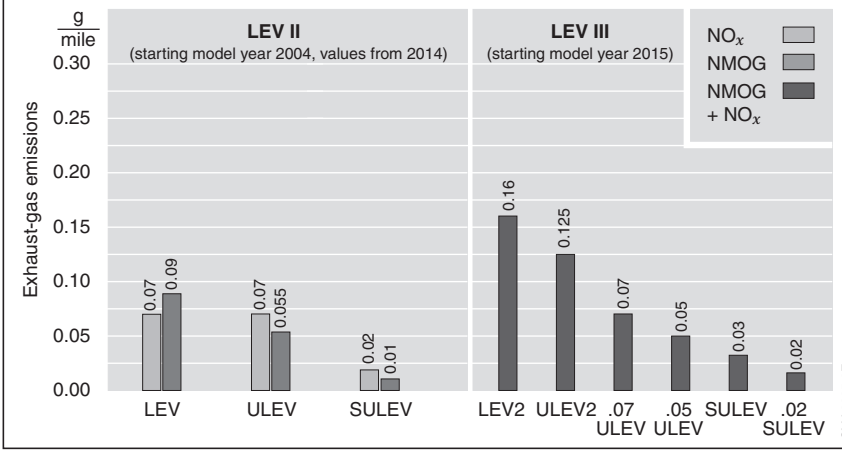


Figure 2: Exhaust-gas categories and emission limits for NO_x and NMOG of CARB legislation for passenger cars and light commercial vehicles

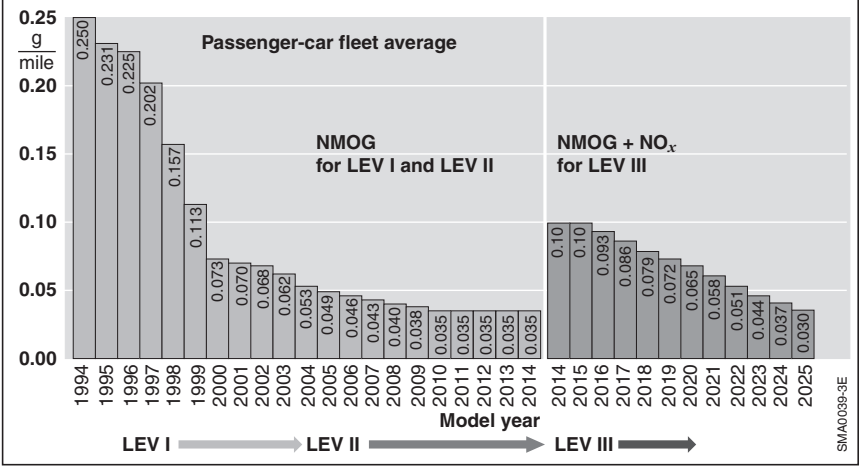
Phase-in
The LEV emission-control standards will not be introduced from one year to the next, but instead by means of a "phase-in", i.e., the incremental introduction of the requirements over a number of years for ever larger proportions of the new-car fleet, e.g. for LEV II 25%/50%/75%/100% of the newly registered vehicles in the model years 2004/5/6/7. This is accompanied by a "phase-out" of the previous regulations.

The LEV III standard will be introduced between 2015 and 2025, phase-out of LEV II by 2019. Particulate emissions are covered by separate phase-in and phase-out from 2017 onwards.

Evaporative emissions
The subject of evaporative emissions is addressed in the chapter "Exhaust-gas measuring techniques".



Durability
In order to gain approval for vehicle types, vehicle manufacturers must certify that the emissions of limited pollutants do not exceed the respective limits over 50,000 miles or 5 years ("half useful life") and 100,000 miles (LEV I) or 120,000 miles (LEV II) or 10 years ("full useful life"). LEV III has extended durability to 150,000 miles.

Durability test
The vehicle manufacturer must supply two vehicle fleets from its production line for the durability test. One fleet in which each vehicle has driven 4,000 miles before the test, and one fleet for the endurance test with which the deterioration factors of individual pollutant components are measured.

Endurance testing entails subjecting the vehicles to specific driving cycles over distances of 100,000 and 120,000 or 150,000 miles. Exhaust-gas emissions are tested at intervals of 5,000 miles and may not exceed the limits. Servicing and maintenance tasks may only be performed at the specified intervals.

Fleet average
Each vehicle manufacturer must ensure that its vehicles do not exceed an average specific emission limit for exhaust-gas emissions (Figure 3). The NMOG and NO_x emissions are used as the criteria in this regard with LEV III (for LEV I/II only NMOG). The fleet average is calculated for LEV I and LEV II from the average of the NMOG limit for "half useful life" produced by all of the manufacturer's vehi-

Figure 3: Passenger-car fleet averages in comparison with NMOG standard

cles are sold within one year. The limits for "full useful life" apply to LEV III. The emission limits for the fleet average are different for passenger cars and light commercial vehicles.

The emission limit for the NMOG fleet average is reduced every year. To meet the lower fleet limit, manufacturers must produce progressively cleaner vehicles in the more stringent emissions categories in each consecutive year.

Fleet consumption (fuel consumption)
US federal lawmakers specify mandatory requirements on vehicle manufacturers with regard to the mean fuel consumption of their vehicle fleets, or the number of miles driven per gallon (federal law, applicable in all states, the relevant authority is the "National Highway Traffic Safety Administration", NHTSA). New vehicles registered in the area of responsibility of CARB are governed by the same CAFE regulations for determining fleet fuel consumption as for EPA (see EPA legislation, section "Fleet consumption").

Emission-free vehicles
The ZEV program ("Zero-Emission Vehicle") is to be used to force the development and market introduction of "zero-emission vehicles" ("technology forcing"), which are also intended to help reduce greenhouse emissions.

The ZEV program defines three categories of zero-emission and partial zero-emission vehicles. Genuine ZEV vehicles may not release any emissions when they are in operation. These vehicles are electric cars which are operated by a battery or a fuel cell.

PZEVs (Partial Zero-Emission Vehicles) are not emission-free, but they do emit particularly low levels of pollutants. They are weighted using a factor of more than 0.2, depending on the emission-limit standard. The following requirements must be satisfied for the minimum factor of 0.2:
– SULEV certification for a durability of 150,000 miles or 15 years,
– Warranty coverage extending over 150,000 miles or 15 years on all emission-related components,
– No evaporative emissions from the fuel system (0 EVAP, zero evaporation). This is achieved by extensive encapsulation of the tank and fuel system. This results in greatly reduced evaporative emissions by the overall vehicle.

AT PZEVs (Advanced Technology PZEVs) are hybrid vehicles with a gasoline or diesel engine and electric motor and gas-powered vehicles (operation with compressed natural gas, with hydrogen).

The ZEV program envisages for the major automobile manufacturers minimum quantities for ZEV, AT PZEV and PZEV vehicles which will increase gradually between 2005 and 2017 and provide for ever greater proportions of AT PZEVs and ZEVs. The quantities are not calculated directly, but instead by means of so-called "ZEV credits", which depend among other things on the technology used, their performance, and the model year. From 2018 the PZEV category will be dropped and the necessary quantities of AT PZEVs (now transitionally TZEVs) and ZEVs will rise dramatically by 2025.

The relevant figures for the ZEV, AT-PZEV and PZEV emission-limit categories are 150,000 miles or 15 years ("full useful life").

In-field monitoring
Non-routine inspection
Random emission testing is conducted on in-use vehicles using the FTP 75 test cycle and – for vehicles with gasoline engines – an evaporative-emission test. Depending on the relevant exhaust-gas category, vehicles with mileage readings below 90,000 or 112,500 miles are tested.

Vehicle monitoring by the manufacturer
Official reporting of claims or damage to specific emissions-related components and systems has been mandatory for vehicle manufacturers since model year 1990. The reporting obligation remains in force for a maximum period of 15 years, or 150,000 miles, depending on the warranty period applying to the component or assembly.

The reporting method is divided into three stages with an incremental amount of detail: Emissions Warranty Information Report (EWIR), Field Information Report (FIR), and Emission Information Report (EIR). The California Air Resources Board is notified of information regarding complaints, fault quotas, fault analysis, and impacts on emissions. The agency uses the Field Information Report as the basis to decide whether to enforce a recall action on the vehicle manufacturer.

USA EPA legislation

EPA (Environmental Protection Agency) legislation applies to all of the states where the more stringent CARB stipulations from California are not in force.

The EPA legislation has been covered by the Tier 2 emission-control standard since 2004. The new Tier 3 emission-control standard will be introduced incrementally between 2017 and 2025. Tier 3 achieves an extensive harmonization of the requirements with the Californian LEV III program, e.g., the same certification categories, albeit with its own designation ("bin").

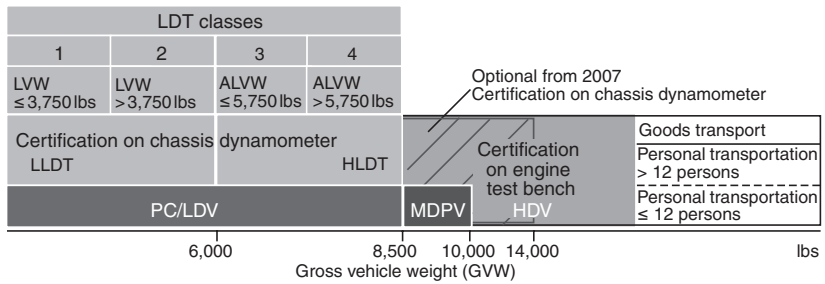
Vehicle classes

With the transition to Tier 2, an additional vehicle class has been introduced in the form of the MDPV (Medium-Duty Passenger Vehicle) (Figure 4). Thus, all vehicles up to a permissible total weight of 10,000 lbs (4.54 t) which are designed to carry up to 12 persons, are certified on a chassis dynamometer.

Light commercial vehicles are divided into two groups: LLDTs (Light Light-Duty Trucks) with a gross vehicle weight of up to 6,000 lbs (2.72 t) and heavier HLDTs (Heavy Light-Duty Trucks) with a gross vehicle weight of up to 8,500 lbs (3.86 t).

Since 2007 certification on a chassis dynamometer has also been optionally possible for vehicles weighing up to 14,000 lbs (6.35 t).

The classification of motor vehicles into the vehicle classes defined in Tier 2 has been retained for Tier 3.



Emission limits

EPA legislation specifies limits for the pollutants carbon monoxide (CO), nitrogen oxides (NO_x), non-methane organic gases (NMOG), formaldehyde (HCHO), and particulate matter (PM). Pollutant emissions are measured in the FTP 75 driving schedule. The emission limits are correlated with the route driven during the test and are expressed in grams per mile.

The SFTP (Supplemental Federal Test Procedure) standard, comprising two further test cycles (SC03 and US06 cycles) has been in force since 2000. Prevailing emission limits must be met in addition to FTP emission limits.

Figure 4: Vehicle classes, EPA legislation

LDT Light Duty Truck, MDV Medium Duty Vehicle, HDV Heavy Duty Vehicle, PC Passenger Car, LLDT Light Light-Duty Truck, HLDT Heavy Light-Duty Truck, MDPV Medium-Duty Passenger Vehicle, LDV Light Duty Vehicle, LVW Loaded Vehicle Weight, GVW Gross Vehicle Weight, ALV Adjusted Loaded Vehicle Weight (0.5 × tare weight + 0.5 × gross weight).

Since the introduction of Tier 2 standards in 2004, vehicles with diesel and gasoline engines have been subject to identical exhaust-emission limits.

Exhaust-gas categories

Tier 2

For Tier 2, the limits were divided into 10 (for LDV and LLDT) and into 11 (for HLDT and MDPV) emission standards (bins) (Figure 5). For LDV and LLDT, Bin 9 and Bin 10 ceased to apply in 2007, and, for HLDT and MDPV, Bin 9 through Bin 11 ceased to apply in 2009.

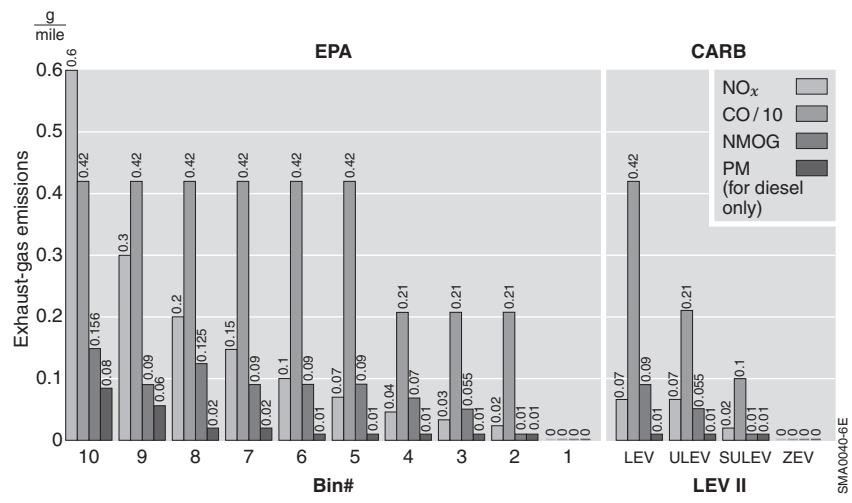
The transition to Tier 2 has produced the following changes:

– Introduction of fleet averages for NO_x,
– Formaldehyde (HCHO) is subject to a separate pollutant category,
– LDV and LLDT are treated identically to the greatest possible extent with regard to FTP limits,
– "Full useful life" is increased, depending on the emission standard (Bin), to 120,000 or 150,000 miles.

Tier 3

Seven selectable certification bins will furthermore be made available for Tier 3. However, the standards are now formulated both for the fleet values and for the bins as an aggregate value of NMOG and NO_x.

The Tier 3 legislation closely follows the Californian LEV III legislation in order to simplify the job of certification in the EPA and CARB areas for the vehicle manufacturers.



Durability has been extended for Tier 3 to 150,000 miles (optional, alternatively 120,000 miles with stricter limits values) or 15 years compared with 100,000 miles or 10 years for Tier 2.

Tier 3 also covers heavy pick-ups and vans with a gross vehicle weight in excess of 6,500 lbs, which are now driven on a chassis dynamometer including the demanding SFTP test cycles. Within the Tier 2 legislation these vehicles were excluded from the SFTP tests.

Particulate-emission limits are prescribed with the Tier 3 legislation for each vehicle. A limit for the particulate number (PN) is currently not provided for.

The Tier 3 legislation is governed by the same fleet values for NMOG + NO_x as for LEV III.

Figure 5: Tier 2 emission limits for EPA legislation compared with CARB emission limits for LEV II

Phase-in
At least 25 % of all new passenger-car and LLDT registrations were required to conform to Tier 2 standards which took effect in 2004. The phase-in rule stipulated that an additional 25 % of vehicles would be required to conform to the Tier 2 standards in each consecutive year. All vehicles have been required to conform to Tier 2 standards since 2007. The phase-in period for HLDT and MDPV terminated in 2009.

Tier 3 will be introduced between 2017 and 2025, phase-out of Tier 2 by 2019. Particulate emissions are covered by separate phase-in and phase-out from 2017 onwards.

Evaporative emissions
The subject of evaporative emissions is addressed in the chapter "Exhaust-gas measuring techniques".

Durability
The same criteria as for CARB apply to durability.

Fleet average
NO_x emissions are used to determine fleet averages for individual manufacturers under the EPA Tier 2 legislation. Up to 2008 the value was 0.2 g/mile, since 2008 it has been 0.07 g/mile. With Tier 3 the NMOG+NO_x fleet average will be introduced as for CARB.

Fleet consumption (fuel consumption)
US federal lawmakers specify mandatory requirements on vehicle manufacturers with regard to the mean fuel consumption of their vehicle fleets, or the number of miles driven per gallon (federal law, applicable in all states, the relevant authority is the "National Highway Traffic Safety Administration", NHTSA). Here it is the metric "miles per gallon of fuel (mpg)" and not as otherwise usual in Europe for example the "amount of fuel used per unit distance" that is used. This representation of "fuel economy" corresponds to the reciprocal value of consumption per unit of distance.

The prescribed CAFE value (Corporate Average Fuel Economy) was until 2010 27.5 mpg for passenger cars. This equates to a fuel consumption of 8.55 *l* of gasoline per 100 km. Up to 2004 the value for light commercial vehicles was 20.7 mpg or 11.36 *l* of gasoline per 100 km and was increased by 2010 to 23.5 mpg.

For model year 2011 the CAFE system was restructured for passenger cars and light-duty trucks (among others the definitions of passenger cars and light trucks) and ambitious target values were set: 33.3 mpg and 22.8 mpg for 2011, 40.1 mpg and 25.4 mpg for 2014, 43.4 mpg and 26.8 mpg for 2016, 46.8 mpg and 33.3 mpg for 2021, and 56.2 mpg and 40.3 mpg for 2025.

For the stages 2012 through 2016 and 2017 through 2025 an EPA regulation harmonized with the CAFE regulation for limiting greenhouse emissions applies in parallel to the CAFE legislation. The target value for a vehicle is dependent on the tire contact area between the wheels ("footprint"). Target values are 34.1 mpg (for CAFE) and 250 g CO_2 equivalent per mile (for EPA) for 2016. In the period from 2017 through 2025 the target values will be further increased in stages, for EPA up to 54.5 mpg (163 g CO_2 equivalent per mile) and for CAFE up to 49.7 mpg (179 g CO_2 equivalent per mile). The values for 2021 through 2025 were suspended in 2018 by the Trump administration. This led to complaints by CARB and many other US states. A reassessment by the Biden administration is expected.

At the end of each year the average "fuel economy" for each vehicle manufacturer is calculated based on the numbers of vehicles sold. The manufacturer must remit a penalty fee of $5.50 per vehicle for each 0.1 mpg its fleet falls short of the target. There is the possibility by way of a "credit/debit system" of balancing overfulfillment and underfulfillment in a year with "credits" and "debits" from other years.

Buyers will also have to pay a gas-guzzler tax on vehicles with especially high fuel consumption. Here, the limit is 22.5 mpg (10.45 *l* per 100 km). These penalties are intended to promote the sale of vehicles offering greater fuel economy.

The FTP 75 test cycle and the highway cycle are applied to measure CAFE fuel economy (see the section entitled "US test cycles").

A Fuel Economy Label provides vehicle buyers with information on fuel consumption. Model year 2008 sees the introduction of "5 cycle fuel economy" (also called "5 cycle method"), which is intended to better reflect real driving conditions. This takes into account measurements in the SFTP schedules and in the FTP at –7 °C, which include among others aggressive acceleration, high final speed, and also operation with air conditioning.

In-field monitoring

Non-routine inspection

EPA legislation, just like CARB legislation, provides for an exhaust-gas emission test in accordance with the FTP 75 test method to be carried out on in-use vehicles on a random-test basis. Testing is conducted on low-mileage vehicles (10,000 miles, roughly one year old) and higher-mileage vehicles (50,000 miles, however at least one vehicle per test group with 90,000 or 105,000 miles, depending on the emission standard; roughly four years old). The number of vehicles is dependent on the number sold. For vehicles with gasoline engines, at least one vehicle per test group is also tested for evaporative emissions.

Vehicle monitoring by the manufacturer

For vehicles after model year 1972, the manufacturer is obliged to make an official report concerning damage to specific emission-related components or systems if at least 25 identical emission-related parts in a model year are defective. The reporting obligation ends five years after the end of the model year. The report comprises a description of damage to the defective component, presentation of the impacts on exhaust-gas emissions, and suitable corrective action by the manufacturer. The environmental authorities use this information as the basis for determining whether to issue recalls to the manufacturer.

EU legislation

The Directives of European emission-control legislation are proposed by the EU Commission and ratified by the Council of Environment Ministers and the EU Parliament. The basis of emission-control legislation for passenger cars and light commercial vehicles is Directive 70/220/EEC [1] from 1970. For the first time it defined exhaust-emission limits, and the provisions have been updated ever since.

The emission limits for passenger cars and light commercial vehicles LCV (light-duty trucks LDT) are contained in the emission-control standards Euro 1 (from 07/1992), Euro 2 (01/1996), Euro 3 (01/2000), Euro 4 (01/2005), Euro 5 (09/2009), and Euro 6 (09/2014).

Instead of a "phase-in" over several years as in the USA, a new emission-control standard is introduced in two stages. In the first stage newly certified vehicle types must adhere to the newly defined emission limits. In the second stage – generally one year later – every newly registered vehicle (i.e., all types) must adhere to the new limits. Legislators can inspect production vehicles for compliance with emission limits (COP, Conformity of Production, and ISC In-service Conformity Check).

EU directives allow tax incentives for vehicles that comply with upcoming exhaust-gas emission standards before they actually become law. Depending on a vehicle's emission standard, there are also a number of different motor-vehicle tax rates in Germany.

Vehicle classes

Until the Euro 4 legislation expired, vehicles with a permissible total weight below 3.5 t were certified on chassis dynamometers; in this respect, a distinction was made between passenger cars (carrying up to nine persons) and light commercial vehicles (LDT) for goods transportation. There are three classes for LDT (Figure 6), depending on the vehicle reference weight (tare weight + 100 kg). Engine certifications are performed for buses (carrying more than nine persons) and for vehicles with a permissible total weight in excess of 3.5 t. LDT engines can

optionally also be certified on an engine test bench.

When the Euro 5 and Euro 6 legislation comes into force, the vehicle reference weight (tare weight + 100 kg) will be the distinguishing criterion with regard to the certification procedure. Vehicles with a reference weight of up to 2.61 t will be certified on a chassis dynamometer. Vehicles with a reference weight in excess of 2.61 t will be certified on an engine test bench. Flexible variations will be possible.

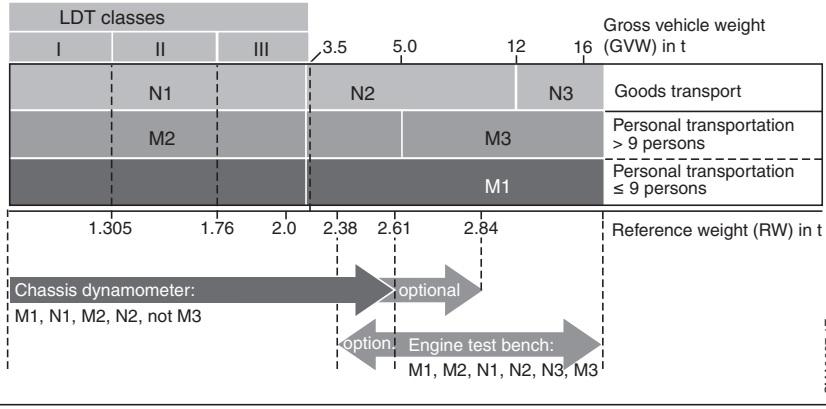
Emission limits

The EU standards specify limits for carbon monoxide (CO), hydrocarbons (THC, Total Hydro Carbons), nitrogen oxides (NO_x), and particulate matter (PM, for direct-injection gasoline engines as from Euro 5) (Figures 7 and 8).

The limits for hydrocarbons and nitrogen oxides for the Euro 1 and Euro 2 stages are combined into an aggregate value ($HC+NO_x$). Since Euro 3 a special NO_x limit in addition to the aggregate value has applied to vehicles with diesel engines; in the case of gasoline vehicles, the aggregate has been replaced by separate HC and NO_x limits.

The Euro 5 stage was introduced in two steps as Euro 5a and Euro 5b. Euro 5a (from September 2009) saw the addition for gasoline engines of an NMHC limit (non-methane hydrocarbons), Euro 5b (from September 2011) for diesel engines a particulate-number limit of $6 \cdot 10^{11}$ particulates per kilometer. This PN limit has also applied from Euro 6b (September 2014) and Euro 6c (September 2017) to vehicles with direct-injection gasoline engines (a higher interim value of $6 \cdot 10^{12}$ particulates/km for Euro 6b is possible on request).

The limits are different for vehicles with diesel and gasoline engines, but with Euro 6 will be brought further into line.



The limits for LDT class 1 are the same as for cars. Passenger cars with a permissible total in excess of 2.5 t were for Euro 3 and Euro 4 treated as LDTs and were therefore likewise categorized into one of the three LDT classes. This option ceases to apply from Euro 5.

The limits are defined based on mileage and indicated in grams per kilometer (g/km). Since Euro 3, emissions are measured on a chassis dynamometer using the MNEDC (Modified New European Driving Cycle).

Figure 6: Vehicle classes, EU legislation

LDT Light Duty Truck, MDV Medium Duty Vehicle, HDV Heavy Duty Vehicle, PC Passenger Car, LDV Light Duty Vehicle, LVW Loaded Vehicle Weight, GVW Gross Vehicle Weight.

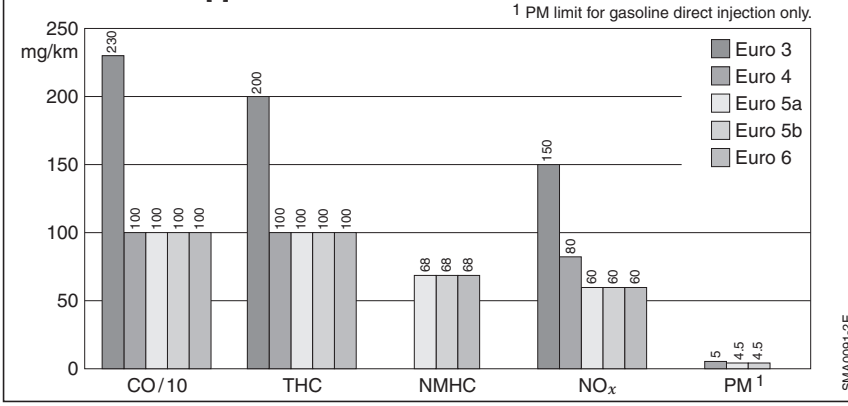
Note: The axes for GVW and RW must be considered separately!

Since September 2017 the MNEDC has been replaced by the WLTC (Worldwide Light-duty Test Cycles, see also Test cycles). The dynamic test cycle derived from road driving is supplemented by a strongly revised test procedure (WLTP, Worldwide harmonized Light vehicles Test Procedure) which is to make possible significantly more realistic consumption and emission measurements. Here the Euro 6c limits defined for the MNEDC have not been adapted to the WLTC. This stage is called Euro 6d-temp since, aside from the change to the WLTC, the new "Real Driving Emissions" test (RDE) will also be introduced with a first stage. Euro 6d with the second RDE stage will apply from January 2020.

Evaporative emissions
The subject of evaporative emissions is addressed in the chapter "Exhaust-gas measuring techniques".

Type approval
Type approval is conducted along similar lines to that in the USA, with the following differences: Test vehicles absolve an initial run-in period of 3,000 kilometers before testing. The limit values in the Type I

Figure 7: EU emission limits for gasoline-engine passenger cars and light commercial vehicles [2]



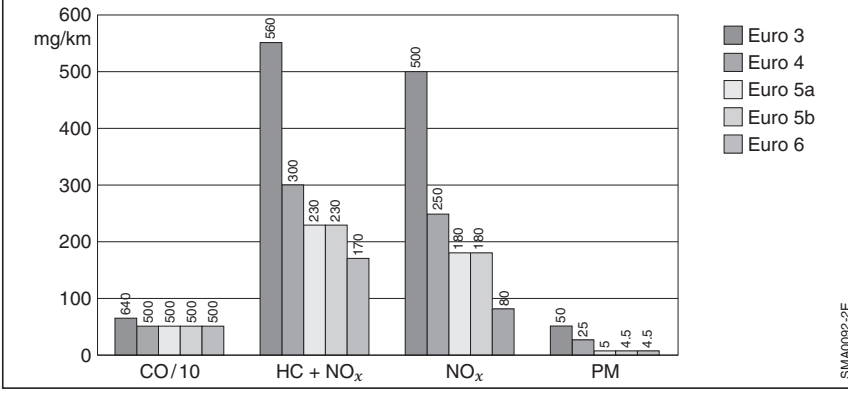


Figure 8: EU emission limits for diesel-engine passenger cars and light commercial vehicles [2]

test are "full useful life" limit values, i.e., they must be complied with even when the durability distance is reached. In order to take into account the aging of components up to the durability distance, deterioration factors are applied to the values measured in the type approval. These are defined in the legislation for every pollutant component; manufacturers are also allowed to present documentation confirming lower factors obtained during specified endurance testing (Type V test) over 80,000 km. From Euro 5 the endurance distance has been increased from 80,000 km to 160,000 km, where further alternative test procedures are possible.

Type tests

There are four essential type tests for type approval. Type I, Type IV, Type V and Type VI tests are used for vehicles with gasoline engines; only Type I and Type V tests are used for vehicles with diesel engines. With Euro 6d-temp the RDE test Type Ia and the Ambient Temperature Correction Test are added for gasoline and diesel (ATCT, Type I test at 14 °C for converting the CO_2 emission from 23 °C to 14 °C, emission limits must be adhered to).

With the Type I test, the primary exhaust-gas test, the exhaust emissions are determined after cold starting in the MNEDC (Modified New European Driving Cycle) and since Euro 6d-temp in the WLTC (Worldwide Light-duty Test Cycles). In addition, the opacity of the exhaust gas is recorded for vehicles with diesel engines.

The Type Ia test "Real Driving Emissions" (RDE) is intended to ensure that the emission limits are adhered to not only in the standardized cycle but also under real road conditions. In the EU the RDE test is used both during the type approval and also in in-field monitoring. To this end a vehicle is equipped with a mobile measurement system (PEMS, Portable Emissions Measurement System, see Exhaust-gas measuring techniques) and driven for 90 to 120 minutes in normal road traffic. Various boundary conditions apply during this test (see Table 3, Test cycles). CO (monitoring, not a limit value), NO_x (for gasoline and diesel), PN (particulate number, only for gasoline direct-injection engines and diesel), and CO_2 (as a normalization quantity) are measured. Valid RDE journeys are evaluated and weighted with software tools. The average NO_x and PN emissions in the urban part and for the entire journey are compared with maximum values which are obtained from the product of emission limit multiplied by "Conformity Factor" CF. For NO_x CF will be introduced in two stages (2.1 in 2017 and 1.43 in 2020), for PN 1.5 will apply from 2017. The CF values are to be adapted to the state-of-the-art (as 1 + 0.x).

Type IV testing measures evaporative emissions from parked vehicles. This primarily concerns fuel vapor that evaporates from the fuel-carrying system (fuel tank, pipes, etc.) (see also Exhaust-gas measuring techniques, also with regard to emission limit and test procedure).

Type VI testing embraces hydrocarbon and carbon-monoxide emissions immediately following cold starts at –7 °C. Only the first section (urban section) of the MNEDC is driven for this test. This test has been binding since 2002. A new test based on WLTC is being elaborated at UN ECE level.

The Type V test assesses the long-term durability of the emissions-reducing equipment. In addition to the specified endurance test, alternative test procedures are possible from Euro 5 (e.g., test-bench aging).

CO_2 emissions

For CO_2 emissions there were no limits laid down by law until 2011; however, the vehicle manufacturers did enter into a voluntary commitment in Europe. Because the manufacturers failed to reach their target, a fleet target value has been laid down by law for passenger cars. Within an introductory phase from 2012 through 2015 a fleet value of 130 g/km must be achieved (equating to 5.3 *l*/100 km gasoline or 4.9 *l*/100 km diesel). For light commercial vehicles a similar regulation stipulates a target value of 175 g/km for 2017. A further reduction for passenger cars to 95 g/km and for light commercial vehicles to 147 g/km has been decided on for 2020/2021. These values are to

understood as mean values for all the passenger cars and LDTs supplied by a vehicle manufacturer (vehicle fleet). The target value for a vehicle is dependent on the vehicle tare weight.

Since September 2017 new vehicle types have had to be certified in the WLTP (with four phases). The determined CO_2 values at 23 °C are corrected to 14 °C (by means of a factor determined in the Ambient Temperature Correction Test) and then converted with the aid of the CO2MPAS tool to MNEDC values, which were used to check whether the targets were achieved up to and including 2020. On the basis of the relative achievement of the target values in 2020 and the underlying MNEDC and WLTP values a manufacturer-specific target value will be defined for 2021 and subsequent years. Further reductions have been agreed for 2025 and 2030, but could be lowered further within the framework of the "Green Deal".

Similarly to the US CAFE regulations, fines must be paid if the target value is not met, however there is no option of credit/debit balancing over a number of years.

In-field monitoring

EU legislation also calls for conformity-verification testing on in-use vehicles as part of the Type I test cycle. The minimum number of vehicles of a vehicle type under test is three, while the maximum number varies according to the test procedure. Vehicles under test must meet the following criteria:

- Mileages vary from 15,000 km to 100,000 km, and vehicle age from 6 months to 5 years (from Euro 4).
- Regular service inspections were carried out as specified by the manufacturer.
- The vehicle must show no indications of non-standard use (e.g., tampering, major repairs, etc.).

If emissions from an individual vehicle fail substantially to comply with the standards, the source of the high emissions must be determined. If several vehicles display excessive emissions in random testing for the same reason, the results of the random test must be classified as negative. If there are various reasons, the test schedule may be extended, providing the maximum sample size is not reached.

If the type-approval authorities detect that a vehicle type fails to meet the criteria, the vehicle manufacturer must devise suitable action to eliminate the defect. The action catalog must be applicable to all vehicles with the same defect. If necessary, a recall action must be started.

Periodic emission testing

In Germany all passenger cars and light commercial vehicles and vans are required to undergo emissions inspections three years after their initial registration, and then at subsequent intervals of two years. For vehicles with gasoline engines, the main focus is on CO levels and λ closed-loop control, while for vehicles with diesel engines, the opacity test is the main criterion. Data from the diagnostic system are taken into consideration for vehicles with On-Board Diagnostic systems (OBD).

Comparable tests are also available in other countries; in Europe, for example, in Austria, France, Spain, and Switzerland, and in many parts of the USA in the form of "Inspection and Maintenance".

Japanese legislation

The permitted emission values are also subject to gradual stages of severity in Japan. The limit values have since September 2007 been subject to further tightening within the framework of the "New Long Term Standards".

Vehicles with diesel engines have since September 2010 been subject to further tightening of the limit values in the form of the "Post New Long Term Regulation". In the case of vehicles with gasoline engines, the previous synthetic test cycles were replaced in two stages (2008 and 2011) by the more realistic JC08 cycle.

In 2018 Japan also introduced the WLTC based on UN GTR No. 15 [3]. Unlike the EU, only the first three phases apply. The NMHC limit values for vehicles with gasoline engines and the NO_x limit values for vehicles with diesel engines are adapted.

Vehicle classes
Vehicles with a permissible total weight up to 3.5t are essentially divided into three classes (Figure 9): passenger cars (up to ten seats), LDVs (Light-Duty Vehicles) up to 1.7t, and MDVs (Medium-Duty Vehicles) up to 3.5t. MDVs have higher limits for CO and NO_x emissions (for vehicles with gasoline engines) than the other two vehicle classes. For diesel engines, the vehicle categories are distinguished by NO_x and particulate limits.

Emission limits
The Japanese legislation specifies limits for carbon monoxide (CO), nitrogen ox-

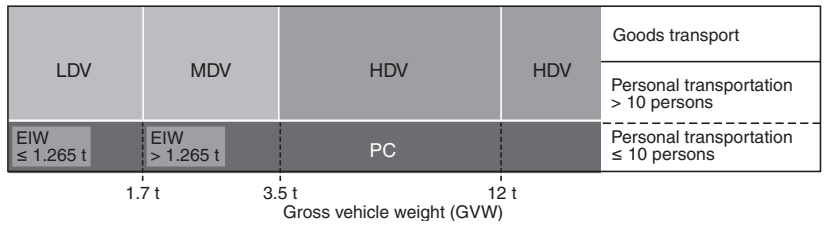

Table 1: Emission limits of Japanese legislation for gasoline-engine passenger cars

Vehicle category	Pass. cars, mini delivery vans, small commercial vehicles GVW ≤ 1.7 t		Medium-duty commercial vehicles 1.7 t < GVW 3.5 t	
Cycle Year (new types)	JC08 10/2009	WLTC 10/2018	JC08 10/2009	WLTC 10/2018
Limit values for gasoline engines				
NMHC [mg/km]	50	100	50	150
NO_x [mg/km]	50	50	70	70
CO [mg/km]	1,150	1,150	2,550	2,550
PM [mg/km] (direct-injection engines only)	5	5	7	7

Table 2: Emission limits of Japanese legislation for diesel-engine passenger cars

Vehicle category	Pass. cars, mini delivery vans, small commercial vehicles GVW ≤ 1.7 t		Medium-duty commercial vehicles 1.7 t < GVW 3.5 t	
Cycle Year (new types)	JC08 10/2009	WLTC 10/2018	JC08 10/2009	WLTC 10/2018
Limit values for diesel engines				
NMHC [mg/km]	24	24	24	24
NO_x [mg/km]	80	150	150	240
CO [mg/km]	630	630	630	630
PM [mg/km]	5	5	7	7

Figure 9: Vehicle classes, Japanese legislation
MDV Medium Duty Vehicle, HDV Heavy Duty Vehicle, PC Passenger Car, LDV Light Duty Vehicle, GVW Gross Vehicle Weight, EIW Equivalent Inertia Weight.

ides (NO_x), non-methane hydrocarbons (NMHC), particulate matter (for vehicles with diesel engines, from 2009 also for gasoline direct injection with leaner NO_x-reducing technology) (Table 1 for gasoline engines and Table 2 for diesel engines).

Pollutant emissions were determined with a combination of 11-mode and 10•15-mode test cycles (see Japanese test cycle). Cold-start emissions were thus also taken into account. A new test cycle was introduced in 2008 (JC08). This replaced initially the 11-mode and as from 2011 also the 10•15-mode, so that only the JC08 will be used as the cold- and hot-start test. Since 2018 the JC08 has been replaced by the WLTC.

Evaporative emissions
The exhaust-gas regulations in Japan include limits on evaporative emissions in vehicles with gasoline engines, which are measured using the SHED method (see Exhaust-gas measuring techniques). Japan is adopting the WLTC-based test procedure of UN GTR 19 [4], which has been influenced by the developments of the EU test procedure. Different tank systems are taken into account.

Durability
Manufacturers must demonstrate a durability of 45,000 km (New Long Term Standards) or 80,000 km (Post New Long Term Standards) for vehicles with diesel engines. 80,000 km apply to all stages for vehicles with gasoline engines.

Fleet consumption
In Japan targets apply to the fleet consumption of a manufacturer for 2010 and 2015, based on target values for vehicle weight classes. For tax-incentive purposes (green tax program) there are two stages rewarding fuel consumption which is improved by 15% and 25% respectively.

Chinese legislation
China has, up to and including Stage 5 (applicable nationally from 2018), adopted the EU legislation to limit exhaust-gas emissions. Leading the way here was Beijing, introducing the stages early, followed by further metropolitan areas such as Shanghai and Guangzhou. With China 6a (7/2020) and 6b (7/2023) China is introducing its own legislation which for exhaust-gas emissions links the WLTC with Euro 6-based and US limit values and adds its own requirements.

For the Type I test the 4-phase WLTC including WLTP of UN GTR 15 [3] is adopted. The limit values are fuel-neutral. For passenger cars and light commercial vehicles (class 1) for China 6a the Euro 6 limit values for gasoline engines apply for HC, NMHC, and NO_x. 0.7 g/km has been defined for the CO limit value. For PM the limit value 4.5 mg/km applies, for PN $6 \cdot 10^{11}$ particulates/km (no exception for gasoline engines with intake-manifold injection). A limit value for N_2O (laughing gas, a greenhouse gas) of 20 mg/km has been adopted from the USA. For China 6b the limit values for HC, NMHC, CO, and NO_x are reduced to approximately 50% of the Euro 6 limit values for gasoline engines. PM is reduced to 3 mg/km, PN and N_2O remain the same.

The durability requirement is 160,000 km for China 6a and 200,000 km for China 6b.

The Type VI test (at –7 °C) applies to vehicles with gasoline and diesel engines as of China 6a. In the first two phases of the WLTC limit values must be observed for HC of 1.2 g/km, CO of 10 g/m, and NO_x of 0.25 g/km.

China is also introducing an RDE test for the type approval and in-field monitoring. As of China 6a RDE tests must be conducted ("monitoring" of CO, NO_x, and PN, without limit values), as of China 6b "Conformity Factors" CF apply of 2.1 for NO_x and PN for all gasoline and diesel engines. The test procedures are based on an intermediate stage of the EU RDE legislation, e.g., the cold-start period is not taken into consideration and additional boundary conditions are defined, e.g., measurements up to an altitude of 2,400 m and lower top speeds for freeway driving. A review of the CF is envisaged by mid-2022.

The metropolitan areas could introduce China 6a and can introduce China 6b early, but restrictions apply, e.g., before

7/2023 for RDE only monitoring and 160,000 km as the durability distance.

China has also developed its own requirements for limiting fuel consumption and thus CO_2 emissions. In four stages (2005 through 2007, 2008 through 2015, 2016 through 2020, and 2021 through 2025) limit values dependent on the vehicle weight in liters of fuel per 100 km apply to individual vehicle types. In parallel there is a Corporate Average Fuel Consumption regulation (CAFC), which similarly to the EU CO_2 fleet targets sets target values dependent on vehicle weight for the consumption for the fleet of a manufacturer in the periods 2012 through 2015 and 2016 through 2020. Target values for the entire fleet are 6.9 *l* gasoline per 100 km for 2015 and 5.0 *l* gasoline per 100 km for 2020. For 2025 the target value is 4.0 *l* gasoline per 100 km.

The subject of evaporative emissions (Type IV test) is addressed in the chapter "Exhaust-gas measuring techniques".

China uses a variety of measures, such as for example tax reductions, to promote the introduction of electrified vehicles (hybrids and plug-in hybrids, pure electric and fuel-cell vehicles). With the "New Energy Vehicle" legislation (NEV) manufacturers must from 2019 fulfill quotas for the sale of these vehicles (cf. CARB ZEV legislation).

Test cycles for passenger cars and light commercial vehicles

US test cycles

FTP 75 test cycle

The FTP 75 test cycle (Federal Test Procedure, Figure 10a) consists of speed cycles that were actually recorded in commuter traffic in Los Angeles. This test is also in force in some countries of South America and in Korea besides the USA (including California).

Conditioning

The vehicle is subjected to an ambient temperature of 20 to 30 °C for a period of 6 to 36 hours.

Collection of pollutants

The vehicle is started and driven on the specific speed cycle on a chassis dynamometer. The emitted pollutants are collected in separate bags during defined phases (see Exhaust-gas measuring techniques).

Phase ct (cold transient)

The exhaust gas is collected during the cold test phase (0 to 505 s).

Phase cs (cold stabilized)

The stabilized phase begins 506 seconds after start. The exhaust gas is collected without interrupting the driving cycle. Upon termination of phase cs, after a total of 1,372 seconds, the engine is switched off for a period of 600 seconds (hot soak).

Phase ht (hot transient)

The engine is restarted for the hot test. The speed cycle is identical to the cold transient phase (Phase ct).

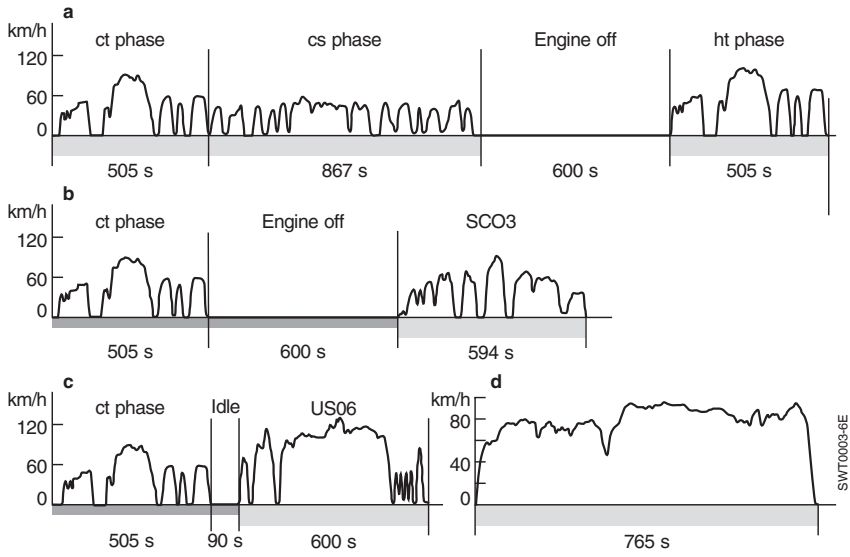
Phase hs (hot stabilized)

For hybrid vehicles, a further phase hs is driven. It corresponds to the progression of phase cs. For other vehicles, it is assumed that the emission values are identical to the cs phase.

Assessment
The bag samples from the first two phases are analyzed during the pause before the hot test. This is because samples may not remain in the bags for longer than 20 minutes.

The sample exhaust gases contained in the third bag are also analyzed on completion of the driving cycle. The total result includes emissions from the three phases rated at different weightings.

The pollutant masses of phases ct and cs are aggregated and assigned to the total distance of these two phases. The result is then weighted at a factor of 0.43.



The same process is applied to the aggregated pollutant masses from phases ht and cs, related to the total distance of these two phases, and weighted at a factor of 0.57. The test result for the individual pollutants (among others HC, CO, and NO_x) is obtained from the sum of the two previous results.

The emissions are specified as the pollutant emission per mile.

SFTP cycles
The tests in accordance with the SFTP standard (Supplemental Federal Test Procedure) were introduced in 2001. These are composed of two driving cycles, the SC03 cycle (Figure 10b) and the US06

Figure 10: US test cycles for passenger cars and light commercial vehicles

	a	b	c	d
Test cycle	FTP 75	SC03	US06	Highway
Cycle distance:	17.87 km	5.76 km	12.87 km	16.44 km
Cycle duration:	1,877 s + 600 s pause	594 s	600 s	765 s
Mean cycle speed:	34.1 km/h	34.9 km/h	77.3 km/h	77.4 km/h
Maximum cycle speed:	91.2 km/h	88.2 km/h	129.2 km/h	96.4 km/h

cycle (Figure 10c). The extended tests are intended to examine the following additional driving conditions:
– Aggressive driving,
– Radical changes in vehicle speed,
– Engine start and acceleration from a standing start,
– Operation with frequent minor variations in speed,
– Periods with vehicle parked,
– Operation with air conditioner on.

For preconditioning, the SC03 and US06 cycles proceed through the ct phase from FTP 75 without exhaust-gas collection. However, other conditioning procedures are also possible.

The SC03 cycle (for vehicles with air conditioning only) is carried out at a temperature of 35 °C and 40 % relative humidity. The individual driving schedules are weighted as follows:
– Vehicles with A/C systems:
  35 % FTP 75 + 37 % SC03
  + 28 % US06.
– Vehicles without A/C systems:
  72 % FTP 75 + 28 % US06.

The SFTP and FTP 75 test cycles must be successfully completed on an individual basis.

Cold-start enrichment, which is necessary when a vehicle with a gasoline engine is started at low temperatures, produces higher emissions. These cannot be measured in current emissions testing, which is conducted at ambient temperatures of 20 to 30 °C. An additional exhaust-gas test is performed at –7 °C on vehicles with gasoline engines in order to limit these pollutants. However, this test only prescribes a limit for carbon monoxide; a nationally applicable fleet limit was introduced for NMHC emissions in 2013.

Test cycles for determining fleet consumption
Each vehicle manufacturer is required to provide data on corporate average fuel economy. Manufacturers that fail to comply with the target values are required to pay penalties.

Fuel consumption is determined from the exhaust-gas emissions produced during two test cycles – the FTP 75 test cycle (weighted at 55 %) and the highway test cycle (weighted at 45 %). An unmeasured highway test cycle (Figure 10d) is conducted once after preconditioning (vehicle allowed to stand with engine off for 12 hours at 20 to 30 °C). The exhaust-gas emissions from a second test run are then collected. The CO_2 emissions are used to calculate fuel consumption.

Further test cycles
FTP 72 test cycle
The FTP 72 test routine – also known as the UDDS (Urban Dynamometer Driving Schedule) – corresponds to the FTP 75 test, but does not include the ht test component (hot test). This cycle is driven during the running-loss test for vehicles with a gasoline engine.

New York City Cycle (NYCC)
This cycle is also an element in the running-loss test (for vehicles with a gasoline engine). It simulates low speeds in urban traffic with frequent stops.

Hybrid cycle
For hybrid vehicles the phase hs (progression corresponding to phase cs) is attached to the FTP 75 cycle. This driving cycle thus corresponds twice to the UDDS cycle, which is why it is called 2UDDS.

European test cycle
MNEDC
The “Modified New European Driving Cycle” (MNEDC, Figure 11) has been in force since Euro 3. Contrary to the “New European Driving Cycle” (Euro 2), in which measurement of emissions only began 40 seconds after the vehicle was started, the MNEDC also includes a cold-start phase (including engine starting).

Conditioning
The vehicle is subjected to an ambient temperature of 20 to 30 °C for a minimum period of six hours. Since 2002 the starting temperature has been lowered to –7 °C for the Type VI test (only for vehicles with gasoline engines).

Collection of pollutants
The exhaust gas is collected in bags in two phases: the Urban Driving Cycle (UDC) at a top speed of 50 km/h and the Extra Urban Driving Cycle (EUDC, overland drive) at a top speed of 120 km/h.

Assessment
The pollutant mass measured by analyzing the bag contents is referred to the distance covered (see Exhaust-gas measuring techniques).

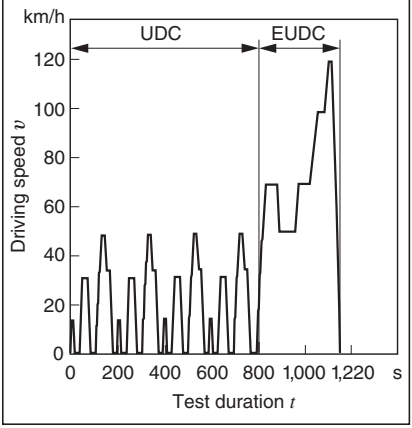
WLTC
Within the framework of the UN ECE a new test cycle WLTC (Worldwide Light-duty Test Cycles) was devised by the EU, Japan, India, and South Korea (among others) for passenger cars and light commercial vehicles and defined in UN GTR No. 15 [3]. The WLTC consists of four phases ("low", "mid", "high", and "extra high speed"). As an option, however, only the first three phases can be used. Further cycles were developed for special vehicle segments: for Japanese "kei cars" a toned-down variant of the WLTC and for the Indian market two cycles for vehicles with very low power-weight ratios ("low powered vehicle test cycles", LPTCs).

The dynamic test cycle derived from road driving is supplemented by a strongly revised test procedure (WLTP) compared with the previous regulation which is to make possible significantly more realistic consumption and emission measurements.

Among other things, the following have been defined for the WLTP test procedure: a method for shift-point calculation for manual transmissions, higher vehicle weights by taking into account payload and equipment options, improved methods for determining the coasting parameters, stepless adjustment of the chassis dynamometer, and 23 °C as the test temperature. Aside from the fundamental test procedure, special requirements for electrified vehicles such as hybrid and electric vehicles have also been elaborated.

Figure 12 shows the WLTC by way of example for class 3b, the class with the biggest-selling passenger cars and light commercial vehicles. Compared with the previous test cycle MNEDC (Figure 11),

Figure 11: MNEDC for passenger cars and light commercial vehicles
Cycle distance: 11 km.
Average speed: 33.6 km/h.
Top speed: 120 km/h.
UDC Urban Driving Cycle,
EUDC Extra Urban Driving Cycle.



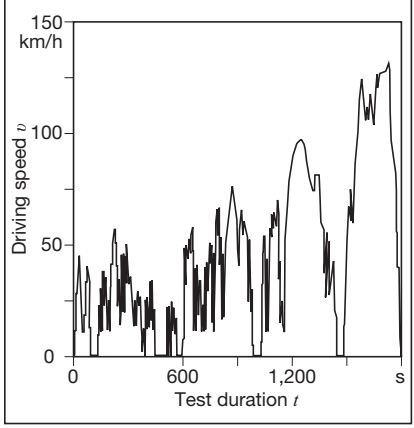


Figure 12: WLTC for passenger cars and light commercial vehicles

the changed dynamics of the WLTC can be clearly discerned.

RDE test

A new element of the legislation for passenger cars and light commercial vehicles is the RDE test ("real driving emissions"), which was developed in the EU and is being adopted by other countries like China and India (for gasoline and diesel) and Korea and Japan (for diesel only). The aim of the RDE test is to ensure that the emissions limits are observed not only in the standardized cycle but also under real road conditions. For the RDE test a vehicle is equipped with a mobile measurement system (PEMS, Portable Emissions Measurement System, see Exhaust-gas measuring techniques) and driven in normal road traffic. Various boundary conditions apply during this test, e.g., with regard to the proportions of city and intercity roads and freeway, the proportions of idle, of average speed, of minimum and maximum speeds, acceleration, cold start, and ambient conditions such as temperature and altitude. Table 3 sets out selected boundary conditions for the EU. RDE journeys can be made under conditions that are quite different from those in the Type I test (23 °C) thanks to the enhanced temperatures of –7 °C to +35 °C.

PEMS systems are available for CO, NO_x, PN (particulate number), and CO_2. Valid RDE journeys (see Table 3) are evaluated and if necessary weighted with software tools. The average emissions for a PEMS journey are compared with maximum values which are obtained from the product of emission limit multiplied by "Conformity Factor" CF. The CF takes into account the measuring inaccuracies

Table 3: Boundary conditions for a valid RDE measurement run (selection, not all specified)

Parameter	Criterion		
Route distribution	Urban 34 % (29 to 44 %)	Interurban 33 % (±10 %)	Freeway 33 % (±10 %)
	In each case at least 16 km		
Speeds	$v \leq 60$ km/h v_D = 15 to 40 km/h (average speed)	60 km/h < $v \leq 90$ km/h	90 km/h < $v \leq 145$ km/h (up to 160 km/h for max. 3 % of the freeway time)
Total driving time	90 to 120 min		
Secondary loads	Operation of the air-conditioning system and the other secondary loads must correspond to their possible use by the load under normal driving conditions on the road.		
Altimeter	Moderated: $h \leq 700$ m Extended: 700 m < $h \leq 1{,}300$ m (measured values are divided by 1.6) Starting and end points may not differ in their height above sea level by more than 100 m.		
Temperature	Moderated: Stage 1: 3 °C ≤ $T \leq 30$ °C Stage 2: 0 °C ≤ $T \leq 30$ °C Extended (measured values are divided by 1.6): Stage 1: –2 °C ≤ T < 3 °C, or 30 °C < $T \leq 35$ °C Stage 2: –7 °C ≤ T < 0 °C, or 30 °C < $T \leq 35$ °C		
Vehicle capacity weight and test weight	Basic capacity weight: driver, front passenger, test equipment. Maximum weight from basic capacity weight and artificial capacity weight: max. 90 % of the sum total of the "weight of passengers" and the "capacity weight".		
Cold start	Cold-start period: until the coolant has reached 70 °C, max. 5 minutes cumulative combustion-engine operation. Speed: average = 15 to 40 km/h, max. 60 km/h. Emissions in the cold-start period are evaluated for the urban part and the total RDE journey with the normal methods.		

which arise from measurements with PEMS conducted on the road compared with a measurement conducted on a chassis dynamometer.

Japanese test cycle

JC08 test cycle

In 2008 a new exhaust-gas test was introduced in the form of the JC08 (Figure 13), which initially replaced the 11-mode test as the cold-start test. Since 2011 only the JC08 has continued to be used (both as the cold-start and the hot-start tests). The cold-start test is weighted at 25 %, the hot-start test at 75 %. The pollutants are converted based on distance traveled, i.e., into grams per kilometer (g/km).

WLTC

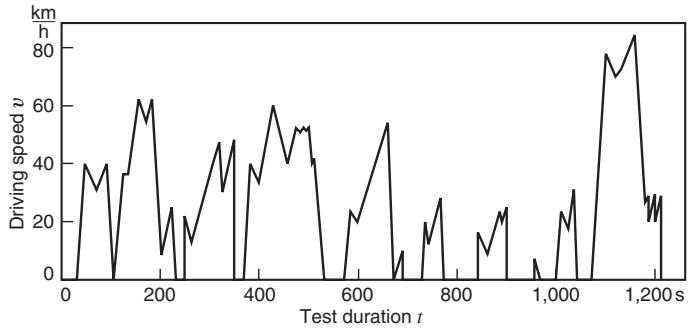
Since 2018 the WLTC with three phases (WLTC without the "extra high speed" part) has replaced the JC08.

Emission-control legislation for heavy commercial vehicles

US legislation

Vehicle classes

Heavy commercial vehicles are defined in EPA legislation as vehicles with a gross vehicle weight over 8,500 lbs or 10,000 lbs (equivalent to 3.9 t or 4.6 t), depending on vehicle type (see Figure 4).



In California, all vehicles over 14,000 lbs (6.35 t) are classified as heavy commercial vehicles (see Figure 1). To a great extent, Californian legislation is identical to parts of EPA legislation. However, there is an additional program for city buses.

Emission limits

The US standards specify limits for diesel engines for hydrocarbons (HC), carbon monoxide (CO), nitrogen oxides (NO_x), particulate matter (PM), exhaust-gas opacity, and in parts for non-methane hydrocarbons (NMHC).

The permissible limits are related to engine power output and specified in g/bhp-h (gram per brake horsepower hour) (Figure 14 with values converted to g/kWh). The emissions are measured on the engine test bench during the dynamic test cycle with cold-starting sequence

Figure 13: Japanese test cycle JC08 for passenger cars and light commercial vehicles
Cycle distance: 8.179 km.
Cycle time: 1,204 s.
Average speed: 24.5 km/h.
Top speed: 81.6 km/h.

(HDDTC, Heavy-Duty Diesel Transient Cycle); the exhaust-gas opacity is measured using the Federal Smoke Test (FST).

New, more stringent regulations have applied to vehicles since model year 2004, with significantly reduced NO_x emission limits. Non-methane hydrocarbons and nitrogen oxides are grouped together in one aggregate (NMHC + NO_x).

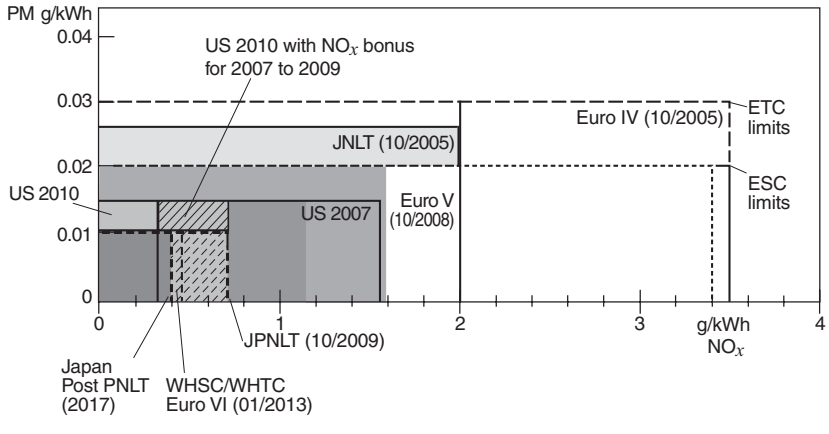
Another very drastic tightening of emission restrictions came into force in model year 2007. The NO_x and particulate emissions are separately limited and are a tenth of the previous values. These are not achievable without the use of exhaust-gas treatment systems (e.g., NO_x reduction measures with NO_x storage catalytic converter or active SCR system, particulate filter).

A gradual phase-in took place for NO_x and NMHC emission limits between model years 2007 and 2010.

From model year 2024 with the introduction of the CARB Low NO_x Regulation (for buses) the nitrogen-oxide limits will be reduced by 90 % and the previous particulate-emission limit halved in California.

Massively increased durability requirements will additionally apply from model year 2027.

A binding share of sales of zero-emission vehicles is prescribed in California for model years 2024 through 2035 (Advanced Clean Truck Regulation, ACT).



To help compliance with severe particulate limits, the maximum permitted sulfur content in diesel fuel was reduced to 15 ppm from mid-2006.

For heavy commercial vehicles – in contrast with cars and light commercial vehicles – there are no limits specified for average fleet emissions and fleet consumption.

Consent Decree

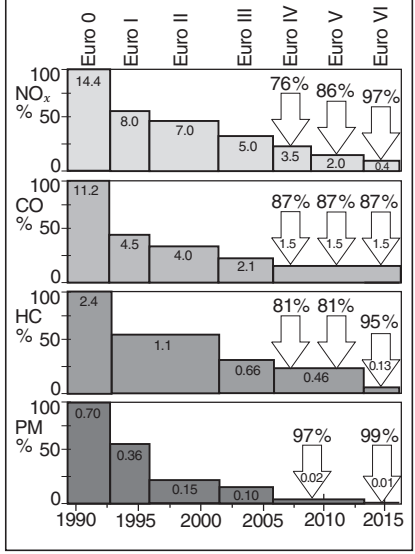
In 1998 a legal agreement was reached between EPA, CARB, and a number of engine manufacturers. It provides for sanctions against manufacturers if they make illegal modifications to engines to achieve optimized consumption in the highway cycle, resulting in higher NO_x emissions. The “Consent Decree” specifies that the applicable emission limits must also undercut the steady-state European 13-stage test in addition to the dynamic test cycle. Furthermore, emissions are not allowed to exceed the limits for model year 2004 by more than 25 %, regardless of driving mode within a specified engine-speed/torque range (Not-to-Exceed Zone).

Figure 14: Comparison of NO_x and PM emission limits for diesel fuel commercial vehicles: EU, USA, Japan [5]

These additional tests have been mandatory for all diesel commercial vehicles since model year 2007. However, emissions in the not-to-exceed zone may be up to 50 % above the emission limits.

Durability
Compliance with emission limits must be demonstrated over a defined mileage or a specific time period in which a distinction is drawn between three classes, each with increasing durability requirements:
– Light commercial vehicles of 8,500 lbs (EPA) and 14,000 lbs (CARB) to 19,500 lbs: 10 years or 110,000 miles.
– Medium-duty commercial vehicles from 19,500 lbs to 33,000 lbs: 10 years or 185,000 miles.
– Heavy commercial vehicles over 33,000 lbs: 10 years or 435,000 miles and 22,000 h (operating time).

Fuel-consumption requirement
In the USA there are separate requirements with regard to greenhouse-gas emissions (since 2014) and fuel consumption (since 2017).



EU legislation
Vehicle classes
In Europe, all vehicles with a permissible gross vehicle weight of over 3.5 t, or capable of transporting more than nine persons, are classified as heavy commercial vehicles (see Figure 6). The emission regulations (Euro standards) are based on the Basic Directive 88/77/EEC [6], which is continuously updated and extended. Euro VI requirements are described by the created Directive (EU) 64/2012 [7]. Supplements to PEMS (Portable Emission Measurement System) and IUC (In Use Compliance) can be found for example in Regulation 2016/1718 EU [8]. The most up-to-date supplement to Euro VI can be found in Regulation (EU) 2020/1181 [9].

Emission limits
As for passenger cars and light commercial vehicles, new emission-limit levels for heavy commercial vehicles are introduced in two stages. New engine designs must meet the new emission limits during type approval. One year later compliance with the new emission limits is a prerequisite for registering a new vehicle. The legislator can inspect conformity of production (COP) by taking engines out of serial production and testing them for compliance with the new emission limits.

For commercial-vehicle diesel engines, the Euro standards define emission limits for hydrocarbons (HC and NMHC), carbon monoxide (CO), nitrogen oxides (NO_x), particulates, and exhaust-gas opacity. The permissible limits are related to engine power output and specified in g/kW (Figure 15).

In October 2000 the limit stage Euro III was binding initially on new engine types and one year later on all newly manufactured engines. Emissions were measured during the 13-stage European Steady-State Cycle (ESC, see Test cycles for heavy commercial vehicles), and exhaust-gas opacity in the supplementary European Load Response (ELR) test. Diesel engines which are equipped with systems for exhaust-gas treatment

Figure 15: EU emission limits for diesel commercial vehicles [5]
Values in g/kWh.
Percentage reductions refer to Euro 0.

(NO_x reduction measures with NO_x storage catalytic converter or active SCR system, particulate filter) furthermore already had to be tested in the dynamic exhaust-gas emission test ETC (European Transient Cycle). These European test cycles were conducted with the engine running at normal operating temperature. Since Euro V a cold-start test has also been required.

Within the Euro III legislation a distinction was still made between large engines (displacement > 0.75 l per cylinder) and small engines (displacement < 0.75 l per cylinder and rated speed > 3,000 rpm), with higher permissible particulate-emission limits for the smaller units. This distinction is dropped for new certifications with the introduction of Euro IV.

In October 2005 the Euro IV emission-limit level came into force initially for new type approvals, and for serial production one year later. All emission limits were significantly lower than specified by Euro III, but the biggest increase in severity applied to particulates, for which the limits were reduced by approximately 80 %. The following changes also applied after introduction of Euro IV:

– The dynamic exhaust-gas emission test (ETC) was obligatory – in addition to ESC and ELR – for all diesel engines.
– The continued functioning of emissions-related components must be documented for the entire service life of the vehicle (see Durability).

The Euro V emission-limit level was introduced in October 2008 for all new engine approvals, and one year later for all new serial-production vehicles. Only the NO_x emission limits were more severe compared to Euro IV.

In January 2013 the Euro VI emission-limit level for new engine types came into force (year later for all newly produced engines). Compared with Euro V, the nitrogen-oxide emissions are again reduced by 80 % and the particulate emissions by more than 60 % (referred to ETC limits for Euro V). New harmonized engine tests have been introduced with Euro VI. Here, too, there is a stationary test (WHSC, World Harmonized Stationary Cycle), a dynamic test (WHTC, World Harmonized Transient Cycle), and random tests within specified engine-speed/torque ranges (WNTE, World Harmonized Not-to-Exceed Zone). Unlike the previous Euro V regulations, from Euro VI no specific particulate-matter limits will be given for the transient test; the limits given will be identical to those for the stationary test. Particulate-number limits are additionally demanded with Euro VI (separately for stationary and transient tests).

Durability

Compliance with emission limits must be demonstrated over a defined mileage or a specific time period in which a distinction is drawn between three classes, each with increasing durability requirements:

– Light commercial vehicles up to 3.5 t gross vehicle weight (GVW): 6 years or 100,000 km (Euro IV and Euro V) and 160,000 km (Euro VI).
– Medium-duty commercial vehicles smaller than 16 t GVW: 6 years or 200,000 km (Euro IV and Euro V) and 300,000 km (Euro VI).
– Heavy commercial vehicles over 16 t GVW: 7 years or 500,000 km (Euro IV and Euro V) and 700,000 km (Euro VI).

Fuel consumption

CO_2 emissions from heavy commercial vehicles with a permissible gross vehicle weight of more than 16 t are to be reduced by 15 % by 2025 and by 30 % by 2030. These targets signify a relative lowering referred to average determined emissions from vehicles of a manufacturer with a reference time period of 07/2019 through 06/2020.

Subcategories are created with regard to the CO_2 output values, depending on vehicle type (box body or semitrailer truck) and axle configuration.

CO_2 is calculated by means of a simulation tool (VECTO, Vehicle Energy and Consumption Calculation tool), which takes into account a large number of parameters (vehicle application, drivetrain configuration, etc.).

Very low-emission vehicles
Prior to the introduction of the Euro V standard it was possible to meet voluntarily at an early stage more demanding, so-called EEV limit values (Enhanced Environmentally-Friendly Vehicle). Voluntary early meeting of these limits permitted tax incentives. EEV limit values for HC, NMHC, CO, and exhaust-gas opacity were lower than the Euro V limit values. NO_x and particulate limits were equivalent to the Euro V ESC limits. Natural-gas-powered city and tourist buses are typical examples of EEV vehicles.

Japanese legislation
Vehicle classes
In Japan, vehicles with a permissible gross vehicle weight of over 3.5 t, or capable of transporting more than ten persons are classified as heavy commercial vehicles (see Figure 9).

Emission limits
In October 2005 the "New Long Term Regulation" was introduced and was valid until the end of 2009. It stipulated emission limits for hydrocarbons (HC), nitrogen oxides (NO_x), carbon monoxide (CO), particulates, and exhaust-gas opacity. Emission levels were measured in the newly introduced transient JE05 test cycle (hot test), and exhaust-gas opacity in the Japanese smoke test. The smoke test was conducted with three full-load operating points at 40.6 % and 100 % rated speed. With the introduction of the "Post New Long Term" emissions stage (09/09) there are now no smoke-test specifications.

The "Post New Long-Term Regulation" came into force in September 2009. The particulate and NO_x limits were reduced by almost two-thirds compared with 2005 levels.

Since October 2016 the "Post Post New Long Term" (Post PNLT, PPNLT) has applied to vehicles > 7.5 t with a renewed NO_x reduction to approximately 60 % of the previous PNLT requirements. The introduction of PPNLT will be completed in October 2018 also with limits for commercial vehicles ≤ 7.5 t. The deadlines at a glance:

– 10/2016 for heavy commercial vehicles > 7.5 t gross vehicle weight (GVW, not including semitrailer trucks),
– 10/2017 for heavy semitrailer trucks > 7.5 t GVW,
– 10/2018 for vehicles with 3.5 to 7.5 t GVW.

The harmonized test cycles WHSC and WHTC are used as the test cycle.

Durability
Compliance with the emission limits must be demonstrated over a defined mileage in which a distinction is drawn between three classes, each with increasing durability requirements.
– Commercial vehicles smaller than 8 t gross vehicle weight (GVW): 250,000 km.
– Medium-duty commercial vehicles smaller than 12 t GVW: 450,000 km.
– Heavy commercial vehicles over 12 t GVW: 650,000 km.

Fuel-consumption requirement
Fuel-consumption limits are prescribed for trucks and buses with a permissible gross vehicle weight of over 3.5 t. Two driving cycles (urban and extra-urban) are used.

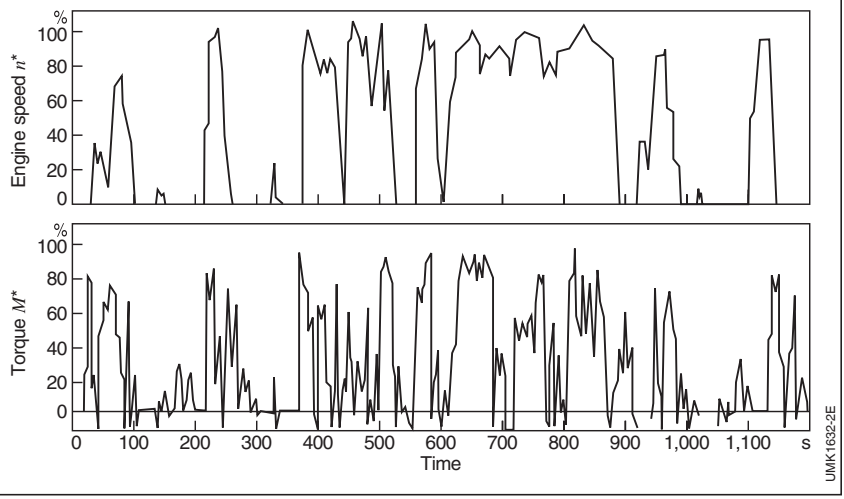
Fuel consumption is determined on the engine test bench. Because consumption is very much dependent on the individual vehicle engine and equipment specification (e.g., drivetrain, rolling resistance, vehicle weight), the calculation is made using a conversion program. The requirements are for a commercial vehicle with a gross vehicle weight smaller than 10 t 13.4 l/100 km, for semitrailer trucks with a gross vehicle weight smaller than 20 t 32.1 l/100 km/l, and for buses with a gross vehicle weight smaller than 14 t 18.9 l/100 km. The figures apply to 2025.

Regional programs
In addition to the nationwide regulations for new vehicles, there are also regional requirements for the overall vehicle population aimed at reducing existing emission levels by replacing or upgrading old diesel vehicles.

The "Vehicle NO_x Law" has been in force since 2003 within, among other places, the greater urban area of Tokyo to vehicles with a gross vehicle weight of over 3,500 kg. It states that 8 to 12 years after a vehicle is first registered, the NO_x and particulate limits of the relevant preceding phase of emission limits must be adhered to. The same principle also applies to particulate emissions. Here, the regulation will already apply seven years after first vehicle registration.

Test cycles for heavy commercial vehicles

For heavy commercial vehicles, all test cycles are run on the engine test bench. In the transient test cycles, the emissions are collected and evaluated according to the CVS principle. The untreated emissions are measured in the stationary test cycles. Emissions are specified in g/kWh.



USA

EPA Engine Dynamometer Schedule for Heavy-Duty Diesel Engines (HD FTP Transient)

Since 1987 engines for heavy commercial vehicles have been tested from a cold start on an engine test bench in a transient driving cycle (US HDDTC, Heavy Duty Diesel Transient Cycle). The test cycle is basically equivalent to operating an engine under realistic road-traffic conditions (Figure 16). It includes significantly more idle sections than the WHTC (see section "Europe").

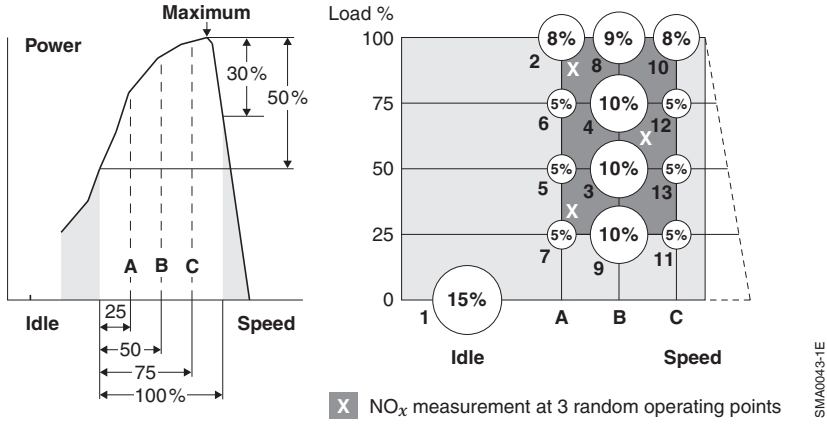
Figure 16: US FTP (Heavy-Duty Diesel Transient Cycle, HDDTC) for heavy commercial-vehicle engines

Both the nominal engine speed n^* and the nominal torque M^* are taken from tables specified by legislation.

Federal Smoke Cycle
An additional test, the Federal Smoke Cycle, tests exhaust-gas opacity under dynamic and quasi steady-state conditions. In this test, for different load conditions (torque specifications), a number of sudden full-load accelerations are run on an engine test bench to determine exhaust-gas opacity.

Additional test cycle
Since model year 2007 US emission limits have also had to comply with the European 13-stage test (ESC). Furthermore, emissions in the not-to-exceed zone (i.e., with any driving mode within a specified engine-speed/torque range) may be max. 50 % above the emission limits.

Figure 17: Steady-state 13-stage test ESC (Europe)



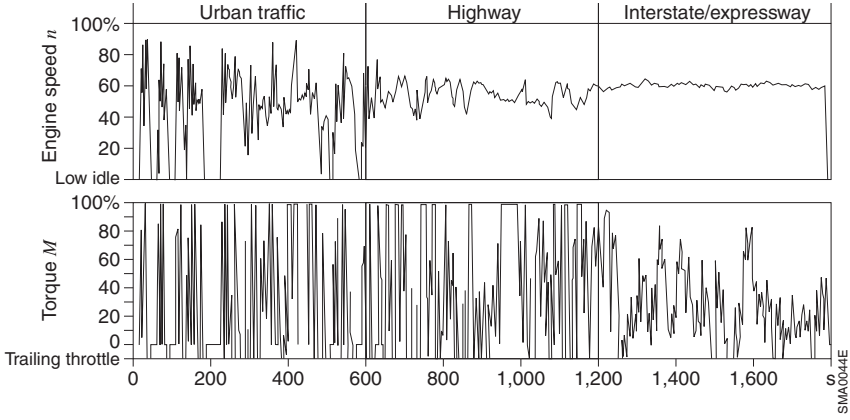


Figure 18: Transient driving cycle ETC (Europe)

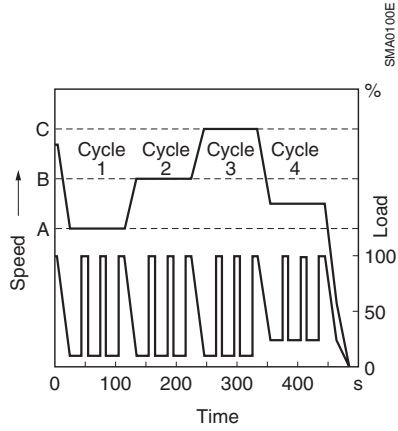
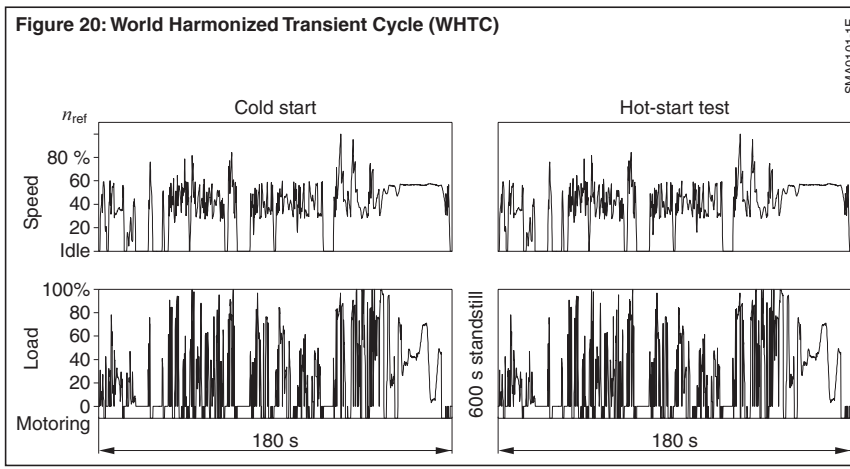


Europe
Up to Euro V all European test cycles started with a hot engine. Since EU VI a cold-start test and a hot-start test have been used

European Steady-State Cycle
For vehicles over 3.5 t permitted gross vehicle weight and more than 9 seats, the 13-stage test ESC (European Steady-State Cycle, Figure 17), has been in force in Europe since the introduction of Euro III (October 2000). The test procedure specifies measurements in 13 steady-state operating states calculated from the engine full-load curve. The emissions measured at each operating point are weighted according to certain factors. This also applies to power output. The test results are obtained for each pollutant by calculating the total of the weighted emissions divided by the total of the weighted power output.



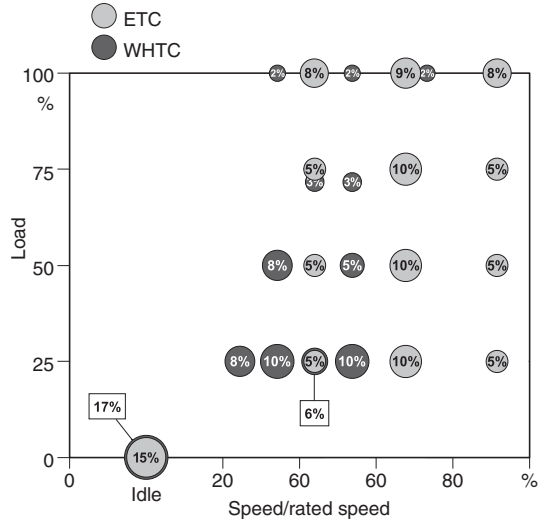
An additional three NO_x tests may be performed in the test range when certification is performed. The NO_x emissions may not vary by a significant degree from the levels measured at the adjacent operating points. The additional measuring has the goal of preventing engine modifications performed specially for the test.

Figure 19: European Load Response Test (ELR)

European Transient Cycle
As well as Euro III, the ETC (European Transient Cycle, Figure 18) was also introduced to determine gaseous emissions and particulate, and the ELR (European Load Response, Figure 19) test to measure exhaust-gas opacity. Under the Euro III standards, the ETC applies only to commercial vehicles with exhaust-gas treatment (particulate filter, NO_x reduction measures with NO_x storage catalytic converter or active SCR system); starting with Euro IV (October 2005) it has been obligatory for all vehicles.

Figure 20: World Harmonized Transient Cycle (WHTC)

The test cycle is derived from realistic road-driving patterns and is subdivided into three sections: an urban section, an extra-urban section, and an expressway section. The length of the test is 30 minutes, and the periods of time for which engine speeds and torque levels must be maintained are specified in seconds.



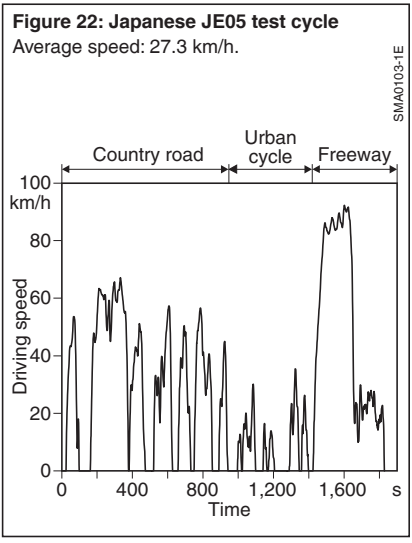
World harmonized cycles
Since 2013 world harmonized engine test cycles have had to be applied with the introduction of the Euro VI emission-limit level. The prescribed limits must be equally met both in the WHSC (World Harmonized Stationary Cycle) and in the WHTC (World Harmonized Transient Cycle, Figure 20). A new feature is a WNTE zone (World Harmonized Not To Exceed Zone), as was previously customary only in the USA. The NTE test is conducted in any driving mode within a specified engine-speed/torque range.

In relation to the WHTC limits WNTE emissions may exhibit an increase for NO_x (by 30 %) and particulates (by 60 %).

Compared with the current European tests, the harmonized engine tests are conceived in the direction of lower loads with fewer full-load operating points (Figure 21) and during the transient test clearly more overrun phases. The associated lower exhaust-gas temperatures pose a challenge to active exhaust-gas treatment systems, which must be regularly regenerated.

Real Road PEMS Tests
With the Euro VI legislation, in addition to the certification tests on the engine test bench, emissions from real road journeys are determined both for type approval and for checking vehicles already in operation (ISC, In-Service Conformity). Commercial vehicles are equipped with a mobile measuring device (PEMS, Portable Emissions Measurement System) for this purpose. The procedure is comparable with the RDE test of passenger cars and light commercial vehicles.

Figure 21: Comparison of ETC and WHTC test cycles



Japan

JE05 test cycle

Pollutant emissions were determined between October 2005 and October 2016 in the transient JE05 test cycle (Figure 22). Similarly to the European transient test for passenger cars, the JE05 test cycle for commercial vehicles comprises an extra-urban part, an urban part, and an expressway part. The test lasts 1,830 seconds and is started when the engine is hot.

Unlike the European and US commercial-vehicle tests, the JE05 test specifies the driving speed instead of the engine speed and engine torque. Because the test is conducted on an engine test bench, the quantities required of engine speed and torque are determined from the specified speeds and from the individual vehicle data using a conversion program. Required quantities include, among others, vehicle weight, tire rolling resistance, transmission ratios, torque curve, and maximum engine speed. With the introduction of the Post PNLT limit stages the harmonized European test cycles WHSC, WHTC, and WNTE are used for certification.

Figure 22: Japanese JE05 test cycle
Average speed: 27.3 km/h.

Emission legislation for motorcycles

The USA also led the way in introducing emission regulations for motorcycles. But because motorcycles only constitute a very small percentage of the overall traffic volume and consequently a very small percentage of the overall emissions and immissions, these requirements were for a long time not subject to further development compared with those for passenger cars and commercial vehicles. It was therefore left to the EU and Asian countries such as Japan to drive forward requirements for motorcycles and other L-category vehicles (i.e., two-, three-, and four-wheel vehicles such as mopeds, three-wheel delivery vans, minicars, and quad bikes). The EU regulations were incorporated into ECE Regulations, which are used by countries where two- and three-wheel vehicles are popular such as India, China, and other Southeast Asian countries as the basis for their national legislation. In these countries motorcycles play an important role as a means of transport for persons and goods, with high mileages in both urban and rural areas. Japan, Taiwan, and Thailand have introduced their own regulations for motorcycles.

The targets and instruments such as emission limits, test cycles, test procedures, and monitoring options are basically the same as those for passenger cars and light commercial vehicles (see Emission-control legislation, Overview).

Only the requirements for motorcycles (category L3/L4) with gasoline engines are considered here.

US legislation

Exhaust-gas emissions

The EPA introduced the first requirements for motorcycles in 1978. California had between 1988 and 2003 its own requirements, which were extended and tightened from 2004/2008. The EPA introduced only in 2006/2010 new requirements which are based on the Californian requirements from 2004/2008 and carry over to the entire USA.

Motorcycles are subdivided into on-highway and off-highway, each with

their own legislation, and encompass two- and three-wheel vehicles. Only on-highway motorcycles are considered here. These have since 2004 (CARB) and since 2006 (EPA) been classified according to their piston displacement into four classes to which the different durability requirements regarding mileage apply:
– Class I-A: < 50 ccm, 5 years/6,000 km,
– Class I-B: 50 to 169 ccm, 5 years/12,000 km,
– Class II: 170 to 279 ccm, 5 years/18,000 km,
– Class III: ≥ 280 ccm, 5 years/30,000 km.

The exhaust-gas emissions are measured in the FTP cycle on a chassis dynamometer at a temperature of between 20 °C and 30 °C. The emission limits are correlated with the route ridden during the test and are expressed in grams per km. The limits depend on the class and are not fuel-dependent.

Class I-A / I-B and Class II from 2004 (CARB) and from 2006 (EPA):
– carbon monoxide (CO) 12.0 g/km,
– hydrocarbons (HC) 1.0 g/km.

Class III 2004 – 2007 (CARB) and 2006 – 2009 (EPA Tier 1):
– carbon monoxide (CO) 12.0 g/km,
– hydrocarbons (HC) + nitrogen oxides (NO_x) 1.4 g/km.

Class III from 2008 (CARB) and from 2010 (EPA Tier 2):
– carbon monoxide (CO) 12.0 g/km,
– hydrocarbons (HC) + nitrogen oxides (NO_x) 0.8 g/km.

For Class III the manufacturer can average the aggregate limit value for HC + NO_x over its sold fleet.

A manufacturer can optionally certify Class I and Class II vehicles in accordance with the requirements for Class III as well.

There are no requirements with regard to particulate emissions. Unlike passenger cars, there are also no further exhaust-gas requirements.

Evaporative emissions
CARB introduced requirements for evaporative emissions from 1983. Since 2001 all classes have been governed by a limit value of 2.0 g per test in the SHED test (cf. Exhaust-gas measuring techniques), which differs in terms of procedure and duration from the test for passenger cars. Here, after the vehicle has undergone preconditioning including preparation of the activated carbon canister and with the tank filled to the defined level of 40 %, the actual tests start.

1st test: Tank-breathing losses
A linear temperature increase is conducted over 60 minutes in the SHED. Here a distinction is made between exposed and non-exposed tank and between fuel-liquid and fuel-vapor temperature. The hydrocarbon emissions given off by the vehicle are measured.

2nd test: Hot-soak losses
Following the first test the vehicle is heated in a defined riding cycle and then the increase in HC concentration is measured in the SHED over a period of one hour as the vehicle cools down.

The limit value applies to the sum total of the HC emissions in the two tests.

The EPA does not demand a SHED test, but instead focuses on limiting the permeability for hydrocarbons from fuel tank and lines by means of permeation limits. To this end, the vehicle manufacturer can either carry out a permeation test, use EPA-certified materials (defined permeation factors), or install certified components from suppliers.

Permeation limits:
– Fuel tank ≤ 1.5 g/m² and day,
– Fuel line ≤ 15 g/m² and day.

There are not requirements for consumption measurement or greenhouse-gas emissions for motorcycles.

CARB is working on an update of the legislation including OBD for motorcycles and checking a harmonization with the EU requirements. EPA is following the development at CARB and within the

framework of UN ECE and is planning from Spring 2021 a reassessment of the motorcycle regulations.

EU/ECE legislation

The basis of the EU emission legislation for motorcycles and other L-category vehicles with two, three and four wheels is the General Type Approval Directive 92/61/EEC [10]. With Directive 97/24/EC [11] limits and exhaust-gas emissions were defined on a European level for the first time and have been constantly updated ever since.

As for passenger cars and light commercial vehicles, so too for L-category vehicles the EU legislation serves as the model for the UN Regulations. These feature all the contents of the EU legislation, i.e., they reflect the EU stages described below. New requirements, which are aiming for worldwide harmonization and acceptance, are elaborated on a UN level. This applies in particular to the Worldwide harmonized Motorcycle Testing Cycle (WMTC) in the Global Technical Regulation GTR No. 2 [12].

The legislative stages for motorcycles are designated Euro or EU and denote an ever-further tightening of the exhaust-gas limits in the Type I test:
- Euro 1 (from 1999),
- Euro 2 (from 2003),
- Euro 3 (from 2006),
- Euro 4 (from 2016),
- Euro 5 (from 2020).

As for passenger cars, a type approval applies to an EU stage up to the point when the next stage is prescribed with binding effect.

The exhaust-gas emissions are measured in a defined test cycle on a chassis dynamometer in the Type I test at a temperature of between 20 °C and 30 °C. The emission limits are correlated with the route ridden during the test and are expressed in milligrams per km. They are in part fuel-dependent, i.e., different for gasoline and diesel engines.

For motorcycles, the test cycle or its applicable parts and their weighting are determined, depending on parameters like piston displacement and top speed. Here, from Euro 3 the synthetic cycle ECE-R40

Table 4: Emission limits Euro 3 to Euro 5 for Class L3 vehicles with gasoline engines (PM only for direct-injection gasoline engine)

Stage	Classification	Cycle/ weighting	CO mg/km	HC mg/km	NMHC mg/km	NO_x mg/km	PM mg/km
Euro 2	Displacement < 150 cm^3	R40 UDC	5,500	1,200	–	300	–
	Displacement ≥ 150 cm^3	R40 UDC	5,500	1000	–	300	–
Euro 3	Displacement < 150 cm^3	R40 UDC	2,000	800	–	150	–
	Displacement ≥ 150 cm^3	R40 UDC + EUDC	2,000	300	–	150	–
	v_{max} < 130 km/h	WMTC	2,620	750	–	170	–
	v_{max} ≥ 130 km/h	WMTC	2,620	330	–	220	–
Euro 4	v_{max} < 130 km/h	WMTC 30:70	1,140	380	–	70	–
	v_{max} ≥ 130 km/h	WMTC 25:50:25	1,140	170	–	90	–
Euro 5	v_{max} < 130 km/h	WMTC 30:70	1000	100	68	60	4.5
	v_{max} ≥ 130 km/h	WMTC 25:50:25	1000	100	68	60	4.5

is superseded by the more realistic dynamic cycle WMTC.

The EU emission legislation specifies for vehicles with gasoline engines limits for the following pollutants:
– Carbon monoxide (CO),
– Hydrocarbons (HC), from Euro 5 also for non-methane hydrocarbons (NMHC),
– Nitrogen oxides (NO_x),
– Particulate matter (PM) (from Euro 5 for gasoline direct-injection engines).

The emission limits for motorcycles (L3) and the test cycles are shown in Table 4. Nominally the Euro 5 limits match the limits for passenger cars Euro 5b.

To obtain approval for each vehicle model, the manufacturer must prove that the emissions of the limited pollutants do not exceed the respective limits over the service life prescribed by law (as distance traveled in kilometers). From Euro 4 for motorcycles with a top speed of 130 km/h or more the service life is 35,000 km, for a top speed of less than 130 km/h it is 20,000 km.

The type-approval test in the Type I test is conducted with a test vehicle which has been broken in for 1,000 km (from Euro 5 2,500 km or 3,500 km for top speed ≤ or > 130 km/h). Since the emission limits apply to the vehicle at the end of its service life, the measured values are multiplied by deterioration factors (from Euro 5 also additive factors) and then compared with the limit values. For this purpose either legally prescribed deterioration factors are used or the manufacturer determines these specially for this vehicle type in the Type V test (vehicle endurance run or from Euro 5 component aging).

Aside from the primary requirement in the Type I test, there is as a further exhaust-gas requirement the Type II test, in which the CO emissions are determined at idle.

As for passenger cars, there is no Type VI test at –7 °C for motorcycles.

OBD I is introduced with Euro 4, OBD II in two stages as of Euro 5.

Evaporative emissions
As with passenger cars, motorcycles with gasoline engines are subject to requirements to limit evaporative emissions (see Exhaust-gas measuring techniques) in the Type IV test. Evaporative emissions are determined from Euro 4 in the SHED (for L3 motorcycles). The procedure and the duration differ from the test for passenger cars and correspond to the Californian SHED test (see Evaporative emissions CARB).

The limit value applies to the sum total of the HC emissions in the two tests (tank-breathing and hot-soak losses):
– 2 g/test for Euro 4 (from 1/2016),
– 1.5 g/test for Euro 5 (from 1/2020).

CO_2 emissions
For motorcycles, the CO_2 emissions must also be measured in the same test as for the Type I test and from them the fuel consumption calculated. There are however no fleet targets as for passenger cars and light commercial vehicles.

Japanese legislation
The permissible emissions are being reduced in stages in Japan (similarly to in the EU).

The Japan-specific legislation with a synthetic cycle was replaced from 2012 on the basis of GTR No. 2 by the WMTC, with limit values equivalent to the previous stage.

The next WMTC stage applies from 10/2016 to new domestic types and from 9/2017 to all types and to imports.

A new requirement added from 10/2017 is the limitation of evaporative emissions. The test procedure corresponds to the Californian SHED test with a limit value of 2.0 g HC per test.

From 10/2017 Japan will also introduce its own J-OBD I regulation. This is based on Euro 4-OBD I and on the general OBD requirements of CARB-OBD II. J-OBD II on the basis of Euro 5 is planned.

For motorcycles there are no requirements with regard to consumption measurement or to CO_2 emissions.

Chinese legislation
China has introduced the EU legislation in stages. The stage China 3 from 7/2008 will be replaced from 7/2018 by China 4, which corresponds in terms of exhaust-gas and evaporative emissions to Euro 4. Euro 4-OBD I on the other hand has not been adopted; instead, a China-specific basic OBD I regulation is being developed. The next stage China 5 based on Euro 5 is in development and is to be published in 2022.

Indian legislation
India has introduced the EU legislation in stages. The stage Bharat IV from 4/2016 corresponds to Euro 3. The stage Euro 4 is to be skipped and from 4/2020 replaced by Bharat VI, which corresponds in terms of exhaust-gas and evaporative emissions to Euro 5. OBD I is to be introduced in 4/2020 and OBD II from 4/2023, if necessary in two stages as in the EU.

Exhaust-gas measuring techniques

Exhaust-gas testing

Requirements
Exhaust-gas tests on chassis dynamometers are used for the type approval to attain General Certification, as well as to develop engine or other components. They differ from exhaust-gas tests that are conducted in Germany for example in the course of “general and partial inspection for exhaust gas” (§29 StVZO, [1]) using workshop measuring devices. In addition, exhaust-gas tests are carried out on engine test benches, for instance for the type approval of heavy commercial vehicles.

Provided for information purposes only, no liability assumed for completeness!

① Path for exhaust-gas measurement via Mix-T (without determination of particulate emission),
② Path for exhaust-gas measurement via dilution tunnel (with determination of particulate emission).

The exhaust-gas test on chassis dynamometers is carried out on vehicles. The methods used are defined to simulate actual vehicle operation on the road as far as possible. Measurement on a chassis dynamometer offers the following advantages here:
– Highly reproducible results, as environmental conditions can be kept constant.
– Good comparability of tests, as a defined speed-time profile can be driven independently of traffic flow.
– Stationary setup of the measuring techniques required.

Test setup

General setup

The test vehicle is parked on a chassis dynamometer with its drive wheels on the rollers (Figure 1). This means that the forces acting on the vehicle, i.e., the vehicle's moments of inertia, rolling resistance and aerodynamic drag, must be simulated so that the trip on the test bench reproduces emissions comparable to those obtained during an on-road trip. For this purpose, asynchronous machines, direct-current machines, or even electrodynamic retarders on older test benches, generate a suitable speed-dependent load that acts on the rollers for the vehicle to overcome. More modern machines use electric flywheel simulation to reproduce this inertia. Older test benches use real flywheels of different sizes attached by rapid couplings to the rollers to simulate the vehicle weight. A blower mounted in front of the vehicle provides the necessary engine cooling.

The test-vehicle exhaust pipe is generally a gas-tight attachment to the exhaust-gas collection system – the dilution system is described below. A proportion of the exhaust gas is collected there. At the end of the driving test, the gas is analyzed for gaseous emission-limit components (hydrocarbons, nitrogen oxides and carbon monoxide) and carbon dioxide (to determine fuel consumption).

Following the introduction of the emission-control legislation, particulate emissions were initially limited in diesel-engine vehicles only. In the last few years, legislators have also begun to limit these emissions in vehicles with gasoline engines. To determine particulate emissions, a "dilution tunnel" is used with a high internal flow turbulence (Reynolds number > 40,000). Particulate filters are also used to calculate particulate emission based on load.

In addition, and for development purposes, part of the exhaust gas flow can be extracted continuously from sampling points in the vehicle's exhaust-gas system or dilution system to analyze the pollutant concentrations.

The test cycle is repeated by a driver in the vehicle. The required and current driving speeds are displayed on a driver control-station monitor. In some cases, an automated driving system replaces the driver to increase the reproducibility of test results.

Test setup for diesel-engine vehicles

To determine the pollutant emissions from diesel vehicles, it is necessary to make some changes to the test-bench setup and to the measuring techniques used. The complete sample-taking system, including the exhaust-gas measuring device for hydrocarbons, must be heated to 190 °C. This is to prevent condensation of hydrocarbons which have high boiling points, and to evaporate the hydrocarbons that have already condensed in the diesel exhaust gas.

Dilution system

Purpose of the CVS method

The most commonly used method of collecting the exhaust gases emitted from an engine is the CVS dilution procedure (Constant Volume Sampling). It was introduced for the first time in the USA in 1972 for passenger cars and light-duty commercial vehicles. In the meantime, it has been improved in several stages. The CVS method is used in other countries, such as Japan. It has also been in used in Europe since 1982. It is therefore an exhaust-gas collection method that is recognized throughout the world.

In the CVS method, the exhaust gas is only analyzed at the end of the test. Therefore the condensation of water vapor and the resulting nitrogen-oxide losses and

secondary reactions in the collected exhaust gas must be avoided.

Principle of the CVS method
The exhaust gases emitted by the test vehicle are diluted in the Mix-T or in the dilution tunnel with ambient air at a mean ratio of 1:5 to 1:10, and extracted using a special system of pumps in such a way that the total volumetric flow composed of exhaust gas and dilution air is constant. The admixture of dilution air is therefore dependent on the momentary exhaust-gas volumetric flow. A representative sample is continuously extracted from the diluted exhaust-gas flow and is collected in one or more exhaust-gas sample bags. The sampling volumetric flow is constant during the bag-filling phase. Therefore, the pollutant concentration in a sample bag at the end of the filling process is identical to the mean value of the concentration in the diluted exhaust gas during the bag-filling process.

While the exhaust-gas sample bags are being filled, a sample of the dilution air is taken and collected in one or more air sample bags in order to measure the pollutant concentration in the dilution air.

Filling the sample bags generally corresponds to the phases in which the test cycles are divided (e.g., the ht phase in the FTP 75 test cycle).

The pollutant mass emitted during the test is calculated from the total volume of the diluted exhaust gas and the pollutant concentrations in the exhaust-gas and air-sample bags.

Dilution systems
There are two alternative methods for achieving the constant volumetric flow in the diluted exhaust gas:
– PDP method (Positive Displacement Pump): A rotary-piston blower (Roots blower) is used.
– CFV method (Critical Flow Venturi): A venturi tube and a standard blower are used in the critical state.

Advances in the CVS method
Diluting the exhaust gas causes a reduction in pollutant concentrations as a factor of the dilution. The concentrations of some pollutants (especially hydrocarbon compounds) in the diluted exhaust gas are comparable to the concentrations in the dilution air (or lower) in certain test phases, since pollutant emissions have been significantly reduced in recent years as emission limits have become more stringent. This poses a problem from the measuring-process aspect as the difference in the two values is crucial for the pollutant emissions. A further challenge is presented by the precision of the measuring devices used to analyze the pollutants.

The following measures have been generally implemented in order to counter the problems described above:
– Lowering the dilution; this requires precautions to prevent water from condensing, e.g., by heating sections of the dilution systems, or drying or warming dilution air on vehicles with a gasoline engine.
– Reducing and stabilizing pollutant concentrations in the dilution air, e.g., by using activated charcoal filters.
– Optimizing the measuring devices (including dilution systems), e.g., by appropriately selecting or preconditioning the materials used and system setups or by using modified electronic components.
– Optimizing processes, e.g., by applying special purge procedures.

Bag Mini Diluter
As an alternative to the improvements in CVS technology described above, a new type of dilution system was developed in the USA: the Bag Mini Diluter (BMD). Here, part of the exhaust gas flow is diluted at a constant ratio with dried, heated, pollutant-free zero gas (e.g., cleaned air). During the test, part of this diluted exhaust-gas flow that is proportional to the exhaust-gas volumetric flow is filled in exhaust-gas sample bags and analyzed at the end of the driving test.

In this procedure, dilution is performed with a pollutant-free zero gas free of pollutants and not with air containing pollutants. This has the purpose of avoiding the air-sample bag analysis and the subsequent differential formation of exhaust-gas and air-sample bag concentrations. However, a more complex procedure is required than that for the CVS method, e.g., one requirement is to determine the (undiluted) exhaust-gas volumetric flow and the proportional sample-bag filling.

Table 1: Discontinuous measuring methods

Components	Procedure
CO, CO_2	Non-dispersive infrared analyzer (NDIR)
Nitrogen oxides (NO_x)	Chemiluminescence detector (CLD)
Total hydrocarbon (THC)	Flame ionization detector (FID)
CH_4	Combined design of gas chromatographic procedure and flame ionization detector (GC FID)
CH_3OH, CH_2O	Combined design of impinger or cartridge process and chromatographic analysis techniques; mandatory in the USA when certain fuels are used
Particulates	1.) Gravimetric method: Weighing of particulate filters before and after the test drive 2.) Particulate counting

Exhaust-gas measuring devices

In vehicles with gasoline engines, the emissions of limited gaseous pollutants are calculated from the concentrations in exhaust-gas and air sample bags (CVS method). Emission-control legislation defines globally standard test procedures for this purpose (Table 1).

Essentially, the same devices are used to measure the concentrations of gaseous pollutants in the exhaust gas of gasoline-engine vehicles as for diesel-engine vehicles. There is however a difference in how the hydrocarbon emissions (HC) are determined. This is done not in the exhaust-gas sample bag, but through continuous analysis of a partial flow of diluted exhaust gas and integration of the measured concentration via the driving test. The reason for this is that the hydrocarbons (which have a high boiling point) condense in the (non-heated) exhaust-gas sample bag.

For development purposes, many test benches also include the continuous measurement of pollutant concentrations in the vehicle exhaust-gas system or the dilution system. The reason is to capture data for the components under control, as well as for other components not subject to legislation. Other test procedures than those listed in Table 1 are required for this, e.g.:

- Paramagnetic method (to measure O_2 concentration).
- Cutter FID: a combination of flame ionization detector and absorber for non-methane hydrocarbons (to measure the CH_4 concentration).
- Mass spectroscopy (multi-component analyzer).
- FTIR spectroscopy (Fourier Transform Infrared, multi-component analyzer).
- IR laser spectroscopy (multi-component analyzer).

A description of the main measuring devices is given below.

Test-bench measuring techniques

NDIR analyzer

The NDIR (Non-Dispersive Infrared) analyzer utilizes the property of certain gases to absorb infrared radiation within a narrow wavelength range. Absorbed radiation is converted to vibration or rotation energy by the absorbing molecules. In turn, this energy can be measured as heat. The phenomenon described occurs in molecules that are formed from atoms of at least two different elements, e.g., CO, CO_2, C_6H_{14} or SO_2.

There are a number of variants of NDIR analyzers; the main component parts are a source of infrared light (Figure 2), an absorption cell (cuvette) through which the test gas is routed, a reference cell generally positioned in parallel (filled with inert gas, e.g., N_2), a rotating chopper, and a detector. The detector comprises two chambers connected by a membrane and containing samples of the gas components under analysis. Radiation from the reference cell is absorbed in one chamber and radiation from the cuvette in the other. Radiation from the cuvette may have already been reduced by absorption in the test gas. The difference in radiant energy causes a flow movement that is measured by a flow sensor or a pressure sensor. The rotating chopper interrupts the infrared radiation in cycles, causing the flow movement to change direction and therefore a modulation of the sensor signal.

NDIR analyzers possess strong cross sensitivity to water vapor in the test gas since H_2O molecules absorb a wide range of infrared radiation wavelengths. This is the reason why NDIR analyzers are positioned downstream of a test-gas treatment system (e.g., a gas cooler) to dry the exhaust gas when they are used to make measurements on undiluted exhaust gas.

Chemiluminescence detector (CLD)

In a reaction chamber, the test gas is mixed with ozone that is produced from oxygen in a high-voltage discharge (Figure 3). The nitrogen monoxide content in the test gas oxidizes to nitrogen dioxide in this environment; some of the molecules produced are in a state of excitation. When these molecules return to their basic state, energy is released in the form of light (chemiluminescence). A detector (e.g., photomultiplier) measures the emitted luminous energy; under specific conditions, it is proportional to the nitrogen-monoxide concentration (NO) in the test gas.

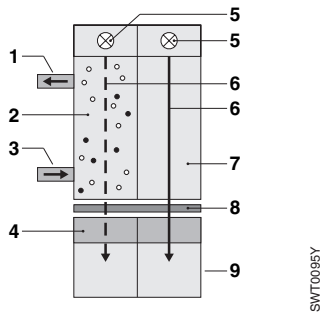

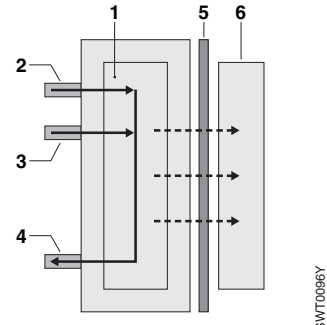

Figure 3: Design of chemiluminescence detector

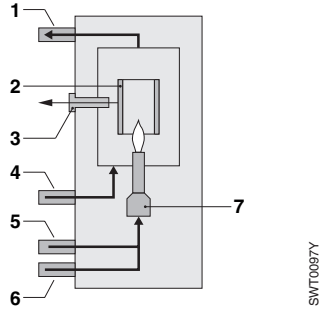
1 Reaction chamber, 2 Ozone inlet,
3 Test-gas inlet, 4 Gas outlet, 5 Filter,
6 Detector.



It is a requirement to measure the NO and NO_2 molecules as the legislation regularizes the emission of the total nitrogen oxides. However, since the test principle of the chemiluminescence detector is limited to measuring the NO concentration, the test gas is channeled through a converter that reduces the nitrogen dioxide to nitrogen monoxide.

Flame Ionization Detector (FID)
The test gas is burned in a hydrogen flame (Figure 4), where carbon radicals are formed and some of these radicals are temporarily ionized. The radicals are discharged at a collector electrode. The current produced is measured and is proportional to the number of carbon atoms in the test gas.

GC FID and Cutter FID
There are two generally common methods to measure the methane concentration (CH_4) in the test gas. Each method consists of the combination of a CH_4-separating element and a flame ionization detector. In these methods, either a gas-chromatography column (GC FID) or a heated catalytic converter oxidizing the non-CH_4 hydrocarbons (cutter FID) are used to separate the methane.

Figure 4: Design of flame ionization detector
1 Gas outlet, 2 Collector electrode, 3 Amplifier output, 4 Combustion air, 5 Test-gas inlet, 6 Combustion gas (H_2/He), 7 Burner.

Unlike the cutter FID, the GC FID can only determine the CH_4 concentration discontinuously (typical interval between two measurements: 30 to 45 s).

Paramagnetic detector (PMD)
There are different constructions of paramagnetic detectors (dependent on the manufacturer). The constructions are based on the phenomenon that forces with paramagnetic properties (such as oxygen) act on molecules in inhomogeneous magnetic fields. These forces cause the molecules to move. The movement is sensed by a special detector and is proportional to the concentration of molecules in the test gas.

Measuring particulate emission
In addition to gaseous pollutants, solid particulates are also measured, as they are also pollutants subject to legislation. Currently, the gravimetric process is the process specified by law to measure particulate emissions.

Gravimetric process (particulate-filter process)
Part of the diluted exhaust gas is sampled from the dilution tunnel (CVS method) during the driving test and then channeled through particulate filters. The particulate loading is calculated from the weight of the particulate filters before and after the test. The particulate emission during the driving test is then calculated from the load, the total volume of the diluted exhaust gas, and the partial volume channeled through the particulate filters.

The gravimetric process has the following disadvantages:
– Relatively high detection limit, only reducible to a limited extent by using complex instrumentation (e.g., to optimize the tunnel geometry).
– It is not possible to measure particulate emissions continuously.
– The process is complex as particulate filters have to be conditioned in order to minimize environmental influences.
– It is not possible to select the chemical composition of particulates or particulate size.

Particulate counting
Because of the disadvantages mentioned and the ongoing reduction of the limit values, increasingly the number of emitted particulates will be limited, as well as the particulate emission (particulate mass per distance traveled).

The "Condensation Particulate Counter" (CPC) has been earmarked as the measuring device for calculating the number of particulates in compliance with legislation (particulate counting). In this counter, a small partial flow of the diluted exhaust gas (aerosol) is mixed with saturated butanol vapor. The process of the butanol condensing on the solid particulates causes the particulates to increase dramatically in size so that it is possible to calculate the number of particulates in the aerosol with the aid of scattered-light measurement.

The number of particulates in the diluted exhaust gas is continuously calculated; integration of the measured values produces the number of particulates over the driving test.

Determination of particulate size distribution
There is increasing interest in acquiring knowledge of the size distribution of particulates in the exhaust gas of a vehicle. Examples of devices that supply this information are the Scanning Mobility Particle Sizer (SMPS), Electrical Low Pressure Impactor (ELPI), and Differential Mobility Spectrometer (DMS).

Portable emission measuring devices
A PEMS measuring device (Portable Emission Measurement Systems) consists primarily of three components to ensure a complete analysis of the vehicle emissions.

Gas PEMS
Gas-analysis apparatus is used to measure the pollutant emissions in the exhaust-gas flow. This consists of an NDUV analyzer (Non-Dispersive Ultraviolet analyzer) to determine NO and NO_2, an NDIR analyzer (see Test-bench measuring techniques) to measure CO and CO_2, and an O_2 sensor.

The NDUV analyzer is a multi-component UV photometer. The measuring principle is based here essentially on the characteristic attribute of NO and NO_2 to absorb luminous radiation in a wavelength range of 200 to 500 nm.

PN PEMS (Particle Number)
Two different measuring principles are used to measure the particulates. Firstly, portable "Condensation Particle Counters" (CPCs) are used which through condensation of the particulates, for example with n-butanol vapor make it possible to detect nanoscale particulates optically (size range: 23 to 700 nm) (see Test-bench measuring techniques, particulate counting).

Secondly, portable "Diffusion Chargers" (DCs) are used to count particulates. The measuring principle is based on the electrostatic precipitation of charged particulates. The particulates are charged by collisions with ions which are created by a gas discharge in a charging chamber in the measuring device. Precipitation of the charged particulates creates a potential difference between the metallic precipitation surface and the surrounding area. It is then possible by means of numerical methods to use this potential difference to determine theoretically the particulate number.

EFM (Exhaust Flow Meter)
The exhaust-gas volumetric flow is measured with an exhaust flow meter (EFM). Here the pressure loss is measured at a defined flow resistance inside the test pipe. The differential pressure can then be used to calculate the volume of exhaust gas.

The EFM is a test pipe mounted on the exhaust tailpipe which contains both pressure and temperature sensors. The sampling point for the gas-analysis apparatus and the sampling point for measuring the particulate number are also integrated on this adapter.

Testing commercial vehicles
In the USA the transient test method has been prescribed since model year 1987 for testing the emissions from diesel engines in heavy commercial vehicles over 8,500 lbs (EPA) and 14,000 lbs (CARB) gross vehicle weight. It is performed on dynamic engine test benches. In Europe this test method was introduced with Euro III for engines with active exhaust-gas-treatment (particulate filter or selective catalytic reduction, SCR) and with Euro IV for all engines in heavy commercial vehicles over 3.5 t gross vehicle weight. Since Euro V the test on the engine test bench is dependent no longer on the gross vehicle weight but on the reference weight (tare weight plus 100 kg).

The transient test method also uses the CVS method. However, the size of the engines demands a test setup with a substantially higher throughput in order to keep to the same dilution ratios as for cars and light-duty commercial vehicles. Double dilution (through a secondary tunnel) approved by legislators helps to limit the increased complexity of instrumentation. The diluted exhaust-gas volumetric flow can be set alternatively using a Roots blower or critical-flow venturi nozzles.

Another possibility would be to calculate the particulate emissions with a partial-flow dilution system, provided that the remaining pollutants in the undiluted exhaust gas are measured.

With Euro VI (2013) limit values for the particulate number are binding on all new model types. The value is $8 \cdot 10^{11}$ particles in steady-state and $6 \cdot 10^{11}$ particles per kWh in transient operation.

Diesel smoke-emission test

Methods
Separate legislation for testing the smoke emissions of diesel-engine vehicles came into force long before the introduction of legislation for testing gaseous pollutants. All existing smoke tests are coupled closely with the measuring devices used. One measure of smoke emission (soot, particulates) is the smoke number.

Two methods are essentially customary for measuring this value. In the absorption method (opacity measurement), the opacity of the exhaust gas is indicated by the degree to which it blocks the passage of a beam of light shining through it (Figure 5). In the filter method (measurement of reflected light), a specified quantity of exhaust gas is routed through a filter element. The degree of filter discoloration provides an indication of the amount of soot contained in the exhaust gas (smoke tester, Figure 7).

Measurement of diesel smoke emissions is relevant only if the engine is under load, since it is only when the engine is operated under load that emission of significant levels of particulates occur. Two different test procedures are also commonly used here. Firstly, measurements under full load, e.g., on a chassis dynamometer, or on a defined test circuit. Secondly, measurements under unrestricted acceleration using a defined throttle burst under the load of the engine flywheel (Figure 6).

As the results of testing for diesel smoke emissions vary according to both test procedure and type of load, they are not generally suitable for direct mutual comparisons.

Opacimeter (absorption method)
Exhaust-gas opacity denotes the attenuation of light by absorption, diffraction, scatter and reflection on the particulates contained in the exhaust gas.

A transmitter and a photodetector are mounted on the exhaust pipe for measurement of the full flow with the opacimeter. In partial-gas devices, the exhaust gas is routed through an exhaust-gas sample probe and heated lines by a pump into the

measuring chamber (Figure 5). Using a longer measuring chamber improves the device's detection limit.

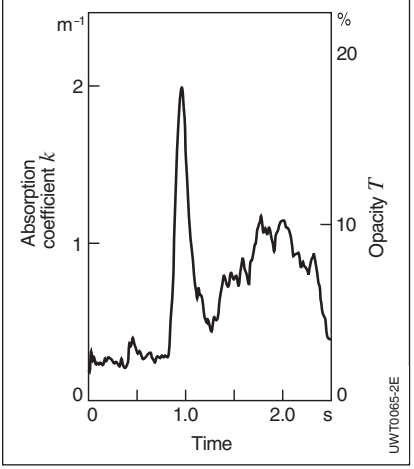
During the unrestricted acceleration part of the exhaust gas is delivered to the measuring chamber. A light beam passes through the measuring chamber now filled with exhaust gas. The attenuation of lights is determined photoelectrically and indicated as opacity T in % or as an absorption coefficient k in m^{-1} (Figure 6). A precisely defined measuring-chamber length and keeping the optical window clear of soot (by air curtains, i.e., tangential air flows) are basic requirements for high levels of accuracy and reproducibility of the measurements.

During testing under load, measurement and display are a continuous process. The opacimeter automatically determines the maximum value and calculates the mean from several gas pulses.

Smoke tester (filter method)

During soot measurement according to Bosch a defined exhaust-gas volume (330 cm^3) is drawn by means of a hand pump through a white filter paper. The blackening of the paper is determined by means of a reflex photometer. The degree of paper blackening is divided into numbers ranging between 0 and 10 (smoke number according to Bosch,

Figure 6: Gas-pulse measurement with the opacimeter



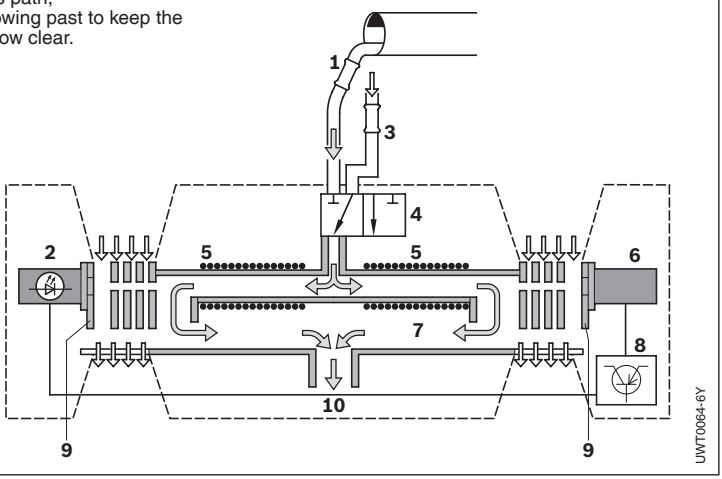


Figure 5: Opacimeter (absorption method)

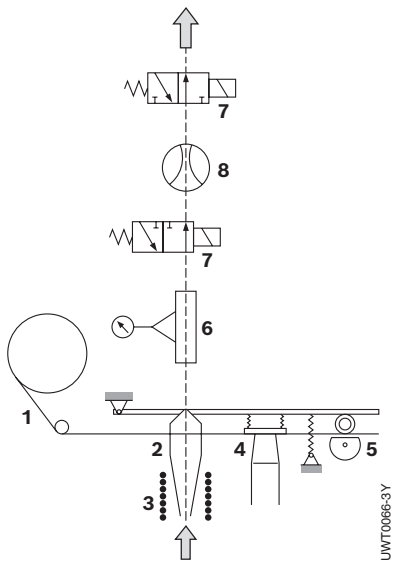
▷ Purge air flowing past to keep the optical window clear.



Bosch number), where 0 denotes white, unused paper and 10 denotes fully blackened measuring points.

An empirical correlation can be used to convert to soot-mass concentration in mg/m^3.

The method has been developed over decades. Thus, the hand pump, for example, was replaced by a continuously operating pump, the dead volume between the sample probe and the filter paper is taken into consideration, and the devices are heated to prevent condensation (Figure 7).

The filter smoke number (FSN) is defined in ISO 10054 [2]. It corresponds to the Bosch number for an effective suction length of 405 mm at a temperature of 298 K and a pressure of 1 bar.

Evaporative-emission test

Independently of the combustion pollutants produced in the engine, a gasoline-engine vehicle emits additional quantities of hydrocarbons (HC) through evaporation of fuel from the fuel tank and fuel system. The quantity evaporated is dependent on the design of the vehicle and on the fuel temperature. An activated carbon canister, in which the fuel vapors are stored, is generally used as a limiting measure. Since it only has a limited absorption capacity, the activated carbon canister must be regenerated at certain intervals. This is done by purging with fresh air while driving. The air/fuel mixture is delivered to the induction tract and combusted in the engine (see Evaporative-emissions control system). Many countries (e.g., the USA and Europe) have regulations which limit these evaporative losses.

Test methods

These evaporative emissions are usually quantified with the aid of a hermetically sealed climate chamber, the SHED (Sealed Housing for Evaporative emissions Determination). For the test, HC concentrations are measured at the beginning and the end of the test with a flame ionization detector (FID), with the difference representing the evaporative losses.

The evaporative losses must – depending on the country – be measured in some or in all of the operating states below and satisfy emission limits:

– Evaporation that emerges from the fuel system when the vehicle is parked with the engine warm following operation: hot-soak test (EU, USA, and others).
– Evaporation emerging from the fuel system as a result of temperature changes in the course of the day: tank-breathing test or diurnal test (EU, USA, and others).
– Evaporative emissions while driving, e.g., due to permeation: running-loss test (USA only).

Test procedures (examples for passenger cars and light commercial vehicles)
Evaporations are measured in several phases during a detailed prescribed test procedure. After the vehicle has undergone preconditioning including preparation of the activated charcoal canister ad with the tank filled to the defined level of 40 %, testing starts.

First test: Hot-soak losses (hot soak)
To measure the evaporative emissions in this test phase, the vehicle is heated up before the test by running through the test cycle valid for the country concerned. The engine is then turned off when the vehicle is in the climate chamber. The increase in HC concentration is measured for a period of one hour as the vehicle cools.

The vehicle's windows and trunk lid must remain open during the test. This allows evaporative losses from the vehicle interior to be included in measurements.

Second test: Tank-breathing losses
For this test, a typical temperature profile for a warm summer day (maximum temperature for EU: 35 °C; for EPA: 35.5 °C; for CARB: 40.6 °C) is simulated inside the hermetically sealed climate chamber. The hydrocarbons emitted by the vehicle under these conditions are then collected.

In the USA, both a 2-day diurnal test (48 hours; in-use test) and a 3-day diurnal test (72 hours; certification) must be carried out (the highest value over the course of the day is used in each case), where the preconditioning runs in each case slightly differently. The aim of the 3-day diurnal test is to check the sufficient capacity of the activated carbon canister. The 2-day diurnal test serves to check whether the activated carbon canister was sufficiently purged during the preconditioning preceding this test.

EU legislation from Euro 3 provided for a 24-hour test. For Euro 6d the test procedure was revised and a new test cycle WLTC, a 48-hour diurnal test and further tests for checking durability were added. Before the test procedure the activated carbon canister is to be aged according to a defined process. For further information, see Emission-control legislation.

Third test: Running losses
The running-loss test is conducted prior to the hot-soak test. It is used to assess the hydrocarbon emissions generated during vehicle operation in the prescribed test cycles (1 x FTP 72, 2 x NYCC, 1 x FTP 72; see US test cycles).

Limits
EU legislation
The total of the measurement results from the first and second days of the 48-hour diurnal test, the hot-soak tests and a double so-called permeation factor measured in an upstream procedure produces the evaporative losses. The tank is checked in a separate test procedure with regard to permeation emissions. The factor calculated from this has a bearing of the final calculation of the evaporative emissions. This total must lie below the demanded limit value of 2 g of evaporated hydrocarbons for all the measurements.

USA
In the USA (legislation according to CARB LEV II and EPA Tier 2), the evaporative losses monitored in the running-loss test must remain below 0.05 g per mile. The limit values for the hot-soak losses and the tank-breathing losses are defined for Tier 2 and LEV II as follows:
– 2-day diurnal + hot soak:
  1.2 g (EPA) / 0.65 g (CARB),
– 3-day diurnal + hot soak:
  0.95 g (EPA) / 0.50 g (CARB).

These limits must be adhered to over 120,000 miles (EPA) or 150,000 miles (CARB). They have been introduced in stages since model year 2004 and have applied in full since model year 2007 (EPA) and 2006 (CARB). Since model year 2009, EPA has alternatively permitted certification in accordance with CARB limits and CARB regulations (harmonization).

For PC (Passenger Car) and LDT1 (Light-Duty Truck), which are certified in accordance with the CARB ZEV legislation, a lower limit value in the SHED test

of 0.350 g HC per test and additionally the "zero evaporative emissions" requirement apply. Practically no emissions of fuel (limit value: 0.054 g HC/test) are meant. To this end, the above-described "3-day diurnal + hot soak" is carried out in the "rig test", i.e., a setup of tank, fuel lines, activated carbon canister, and engine by arrangement between CARB and the vehicle manufacturer.

With LEV III (phase-in 2015 through 2022) and Tier 3 (phase-in 2017 through 2022) the requirements for limiting evaporative emissions of the ZEV legislation is extended to all vehicles. The manufacturers can either adhere to the above-described ZEV limit values or alternatively the combination of slightly stricter limit values in the SHED test (for PC/LDT1 0.300 g HC/test) and the new BETP test ("Bleed Emissions Test Procedure"), with which the tightness and the purging performance only of tank, fuel lines and carbon canister but without engine are tested (limit value for PC/LDT1 0.020 g HC per test). The durability requirement is 150,000 miles.

China

China has adopted up to and including Stage 5 the EU requirements for limiting evaporative emissions. With China 6a (7/2020) China introduced its own legislation, which combines the US procedure with WLTC elements. The limit value for the sum total of hot-soak test and 2-day diurnal test (max. temperature 38 °C, counting the higher 24-hour HC value) is 0.7 g HC.

Refueling emissions

Refueling test

In the refueling test the HC emissions when refueling are measured in order to monitor evaporation of the fuel vapors displaced during refueling (limit value Tier 2/3 / LEV II/III: 0.053 g HC per liter of pumped fuel, corresponds to 0.20 g per gallon). In the USA, this test applies to both CARB and EPA.

With China 6a (7/2020) China introduced its own legislation, which combines the US procedure with WLTC elements. The limit value is 0.05 g HC/test.

There is to date no refueling test in Europe and in Japan.

Spitback test

In the spitback test, the quantity of fuel splashed out during each refueling operation is measured. The tank must be refueled to at least 85 % of its total volume (limit value only for EPA: 1 g HC per test).

The spitback test does not have to be carried out in the refueling test; instead, a declaration that the vehicle meets the requirements of the spitback test is sufficient.

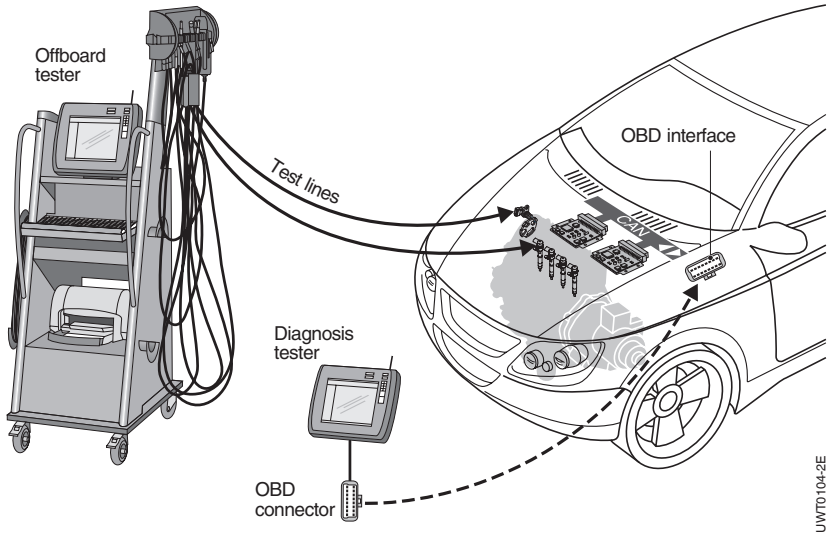
Diagnostics

The rise in the sheer amount of electronics in the vehicle, the use of software to control the vehicle, and the increased complexity of modern electronic systems place high demands on the diagnostic concept, monitoring in driving mode (on-board diagnostics), and workshop diagnostics.

As emission-control legislation becomes more and more stringent and continuous monitoring in driving mode is now called for, lawmakers have now acknowledged on-board diagnostics as an aid to monitoring exhaust-gas emissions, and have produced manufacturer-independent standardization. This additional system is termed the OBD system (On-Board Diagnostic system). Diagnosis of engine management systems is thus particularly important.



Provided for information purposes only, no liability assumed for completeness!

Monitoring in driving mode

The diagnosis integrated in the control unit is a basic feature of electronic engine management systems. Besides a self-test of the control unit, input and output signals, and control-unit intercommunication are monitored.

Monitoring algorithms check input and output signals during vehicle operation, and check the entire system and all the relevant functions for malfunctions and disturbances. Any errors or faults detected are stored in the control-unit fault memory. When the vehicle is serviced in the dealer's workshop, the stored information is exported over a serial interface. This allows troubleshooting and repairs to be carried out quickly and reliably (Figure 1).

Figure 1: Diagnostic system consisting of a diagnostic tester for reading out OBD data and an external offboard tester for further selective troubleshooting and fault localization

Monitoring input signals
The sensors, connectors and connecting lines (in the signal path) to the control unit are monitored by using the evaluated input signals. With this monitoring strategy, it is possible to detect sensor faults, short circuits to battery voltage U_B and to ground, and open circuits. The following procedures are used for this purpose:
– Monitoring sensor supply voltage (if applicable)
– Examining measures recorded for permissible value ranges (e.g. 0.5 to 4.5 V)
– Plausibility check of different physical signals (e.g. comparison of crankshaft and camshaft speeds)
– Plausibility check of a physical variable which is detected redundantly with different sensors (e.g. pedal-travel sensor)

Monitoring output signals
Actuators triggered by a control unit via output stages are monitored. The monitoring functions detect open circuits and short circuits in addition to actuator faults. The following procedures are used for this purpose: On the one hand, the electric circuit of an output signal is monitored by the output stage; the circuit is monitored for short-circuits to battery voltage U_B, to ground, and for open circuit. On the other hand, impacts on the system by the actuator are detected directly or indirectly by a function or plausibility monitor. System actuators, e.g. the exhaust-gas recirculation valve or the throttle valve, are monitored indirectly via closed-control loops (e.g. for continuous control variance), and also partly by means of position sensors (e.g. position of throttle valve).

Monitoring of internal ECU functions
Monitoring functions are implemented in control-unit hardware (e.g. "intelligent" output-stage modules) and software to ensure that the control unit functions correctly at all times. The monitoring functions check each of the control-unit components (e.g. microcontroller, flash EPROM, RAM). Many tests are performed immediately after switch-on. Further monitoring functions are repeated at regular intervals during normal operation so that component failure can also be detected during operation. Test procedures that require a high amount of computing capacity, or which cannot be performed during vehicle operation for other reasons, are carried out in the after-run after "engine off". This avoids impacting the other functions. An example of such a function is the checksum check of the flash EPROM.

Monitoring ECU communication
Communication with the other control units normally takes place over the CAN bus. Control mechanisms for error detection are incorporated in the CAN protocol so that transmission errors can be detected in the CAN chip already. The control unit also runs a variety of other tests. Since the majority of CAN messages are sent at regular intervals by the individual control units, the failure of a CAN controller in a control unit is detectable by checking these regular intervals. If redundant information is stored in the control unit, all input signals are checked against this information.

Error/fault handling
Error/fault detection
A signal path (e.g. sensor with plug connector and connecting line) is categorized as totally defective if a fault occurs over a specific length of time. The system will continue to use the last valid value until the defect is categorized. When the defect is categorized, a standby function is triggered (e.g. engine-temperature substitute value T = 90 °C).

A healing or "restored-signal recognition" feature is available during driving mode for most errors. The signal path must be detected as intact for a specific period of time for this purpose.

Error/fault storage
All faults are stored as a fault code in the non-volatile area of the data memory. The fault code also describes the fault type (e.g. short circuit, open circuit, plausibility, value range exceeded). Each fault-code input is accompanied by additional information, e.g. the operating con-

ditions (freeze frame) at the time of fault occurrence (e.g. engine speed, engine temperature).

Limp-home functions
If a fault is detected, limp-home strategies can be triggered in addition to substitute values (limp home, e.g. engine output power or speed limited). These measures are used to maintain driving safety, prevent consequential damage (e.g. catalytic converter overheating), and minimize exhaust-gas emissions.

On-board diagnostics

The engine system and components must be continuously monitored in driving mode so that compliance with the emission limits required by law can be achieved in everyday use. Therefore, starting in California, regulations were adopted to monitor exhaust-gas-related systems and components. This has standardized and expanded manufacturer-specific on-board diagnostics (OBD) with respect to the monitoring of emission-related components and systems [6].

OBD I (CARB)
In 1988 the first stage of CARB legislation (California Air Resources Board) came into force in California with OBD I. This first OBD stage requires the monitoring of emission-related electrical components (short-circuits, line breaks) and storage of the faults in the control-unit fault memory as well as a malfunction indicator lamp (MIL) that alerts the driver to detected faults. On-board means (e.g. flashing code on a diagnosis lamp) must also be in place to provide a readout of which component has malfunctioned.

OBD II (CARB)
In 1994 the second stage of diagnosis legislation was introduced in California with OBD II. OBD II became mandatory for diesel-engine cars with effect from 1996. In addition to the scope of OBD I, system functionality was now monitored (e.g. plausibility check of sensor signals).

OBD II stipulates that all emission-related systems and components must be monitored if they cause an increase in toxic exhaust-gas emissions (and thus the OBD threshold values to be exceeded) in the event of a malfunction. In addition, all components used to monitor emission-related components or which affect the diagnosis result must be monitored.

Normally, the diagnostic functions for all components and systems under surveillance must run at least once during the exhaust-gas test cycle (e.g. FTP 75, Federal Test Procedure).

The OBD II legislation furthermore prescribes standardization of the fault-memory information and access to the information (connector, communication) compliant with ISO 15031 [1] and the corresponding SAE standards (Society of Automotive Engineers), e.g. SAE J1979 [2] and SAE J1939 [3]. This permits a fault-memory readout over standardized, commercially available testers (scan tools).

OBD II expansions

From model year 2004

The law has been revised several times since OBD II was introduced. The legal requirements are generally revised by the authorities every two years ("biennial review"). Since model year 2004 it has been necessary, in addition to meeting tighter and additional functional requirements, to check the diagnostic frequency (from model year 2005) in everyday operation (In-use Monitor Performance Ratio, IUMPR).

From model year 2007 through 2013 for gasoline passenger cars

New requirements for gasoline engines are essentially the diagnosis of cylinder-individual mixture trimming (air/fuel imbalance), extended requirements with regard to diagnosis of the cold-start strategy, and permanent error/fault storage, which also applies to diesel systems.

From model year 2007 through 2013 for diesel vehicles

For diesel passenger cars and light commercial vehicles the tightened OBD emission limits are classified into three stages (up to model year 2009, model years 2010 through 2012, from model year 2013). Significantly extended functions are additionally required for the fuel-injection system, the air system, and the exhaust-gas treatment system. Thus, for example, the fuel-injection system is required to monitor the injected fuel quantity and the injection timing. The air system is required, for example, to monitor boost-pressure control and additionally the dynamic response of exhaust-gas recirculation control and boost-pressure control. In the exhaust-gas treatment system, new monitoring functions are required of the oxidation-type catalytic converter, the particulate filter, the NO_x storage catalytic converter, and the SCR dosing system (Selective Catalytic Reduction) with SCR catalytic converter. Thus, to be monitored are, for example, the regeneration frequency in the particulate filter and the dosing quantity of the NO_x reducing agent in the SCR dosing system.

One of the new requirements for diesel systems since 2009 is that, as well as the regulators, controlled functions – where they are relevant to exhaust gas – are to be monitored as well. Likewise, the monitoring of cold-start functions is subject to extended requirements.

From model year 2014/2015

Enhanced requirements have already been formulated for model year 2015 for individual components in diesel passenger cars, light commercial vehicles, and general commercial vehicles. These relate to the monitoring of the oxidation catalytic converter for "feedgas" (ratio between NO and NO_2 to operate the SCR catalytic converter), to the monitoring of the coated particulate filter for NMHC conversion (non-methane hydrocarbons), and to the monitoring of the injection system for quantity-encoded injectors. Likewise, in the course of the revision of the LEV III emission legislation some requirements pertaining to hybrid vehicles were defined more precisely with an impact on the IUMPR calculation.

From model year 2017/2023

The last revision of the OBD legislation saw among others an adaptation of the OBD threshold values to the LEV III emission legislation. The OBD II threshold value for NO_x and NMHC will be defined from LEV III as a quantity (NO_x + NMHC). The OBD threshold values as multiples of the emission limit (multipliers) were adapted in stages to the new emission categories (ULEV 50, ULEV 70, SULEV 20). For the first time an OBD threshold value was also de-

Table 1: OBD threshold values

[1] For gasoline direct injection.

[2] g/bhp-hr: grams per “brake horse power” × “hour” (brake horse power corresponds to the German unit PS).

fined for the particulate matter for gasoline engines from model year 2019 at a fixed value of 17.5 mg per mile. Further new requirements are, for example, the output of characteristics for assessing the use and activation of "Active off-cycle technologies" and fuel-consumption-specific quantities from model year 2019, improved monitoring of the crankcase-breather lines from model year 2023, and specification of a multitude of diagnostic requirements for components of hybrid vehicles.

Considerations are being given to extending the OBD requirements to CO_2 monitoring for future legislation.

Scope of application
The previously presented OBD regulations for the CARB and apply to all passenger vehicles with up to 12 seats as well as small commercial vehicles up to 14,000 lbs (6.35 t).

The current CARB OBD II legislation for California is at present also in force in some other US states. Furthermore, other US states are planning to adopt this legislation in future.

EPA OBD
Laws enforced by the EPA (Environmental Protection Agency) have been in force since 1994 in those US states which have not adopted the CARB legislation. The requirements of this diagnosis are essentially equivalent to the CARB legislation (OBD II). Within the framework of revising the Tier 3 emission legislation, from model year 2017 the EPA OBD requirements were adapted to the CARB OBD requirements. A CARB certificate is already recognized now by the EPA.

EOBD (European OBD)
On-board diagnostics attuned to European conditions is termed EOBD. EOBD has applied since January 2000 to passenger cars and light commercial vehicles with gasoline engines. The regulation has been valid for passenger cars and light commercial vehicles equipped with diesel engines since 2003, and for heavy commercial vehicles since 2005 (see OBD requirements for heavy commercial vehicles).

In 2007 and 2008 new EOBD requirements were adopted for gasoline and diesel passenger cars within the framework of the Euro 5 and Euro 6 emission and OBD legislation (Euro 5 emission level from September 2009; Euro 6 from September 2014).

A general new requirement for gasoline and diesel passenger cars is for checking the diagnostic frequency in everyday operation (In-Use Performance Ratio, IUPR) in accordance with the CARB OBD legislation (In-use Monitor Performance Ratio, IUMPR) as from Euro 5+ (September 2011).

EOBD Euro 5 and Euro 5+ requirements for diesel and gasoline engines
For gasoline engines, the introduction of Euro 5 as from September 2009 involved primarily a reduction in the OBD threshold values. In addition to a particulate-matter OBD threshold value (for direct-injection engines only), an NHMC OBD threshold value was introduced (non-methane hydrocarbons, instead of the previous HC). Direct functional OBD requirements result in the monitoring of the three-way catalytic converter for NMHC. Since September 2011 the Euro 5+ level has applied with unchanged OBD threshold values compared with Euro 5. A significant functional requirement with regard to EOBD is the additional monitoring of the three-way catalytic converter for NO_x.

For diesel passenger-car engines, Euro 5 involved a reduction of the OBD threshold values for particulate matter, CO and NO_x. In addition, there are extended requirements with regard to the monitoring of the exhaust-gas recirculation system (cooler) and above all with regard to the exhaust-gas treatment components. Here, monitoring of the SCR DeNOx system (dosing system and catalytic converter) is subject to very stringent requirements. Functional monitoring of the particulate filter is mandatory, irrespective of the untreated emissions.

EOBD Euro 6 requirements for diesel and gasoline vehicles
With Euro 6-1 from September 2014 and Euro 6-2 from September 2017 a further two-stage reduction of some OBD threshold values has been decided on (see Table 1). Furthermore, diesel systems are governed by tighter regulations for monitoring the oxidation catalytic converter and the NO_x exhaust-gas treatment system (NO_x storage catalytic converter or SCR catalytic converter with dosing system).

From September 2017 the NEDC is being replaced by the WLTC with Euro 6d-temp for the Type 1 emission test [8]. Here the emission limits as well as the OBD threshold values have not been adapted, but rather adopted unchanged. With regard to the OBD test the vehicle manufacturer can choose whether the die OBD threshold-value check is carried out on the basis of the NEDC or the WLTC. This right to choose will only exist until the end of 2021. From this point on, the OBD threshold values will exclusively be checked on the basis of the WLTC.

China OBD
In December 2016 the MEP (Ministry of Environmental Protection of the People's Republic of China) published a new law with significantly tightened emission and OBD requirements will come into force with regard to emissions in two stages (CN6a from 07/2020 and CN6b from 07/2023). The OBD requirements from 07/2020 will also apply unchanged to stage CN6b. While the previous Chinese legislation was geared very closely towards the European standard, the new CN6 law combines elements of the EU and US legislation and some country-specific new requirements. With regard to OBD, the requirements are based to the greatest possible extent on US requirements of the legislation from 2013, where some requirements have been removed or simplified and others have been enhanced. While the actual OBD requirements are geared towards the US standard, the European OBD threshold values for Euro 6-2 and the European test cycle WLTC have on the other hand been adopted.

Other countries
Some other countries have adopted different stages of the EU or the US OBD legislation (Russia, South Korea, India, Brazil, Australia).

OBD system requirements
The engine control unit must use suitable measures to monitor all on-board systems and components whose malfunction may cause a deterioration in exhaust-gas test specifications stipulated by law. A malfunction must be displayed to the driver by means of the malfunction indicator lamp (MIL) if a fault results in an excess in OBD threshold values.

OBD threshold values
US OBD II (CARB and EPA) prescribes thresholds that are defined based on emission limits. Accordingly, there are different permissible OBD threshold values for the various exhaust-gas categories that are applied during vehicle certification (e.g. LEV, ULEV, SULEV). The European EOBD regulations are based on absolute threshold values (Table 1).

Functional requirements
All exhaust-gas-related systems and components must, within the framework of On-Board Diagnostics (OBD) required by law, be monitored for malfunctions and for exceeded exhaust-gas threshold values.

Legislation demands the monitoring of electrical functions (short-circuit, line breaks), a plausibility check for sensors, and a function monitoring for actuators.

The pollutant concentration expected as the result of a component failure (can be measured in the exhaust-gas cycle) and the monitoring mode partly required by law determine the type of diagnostics. A simple functional test (black/white test) only checks system or component operability (e.g. swirl control valve opens or closes). The extensive functional test provides more detailed information about system operability and also identifies if necessary the quantitative influence of

defective components on emissions. As a result, the limits of adaptation must be monitored when monitoring adaptive fuel-injection functions (e.g. zero delivery calibration for a diesel engine, λ adaptation for a gasoline engine).

Diagnostic complexity has constantly increased as emission-control legislation has evolved.

Malfunction indicator lamp
The malfunction indicator lamp (MIL), also called the warning lamp, informs the driver that a component has malfunctioned. When a malfunction is detected, the CARB and the EPA stipulate that it must light up no later than after one driving cycle of its occurrence. In the area where EOBD applies, it must light up no later than the third driving schedule after the fault was detected.

If the malfunction disappears (e.g. a loose contact), the malfunction remains entered in the fault memory for 40 trips ("warm-up cycles"). The malfunction indicator lamp goes out after three fault-free driving schedules. The malfunction indicator lamp flashes for faults in the gasoline system if such a fault could cause damage to the catalytic converter (e.g. combustion misses).

Communication with the scan tool
The OBD legislation prescribes standardization of the fault-memory information and access to the information (connector, communication interface) compliant with the standard ISO 15031 and the corresponding SAE standards (e.g. SAE J1979, [2]). This permits a fault-memory readout over standardized, commercially available testers (scan tools).

Only diagnostics via CAN (ISO 15765 [4]) has been permitted for CARB since 2008 and for the EU since 2014.

Vehicle repair
Any workshop can use a scan tool to read out emission-related fault information from the control unit. This permits even non-franchised workshops to carry out repairs.

Manufacturers are obliged to provide the required tools and information (repair manuals on the Internet), for a suitable fee, to ensure that repairs can be carried out with the correct degree of expertise.

Switch-on conditions
The diagnostic functions are only executed if the physical switch-on conditions are fulfilled. These include, for example, torque thresholds, engine-temperature thresholds, and engine-speed thresholds or limits.

Inhibit conditions
Diagnostic functions and engine functions cannot always operate simultaneously. There are inhibit conditions that prohibit the performance of certain functions. For instance, tank ventilation (with evaporative-emissions control system) in the gasoline engine cannot function while catalytic-converter diagnosis is in operation. In the diesel engine the hot-film air-mass meter can only be monitored satisfactorily if the exhaust-gas recirculation valve is closed.

Temporary interruption of diagnostic functions
Diagnostic capabilities may only be disabled under certain conditions in order to prevent false diagnosis. Examples of such conditions are high elevation (low air pressure), during engine starting low ambient temperature, or low battery voltage.

Readiness codes
When the fault memory is checked, it is important to know that the diagnostic functions have run at least once. This can be checked by reading out the readiness codes over the diagnostics interface. These readiness codes are set for the most important monitored components on completion of the relevant diagnoses required by law.

Diagnostic System Management
The diagnostic capabilities for all components and systems checked must regularly run in driving mode, but also at least once during the exhaust-gas test cycle (e.g. FTP 75, NEDC). The Diagnostic System Management (DSM) can dynamically change the sequence for running the diagnostic functions depending on the driving condition. The objective here is to run the diagnostic functions frequently in everyday vehicle operation. Diagnostic System Management consists of the following components:
– Diagnostic Fault Path Management for storing fault states and associated ambient conditions (freeze frames),
– Diagnostic Function Scheduler for coordinating the engine and diagnostic functions,
– Diagnostic Validator for deciding centrally when faults are detected whether they are the cause or a consequential fault. As well as central validation there are also systems with decentralized validation, i.e. validation is performed in the diagnostic function.

Vehicle recall
If vehicles fail to comply with OBD requirements by law, the authorities may demand the vehicle manufacturer to start a recall at their own cost.

OBD functions

Overview
Whereas EOBD only contains detailed monitoring specifications for individual components, the specific requirements in CARB OBD II are much more detailed. The list below shows the current state of the most significant CARB requirements (as at 2017) for gasoline-engined and diesel-engined vehicles. The requirements that are also described in detail in the EOBD legislation are marked by (E).

Gasoline and diesel system:
– Exhaust-gas recirculation system (E),
– Cold-starting emission-control system,
– Crankcase ventilation,
– Combustion misses/misfiring (E, for gasoline system only),
– Fuel system,
– Variable valve timing,
– Exhaust-gas sensors (λ oxygen sensors (E), NO_x sensors (E), particulate sensor),
– Engine cooling system,
– Air-conditioning system (in the event of influence on emissions or on OBD)
– Other emission-related components and systems (E),
– In-use Monitor Performance Ratio (IUMPR) for checking the frequency of diagnostic functions in everyday operation (E),
– Requirements which apply to diesel/(gasoline) engines must, if the same technologies are used for the gasoline/(diesel) engine, be evaluated according to the diesel/(gasoline) requirements and the diagnostic concept of the authority/agency presented.

Gasoline system only:
– Secondary-air injection,
– Three-way catalytic converter (E), heated catalytic converter,
– Tank-leak diagnosis, with (E) at least electrical testing of the canister-purge valve,
– Direct ozone-reduction system,
– Cylinder-specific λ irregularity.

Diesel system only:
– Oxidation-type catalytic converter (E),
– SCR DeNOx system (E),
– NO_x storage catalytic converter (E),
– Particulate filter (E),
– Fuel-injection system (rail-pressure control, injected fuel quantity, and injection timing),
– Cooler for exhaust-gas recirculation (E),
– Boost-pressure control,
– Intercooler.

Other emission-related components and systems refer to components and systems not mentioned in this list that, if they malfunction, may cause the exhaust-gas emissions to be increased (CARB-OBD II), the OBD threshold values to be exceeded (CARB OBD II and EOBD), or the diagnostic system to be negatively influenced (e.g. by inhibiting other diagnostic functions). Minimum values must be maintained with regard to the frequency of diagnostic functions.

Examples of OBD functions

Catalytic-converter diagnosis

Gasoline system

This diagnostic function monitors the conversion efficiency of the three-way catalytic converter. This is measured by the catalytic converter's oxygen retention capability. Monitoring is performed by observing the signals from the λ oxygen sensors in reaction to a specific alteration of the setpoint value of the λ closed-loop control.

Additionally, the NO_x storage capacity (catalytic-converter quality factor) must be assessed for the NO_x storage catalytic converter. For this purpose, the actual NO_x accumulator content resulting from consumption of the reduction agent during regeneration of the catalytic converter is compared with an expected value.

Diesel system

In the diesel system, carbon monoxide (CO) and unburned hydrocarbons (HC) are oxidized in the oxidation-type catalytic converter (pollutant minimization). Diagnostic functions are used to monitor the operation of the oxidation-type catalytic converter on the basis of the temperature differential before and after the catalytic converter (exothermy).

The storage and regeneration capacity of the NO_x storage catalytic converter is monitored. The monitoring functions run based on loading and regeneration models, and the measured regeneration duration. This requires the use of λ or NO_x sensors.

The SCR DeNOx catalytic converter is monitored using efficiency diagnostics. NO_x sensors located before and after the catalytic converter are required for this purpose. The components of the dosing system and the quantity and dosing of the reducing agent are monitored separately.

Tank-leak diagnosis

Gasoline system

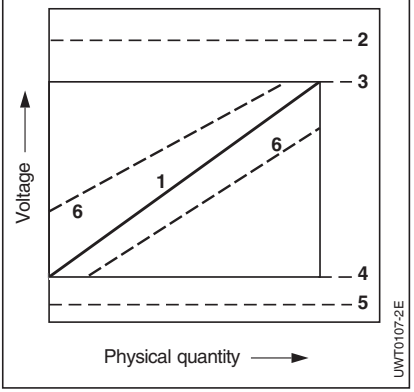
Tank-leak diagnosis detects evaporation from the fuel system that may cause an increase in HC values, in particular. EOBD is limited to simply testing the electrical control circuit of the tank-pressure sensor and the canister-purge valve (evaporative-emissions control system). In the USA, on the other hand, it must be possible to detect leaks in the fuel system. There are two different methods of doing this.

The low-pressure method observes the tank pressure and first tests its operability by deliberately actuating the tank ventilation and carbon-canister check valves. A conclusion can then be drawn on the leak size using the time curve of the tank pressure – again by deliberately actuating the valves.

The overpressure method uses a diagnosis module with an integrated electrically powered vane pump that can be used to pump up the tank system. The flow from the pump is high when the tank is hermetically sealed. A conclusion can then be drawn on leak size by evaluating the flow from the pump.

Particulate-filter diagnosis
Diesel system
The diesel particulate filter is currently monitored for the most part for filter breakage, removal, or blockage. A differential-pressure sensor is used to measure the pressure differential (exhaust-gas backpressure downstream and upstream of the filter) at a specific volumetric flow. The measured value can be used to verify whether the filter is defective. An extended function uses load models to monitor the efficiency of the particulate filter.

Since model year 2010 the regeneration frequency has also had to be monitored. Since model year 2013 a particulate sensor has been used to monitor the particulate filter in response to tightened OBD requirements in the USA. The particulate sensor (from Bosch) operates according to the "collection principle", i.e. the soot collected over a specific distance driven is evaluated using a model for a threshold-value filter. If the collected soot matter, as a function of different parameters, exceeds a certain threshold, the particulate filter is detected as faulty. Combined particulate-filter faults (e.g. broken and melted filters) can also be detected with the particulate sensor.



Exhaust-gas recirculation system diagnosis
Diesel system
In the exhaust-gas recirculation system (EGR) the regulator, the exhaust-gas recirculation valve, the exhaust-gas cooler, and other individual components are monitored.

Functional system monitoring is performed by air-mass regulators and position controllers. They check for permanent control variances. An excessively high or low EGR throughflow must be detected. System response ("slow response") must also be monitored.

The exhaust-gas recirculation valve itself is monitored for its electrical and functional operability.

The EGR cooler is monitored by means of additional temperature measurement after the cooler and with model values. This allows the cooler efficiency to be calculated.

Figure 2: Sensor monitoring
1 Sensor curve,
2 Upper threshold for "Signal Range Check",
3 Upper threshold for "Out of Range Check",
4 Lower threshold for "Out of Range Check",
5 Lower threshold for "Signal Range Check",
6 Plausibility check "Rationality Check".

Comprehensive components
On-board diagnostics requires that all sensors (e.g. air-mass meter, speed sensor, temperature sensors) and actuators (e.g. throttle valve, high-pressure pump, glow plugs) having either an impact on emissions or are being used to monitor other components or systems (and consequently may if necessary disable other diagnoses) have to be monitored.

Sensors monitor the following faults (Figure 2):
– Electrical faults, i.e. short-circuits and line breaks ("Signal Range Check"),
– Range faults ("Out of Range Check"), i.e. undercutting or exceeding voltage limits set by the sensors' physical measurement range,
– Plausibility faults ("Rationality Check"); these are faults that are inherent in the components themselves (e.g. drift), or which may be caused by shunts, for instance. Monitoring is carried out by a plausibility check on the sensor signals, either by using a model or directly by other sensors.

Actuators must be monitored for electrical faults and – if technically possible – also for function. Functional monitoring means that, when a control command (setpoint value) is given, it is monitored by observing or measuring (e.g. by a position sensor) the system reaction (actual value) in a suitable way by using information from the system.

The actuators to be monitored include all output stages, the throttle valve, the exhaust-gas recirculation valve, the variable turbine geometry of the exhaust-gas turbocharger, the swirl flap, the injectors, the glow plugs (for diesel systems), the tank-ventilation system (for gasoline systems), and the active-charcoal check valve (for gasoline systems).

OBD requirements for heavy commercial vehicles

Europe
For commercial vehicles, the first stage of On-Board Diagnostics was introduced in the EU (EOBD) together with Euro IV (10/2005), the second stage together with Euro V (10/2008). A new OBD regulation came into force together with Euro VI in 2013.

Monitoring requirements in Stage 1
– Fuel-injection system: monitoring for electrical faults and for total failure,
– Engine components: monitoring of emission-related components for compliance with the OBD threshold value,
– Exhaust-gas treatment systems: monitoring for serious faults.

Additional requirements in Stage 2
– Exhaust-gas treatment systems: monitoring for compliance with the OBD threshold value.

Additional requirements
Since November 2006 it has been required to monitor the NO_x control systems for correct operation. The systems are monitored for their own emission limits, which are more stringent than the OBD threshold values.

SCR system
The aim is to ensure that the systems are supplied with the correct reagent (urea/water solution, the customary brand name is AdBlue). The availability of the reagent must be monitored by way of the tank fill level. To check the correct quality, it is necessary to monitor the NO_x emissions either with an exhaust-gas sensor or alternatively via a quality sensor. In the latter case, it is also necessary to monitor for correct reagent consumption.

Exhaust-gas recirculation system
The exhaust-gas recirculation system is monitored for correctly recirculated exhaust-gas mass flow and for deactivation of exhaust-gas recirculation.

NO_x storage catalytic converters
Exhaust-gas sensors are used to monitor NO_x emission.

Monitoring of NO_x control systems
Faults in NO_x control systems must be permanently stored (i.e. non-erasable) for 400 days (9,600 hours). Engine power must be throttled if the NO_x OBD threshold value is exceeded or if the urea tank is empty.

Euro VI
The OBD part of the Euro VI regulation is based on the Global Technical Regulation (GTR) "World Wide Harmonized OBD" (WWH OBD). In terms of structure this WWH OBD GTR corresponds to the Californian OBD legislation (passenger cars and commercial vehicles).

WWH OBD leaves opens which monitoring operations are actually selected in a national regulation (here Euro VI) which implements WWH OBD.

In addition, emission limits and OBD threshold values as well as the choice of test cycles are established by way of the national regulations.

Special aspects of WWH OBD involve the introduction of new fault storage and new scan-tool communication (ISO 27145 [5]).

Faults must be classified according to their severity with regard to emission deterioration. Emission-related faults can be distinguished by means of malfunction-indicator-lamp behavior and scan-tool communication. The following different categories are applied:
– A: Emissions above the OBD threshold value,
– B1: Emissions above or below the OBD threshold value,
– B2: Emissions below the OBD threshold value, but above the emission limit,
– C: Influence on emissions below the emission limit.

According to this principle all emission-related faults are output, even those which exert a very small influence.

Data for Euro VI
– Drastic reduction of the emission limits and OBD threshold values for NO_x and particulate matter compared with Euro V,
– Emission limits to be introduced for NH_3 and the number of particulates,
– Use of the harmonized WHSC and WHTC test cycles,
– The OBD demonstration is performed with a double WHTC hot start part,
– Introduction of a facility for checking system conformity with regard to emissions in the field by means of random measurements with portable emission measurement systems (PEMS),
– Checking of the diagnostic frequency of OBD monitoring in everyday operation (In-Use Monitoring, IUMPR).

Euro VI A
– For new type approvals mandatory since 31 December 2012,
– Valid up to 31 August 2015,
– Strict OBD threshold values for NO_x and particulate matter (only for engines with auto-ignition). For particulate-filter monitoring a functional, non-emission-correlated diagnosis is possible as an alternative to OBD threshold-value diagnosis.

Euro VI B
– For new type approval mandatory as from 1 September 2014,
– Valid up to 31 December 2016,
– Affects only engines with externally supplied ignition,
– Introduction of an OBD threshold value for CO.

Euro VI C
– For new type approval mandatory as from 31 December 2015,
– Changes in respect of Euro VI A and Euro VI B: Tightened NO_x OBD threshold value and tightening of the NO_x control-system requirements for SCR reagent quality and consumption monitoring. Monitoring is performed with regard to the long-term drift behavior of the fuel injectors. Monitoring of the OBD diagnostic-frequency rate is mandatory.

Euro VI D and Euro VI E
– For new type approval mandatory as from 1 September 2018 or 1 January 2021,
– No change with regard to OBD.

Required diagnoses from WWH OBD
These diagnoses are compulsory for particulate filter, SCR catalytic converter, NO_x storage catalytic converter, oxidation catalytic converter, exhaust-gas recirculation, fuel-injection system, charge-air pressure system, variable valve control, cooling system, exhaust-gas sensors, idle control system, and components.

Required diagnoses outside the WWH OBD scope
For the particulate filter, the exhaust-gas recirculation system and the charge-air pressure control system no exceptions are permitted in monitoring for specific diagnoses. The relevant faults must not be defined as Class C.

Furthermore, as from Euro VI C the monitoring of possible component-damaging effects of a long-term drift of fuel injectors is required.

Fundamentally the definition of the non-emission-correlated "performance monitors" in WWH OBD has been changed. In Euro VI these diagnoses must be demonstrated with emission correlation for the first certification of an engine from an engine family.

Gas engines
Gas engines are covered by specific monitoring requirements with regard to compliance with the λ setpoint value, to NO_x and CO conversion of the three-way catalytic converter, and to the λ sensor. Furthermore, catalytic-converter-damaging combustion-miss detection is required.

Requirements with regard to NO_x control systems
For SCR systems, monitoring of the reagent tank fill level, of the reagent quality, of reagent consumption, and of dosage interruption is required.

For exhaust-gas recirculation systems, monitoring of the exhaust-gas recirculation valve is required.

Furthermore, all the NO_x control systems must be monitored for system deactivation by tampering.

Detected faults in the NO_x control system result in a reduction in stages of vehicle drivability. Torque limitation as the first stage is followed by vehicle-speed limitation to crawling speed as the second stage.

USA
CARB, model year 2007
In California "Engine Manufacturer Diagnostics" (EMD) has been called on for heavy commercial vehicles since model year 2007. This can be viewed as a precursor to an OBD regulation. EMD calls for the monitoring of all components and of exhaust-gas recirculation.

The requirements are not reflected in a separate emission limit. Furthermore, no standardized scan-tool communication is required.

Model year 2010 and following
With model year 2010 an OBD system as for passenger-car OBD II was introduced. The technical requirements are at the same level as the respective requirements for passenger cars.

Differences ensue due to the fact that commercial vehicles are subject to engine certification. All the emission limits and OBD threshold values apply here to engine cycles. The absolutely applicable values are scaled with the work performed in the cycle.

In contrast to passenger-car LEV III, a new emission regulation (introducing an NO_x and NMHC aggregate limit value) is not planned for commercial vehicles. The OBD threshold values for NO_x and NMHC thus remain unchanged, i.e. separate, for commercial vehicles.

Time frame for introducing OBD requirements
Model year 2010
A performance variant of a manufacturer's top-selling engine family must be equipped with an OBD system. The other performance variants of this engine family are covered by a simplified certification procedure.

Model year 2013
An engine family of a manufacturer must be equipped in all the performance variants with an OBD system. Furthermore, an OBS system is required in each case for a performance variant in every engine family. The other performance variants of these engine families are covered by a simplified certification procedure.

Model year 2016
All the engine families of a manufacturer must have an OBD system in all the performance variants.

Model year 2018
Engines powered by alternative fuels (e.g. gas) are subject to the OBD requirements.

Japan
Japan has had its own OBD regulation for commercial vehicles in force since 2004. The requirements are comparable in terms of content with EMD in California for model year 2007.

China
China VI has applied in China since 2020; this is based on Euro VI and additionally imposes some further requirements that also relate to OBD.
- Additional demonstration of the OBD diagnoses at the vehicle on a special commercial-vehicle chassis-dynamometer test cycle C-WTVC,
- Monitoring of the injected fuel quantity with regard to the OBD threshold values,
- Remote transmission of live operating data which are determined via the OBD system by way of remote data transmission to a server,
- So-called “Permanent DTC” fault storage similar to CARB OBD, adapted to WWH OBD fault storage,
- Special temperature monitoring for vanadium catalytic converters,
- Use of a warning and prompt system, as there is for Euro VI for NO_x control-system requirements, for OBD faults too. This relates to the OBD faults for a loss of efficiency of the most important exhaust-gas treatment systems DPF (diesel particulate filter), SCR catalytic converter (selective catalytic reduction), NO_x storage catalytic converter, and three-way catalytic converter,
- Specifically for gas engines: monitoring of crankcase ventilation.

Other countries
Further countries have in the meantime introduced OBD for commercial vehicles. These include India, Korea, Australia, Brazil, and Russia. These countries have adopted EU regulations in this regard (Euro IV, Euro V or Euro VI (Korea)).

On-board diagnostics for motorcycles

While there have hitherto been no OBD requirements for motorcycles in the USA, OBD is being introduced in three stages in the EU. Emission stage Euro 4 as from 2016 saw the introduction of OBD I, which requires the monitoring of electrical faults for emission-relevant sensors and actuators. Which diagnoses of electrical faults are required is dependent on the component. The additional requirements such as fault detection and fault storage, MIL activation, scan-tool communication, etc. conform to the EOBD passenger-car requirements.

With emission stage Euro 5 as from 2020 OBD I will be extended to include plausibility checks for sensors and function checks for actuators. The diagnostic range is dependent on the component. It will furthermore be necessary to monitor for faults which lead to a reduction of the maximum torque by more than 10 %. At the same time OBD II requirements as for EOBD apply as well. Catalytic-converter diagnosis is excluded. The detection of misfires on motorcycles is covered by engine-speed load ranges. The functional IUPR requirements must be satisfied, but without prescribed minimum ratios. From 2024 reduced OBD threshold values will reply; furthermore, catalytic-converter diagnosis is prescribed and a minimum ratio of 0.1 will apply to all diagnoses.

The first OBD I stage was carried over to UN GTR 18, which alternatively also provides for reduced scopes. The carry-over of OBD I stage 2 and of OBD II in Amendment 1 to UN GTR 18 took place in 2020. India introduced EU OBD I from 4/2020 and is expected to introduce EU OBD II from 4/2023. Discussions are being held as to whether the OBD II stage is, as in the EU, to be split into two stages.

Japan introduced its own OBD I with a similar scope to EU OBD I in 2016. A further stage OBD II is to be based on the previously mentioned UN GTR OBD II.

China has its own simplified variant of the EU OBD I legislation, valid from 7/2018.

ECU diagnostics and Service Information System

Function
The function of diagnostics in the workshop is to locate quickly and reliably the smallest replaceable defective unit. In modern vehicles it is essential to use a generally PC-based diagnostic tester. Diagnostics in the workshop utilizes the results of diagnostics conducting in driving mode (fault-memory entries), employing special workshop diagnostic modules in the vehicle ECU or diagnostic tester and additional test and measuring equipment. These diagnostic options are integrated in the diagnostic tester in prompted troubleshooting.

Prompted troubleshooting
The main element of workshop diagnostics is the prompted troubleshooting procedure. The workshop employee is guided, starting out from the fault pattern or from the fault-memory entry, through the relevant diagnostic steps. The choice and order of the diagnostic steps is dynamic and depends on the result of the previous diagnostic step. The diagnostic results contain the use of test equipment, additional sensors or workshop diagnostic modules.

Symptoms
Faulty vehicle behavior can be either perceived directly by the driver or documented by way of a fault-memory entry. At the beginning of fault diagnosis the workshop employee must identify the existing symptom as the starting point for prompted troubleshooting.

Fault-memory entries
All the faults that occur during driving are stored in the fault memory together with defined ambient conditions prevailing at the time of their occurrence, and can be read out via an interface protocol. This protocol is based on one of the established standards and is generally extended to include manufacturer-specific components. The fault memory can also be deleted with the diagnostic tester.

Additional test equipment and sensors
The diagnostic options in the workshop are expanded by using additional sensors (e.g. clamp-on current pickup, clamp-on pressure pickup) or test equipment (e.g. Bosch vehicle-system analyzer). In the event of a fault detected in the workshop, the equipment is adapted to the vehicle. The measurement results are generally evaluated by the diagnostic tester.

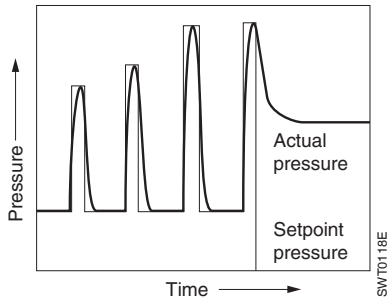
Workshop diagnostic modules
All the workshop diagnostic modules can be used only when a diagnostic tester is connected and generally only when the vehicle is stationary. The operating conditions are monitored in the ECU. These diagnostic modules integrated in the ECU, after being started by the diagnostic tester, run completely autarkically in the ECU and on completion signal the result back to the diagnostic tester. ECU-based workshop diagnostic modules differ from simple actuator tests with acoustic feedback in that they can place the vehicle to be diagnosed in the workshop into as a rule no-load operating points, excite actuators depending on the boundary conditions set, and independently evaluate the result via sensor values with an evaluator logic circuit. Examples of such modules are the high-pressure test as system test for the diesel injection system (Figure 1) and the run-up test as component test for the diesel injectors (Figure 2).

Tester-based diagnostic modules
The functional sequence and evaluation are executed in the case of tester-based diagnostic modules in the diagnostic tester, where the measurement data used for evaluation are determined with the aid of the ECU by sensors in the vehicle or by additional test sensors.

The performance of the tester-based diagnostic modules is dependent on the released interfaces in the engine ECU and the data transfer between engine ECU and tester. On the other hand, high flexibility

Figure 1: High-pressure test for the diesel injection system

Detection of leaks in the high-pressure system and efficiency of high-pressure generation.
Steps:
Start test – Increase setpoint pressure – Measure pressure build-up time – Reduce setpoint pressure – Measure pressure reduction time – Variation of engine speed and pressure – Measure pressure reduction time with engine stopped at end of test – Diagnostic results.



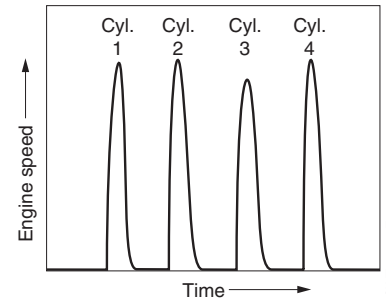


Figure 2: Run-up test for the diesel injectors

Detection of deviations of injected fuel quantity of individual injectors.
Steps:
Start test – Cutout of individual cylinder – Quantity jump – Measure maximum speed – Repeat with further cylinders – Diagnostic result.

is also possible after series introduction since new diagnostic modules can also be used thanks to a simple update of the tester software. Selective diagnostics is therefore possible when field problems occur.

Further contents of fault-finding instructions

The fault-finding instructions also include function descriptions, electrical terminal diagrams, installation positions for components, read-outs of actual values, and actuator diagnostics.

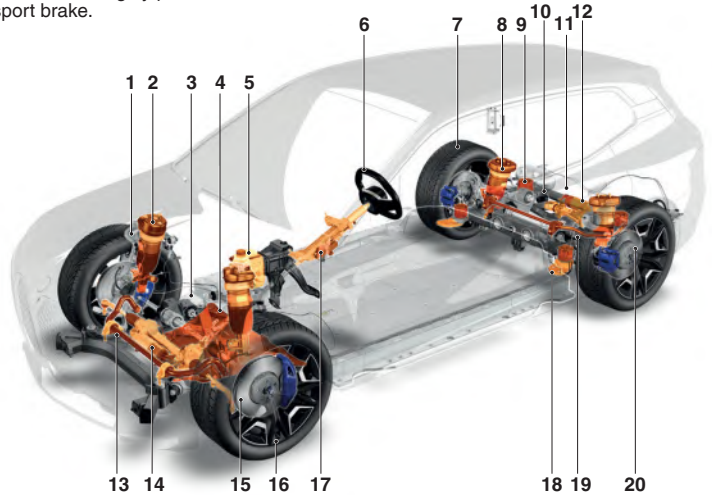
Chassis systems

Overview



Definition

Aside from the drive (engine, transmission) and the vehicle body (body, interior), the chassis constitutes one of the classic, property-determining main assemblies of a motor vehicle. As the link between the vehicle body and the road, the chassis is crucial to generating and transmitting the horizontal and vertical forces between the tires and the road which make it possible to propel, brake, and steer a vehicle. With the exception of the aerodynamic influences all the external forces and moments are introduced to the vehicle via the tire contact area (tire contact patch, footprint). During driving it is imperative that contact between the tire and the roadway is not lost. The higher the driving speed, the more exacting the demands on the transmission of force to the tire contact patches. The chassis and its properties therefore have a significant impact on a vehicle's driving dynamics (handling), ride comfort, and driving safety.

Because of the many and sometimes contrary requirements imposed on a vehicle between the conflicting priorities of driving dynamics, ride comfort, and driving safety, the design and tuning of a chassis are subject to high levels of complexity.

Chassis design
A chassis in the classic sense is divided into the following subsystems:
– suspension (body suspension and anti-roll bars),
– shock absorbers,
– wheel suspension and suspension linkage (wheel control),
– wheels with tires,
– steering, and
– brake system.

Figure 1 shows a typical chassis and its components. The fundamentals and particulars of the individual subsystems of a chassis will be addressed in greater detail in the following.

Functions of the chassis
The fundamental function of the chassis is to move the car by transmitting the drive torque to the roadway. The driver influences the horizontal movement by steering; in the process, the vehicle should hold its course and allow the driver to guide the vehicle safely and comfortably.

The vertical movement of the vehicle is determined by the course of the road and road-surface irregularities, which excite vibrations. The chassis decisively determines these vibration effects occurring during driving in the longitudinal, lateral, and vertical vehicle directions. The function of the chassis is to reduce these vibrations in as controlled a manner as possible. It is essential to avoid as far as possible the transmission of these vibrations to the vehicle body so as to reduce rolling, yawing, and pitching and to prevent the bonanza effect (rocking).

Further functions of the chassis are to support the vehicle mass and to bear, guide, steer, and brake the wheels.

A dynamically well tuned chassis enables the driver to drive comfortably and safely because it implements the driver's inputs precisely. The driver can safely keep on top of or avoid entirely critical situations.

Lightweight construction
The chassis has a substantial influence on the weight. But the lightweight construction of the chassis components also plays a significant role in that the entire unsprung mass of the vehicle (wheels, tires, wheel carriers and wheel bearings, wheel suspension, springs, and shock absorbers) is located in the chassis. The lower unsprung mass of the chassis influences vehicle handling in a positive way; the lower it is, the less the wheel vibrations affect the body. This reduces disturbance variables and as a result increases driving safety and ride comfort.

Influence of driver-assistance systems
The driver-assistance systems assigned to active safety (e.g., driving-dynamics control, lane-keeping support) affect the stabilization and course holding of the vehicle via chassis components. This also illustrates the significance of the chassis.

Further chassis developments
Where the chassis in the past was characterized above all by mechanical components, so today active components (e.g., adjustable shock absorbers, rear-axle steering) and networked chassis systems are – above all in the passenger-car sector – state of the art. The interaction of active components, sensors for monitoring and calculating the driving condition, and intelligent control approaches open up a multitude of new possibilities for influencing relevant chassis properties in response to specific situations. These possibilities for the individual subsystems will also be addressed in greater detail in the following.

Basic principles

Dynamic behavior of a vehicle

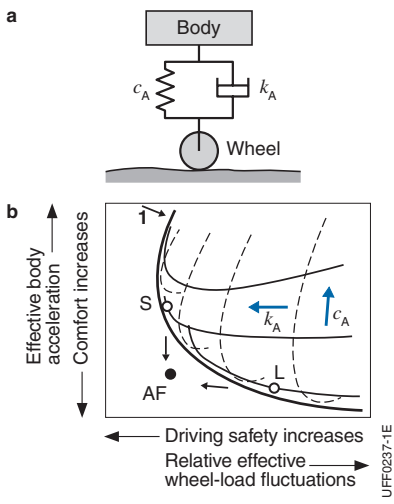
Vertical movement

The roads normally used by motor vehicles feature irregularities that cover a frequency range of up to around 30 Hz and are the most intensive source of excitation in the vehicle. The resulting excitation leads to vertical movements (vertical accelerations) of the vehicle and its occupants. The interface between the road surface and the vehicle is the chassis system, the main task of which is power transmission between the environment and the vehicle body. This means that both the dynamic characteristics of the vehicle and driving safety (due to wheel-load fluctuations), as well as ride comfort (due to body acceleration), are heavily influenced by the choice of chassis system (Figure 2). Driving safety increases with decreasing effective wheel-load fluctuations, comfort increases with decreasing effective body accelerations.

Influencing the vehicle dynamics

The dynamics of the vehicle response, however, are not exclusively determined by the chassis system components, but rather are much more a consequence of the combination of different overall vehicle parameters. As a rule, influencing the vehicle dynamics with measures on the chassis system involves high complexity, in particular because the effects of parameter variations have to prevail among the conflicting priorities of driving safety and ride comfort.

Driving safety



Driving safety depends decisively on the contact relationships between the tires and the road surface, and thus on the longitudinal and lateral forces that can be transferred. A fundamental aim in chassis configuration with regard to driving safety is therefore always to minimize the dynamic wheel load fluctuations that cause a reduction in the level of force that can be transferred.

Ride comfort

The ride comfort, on the other hand, depends on the movements and accelerations that affect the occupants (above all in the vertical direction). Depending on the area of application, comfort is of great relevance and should in no way be regarded merely as a concomitant of system development. In the case of professional drivers in particular, adequately high ride comfort is to be ensured in order to prevent long-term damage to health. The effective value of the body acceleration has proven to be a good evaluation parameter in this context.

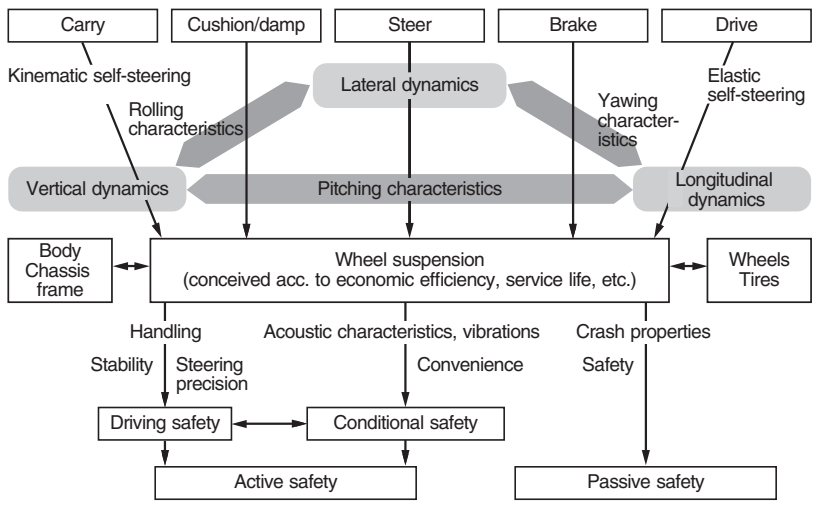
L Sedan, conventionally configured, passive,
AF Active chassis, controlled.

Fundamental requirements for a chassis

These core parameters, however, initially only describe the potentials of a chassis system to meet the corresponding requirements. The actual dynamics of the vehicle, the driving safety, and the comfort also depend decisively on the choice of road-surface parameters (environment) and vehicle-internal manipulated variables (e.g., steering angle and accelerator-pedal position) set by the driver. The fundamental requirements for a chassis are shown in Figure 3 [1]. The chassis as a system (without electronics) is traditionally divided into the following subsystems:

– suspension,
– shock absorbers,
– wheel suspension and suspension linkage (wheel control),
– wheel-and-tire combination,
– steering, and
– brake system.



Alongside the adaptation of the oscillatory system to the external road excitations, vehicles also require the influence of internal sources of excitation on the vibration characteristics (drivetrain, wheel, and tire) to be minimized [2].

Knowledge and a description in the form of objective variables of the road excitation that causes vibrations are required in order to examine the vibration characteristics and to configure the suspension/shock absorber system of a chassis. (See Dynamics of vertical motion.) Whereas minor irregularities can already be compensated for by the suspension characteristics of the tire, an element between the wheels and body that changes its length is required to reduce greater body movements. Steel springs are used most frequently here, delivering a return force that depends on the change in length. The result is – taking account of the wheel and body masses – a system that can vibrate and requires other elements for damping.

Measures for vibration minimization

Road excitations lead to axle and body vibrations in vehicles. These are to be avoided in the course of minimizing dynamic wheel-load fluctuations (driving safety increases) and body accelerations (comfort increases). They are reduced

Figure 3: Requirements for a passenger-car chassis

by means of the corresponding components for suspension and damping within the wheel suspension, whereby different systems for suspension, damping, and suspension linkage have proven effective depending on the area of application. The influence of different suspension/shock absorber parameters and their effects on different frequency ranges is shown in Table 1.

Body springs and body dampers are traditionally used for these tasks. Coupled with kinematics and elastokinematics in the wheel suspension that are configured in line with requirements, these are intended to ensure optimal power transmission between the tires and road surfaces and, simultaneously, high levels of comfort. Sportier or comfortable tuning of the chassis can be achieved with passive elements, as the conflict diagram in Figure 2 shows. This conflict of aims can be resolved to a large extent by the use of active or adjustable-characteristic springs and dampers.

However, with the increasing use of actuators in the chassis area (e.g., superimposed steering, torque vectoring), the application overhead for optimization of the subsystems is becoming increasingly important, this being met among others by the integration of functions in a Central Chassis Control unit [3]. One of the most important reasons for this is the increase in the product added value due to low-cost function integration on the software side (i.e., the complete implementation of various functions of different subsystems in the software environment – without being forced to increase the technological overhead). In addition, the technical and economic synergy potentials in overall vehicle networking can be increased significantly and the differentiation potential of various derivatives can be enhanced using the same electronic and software modules. This means that electronics and software are becoming increasingly important in the area of chassis systems as complexity increases.

Table 1: Effects of changes to the suspension/shock-absorber system on the vertical vehicle vibration characteristics

	Design parameters	Effects in the low-frequency range (body natural frequency)	Effects in the middle frequency range	Effects in the higher-frequency range (axle natural frequency)
Body data	Spring constant	Body natural frequency and body acceleration drop radically when the spring rigidity is reduced	Body acceleration drops slightly on reduction of the spring rigidity	Body acceleration remains virtually constant on reduction of the spring rigidity
	Dampening rate	Body acceleration rises radically on reduction of the dampening rate	Body acceleration drops radically on reduction of the dampening rate	Dynamic wheel load fluctuation rises radically on reduction of the dampening rate
Tire data	Spring constant	Natural frequency and amplitude remain approximately constant		Natural frequency and amplitude of the body acceleration and wheel load fluctuations drop approximately proportionally to the reduction in vertical wheel spring rigidity
	Dampening rate	Natural frequency and amplitude remain approximately constant		Amplitude of the body acceleration and wheel load fluctuation drops slightly with increasing damping at consistent wheel natural frequency

Characteristics

Characteristics of the complete vehicle

The handling of the complete vehicle comprises essentially the behavior of the body – i.e., bodywork, passenger cell, engine, and transmission – and the suspension linkage (wheel control) – i.e., axle, steering, wheels, and tires. The motion of the body can generally be described as a rigid body. Even in the bodies of convertibles, deviations from rigid-body motion only occur above the frequency range of 10 to 15 Hz.

Characteristics of the complete vehicle, the wheel suspension, the steering kinematics, and the tire are defined for the purpose of describing the handling. The basic terms explained in the following (for quantities and units, see Table 2) describe vehicle handling in the important frequency range up to approx. 8 Hz. Many of these characteristics are described in the standards ISO 8855 [4] and DIN 70000 [5] (withdrawn standard).

Figure 4 shows the system of coordinates to which the layout of the components and quantities refer.

Wheel contact point

The wheel center plane and the road plane have an intersection line on which the wheel contact point is situated at the point where the connection of the wheel

center to this intersection line intersects the intersection line vertically.

Wheelbase
The wheelbase l according to ISO 612 [6] is the distance between the wheel contact points of the front and rear wheels.

A long wheelbase delivers a lower pitch behavior and thereby facilitates better ride comfort. At the same time a long wheelbase reduces the yaw velocity which is generated by predefined wheel steering angle. A short wheelbase on the other hand delivers better maneuverability (e.g., when parking). The ratio of wheelbase to vehicle length is in the range of 0.6 to 0.7. A ratio of approximately 0.7 is established for small vehicles.

Track width
The track width s is the distance between the wheel contact points of the wheels on one axle.

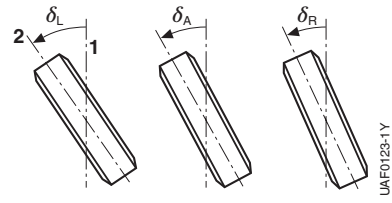
A wide track width generally results in better handling and greater ride comfort. The drawbacks of a wider vehicle are the greater weight and the higher aerodynamic drag. Typical values for the ratio of track width to vehicle width are in the range of 0.80 to 0.86.

Center of gravity
The concentrated total mass of the vehicle is assumed at the center of gravity.

A low center of gravity results in good handling (typical of sports cars), low rolling and pitching.

Wheel load
The wheel load is the force acting on the wheel contact point between the roadway and the wheel vertically to the roadway.

When the vehicle is stationary on a level surface the sum total of the wheel loads is equal to the force due to weight of the complete vehicle.



Axle-load distribution
The axle-load distribution specifies the ratio of the axle loads on the front and rear axles with regard to the total vehicle mass. For traction reasons on vehicles with front-wheel drive the axle load is 55 % on the front axle and accordingly 45 % on the rear axle. For rear-wheel drives the ratio can be established at 50:50.

Characteristics of the wheel suspension
The front wheels have two degrees of freedom, i.e., the degree of freedom for compression and rebound and that for steering. The rear wheels generally only have the one degree of freedom for compression and rebound. In the case of vehicles with four-wheel steering, the rear wheels also have the degree of freedom for steering. These degrees of freedom are defined by the kinematics and elastokinematics of the axle. Kinematics of the axle is the pure rigid-body motion of the individual suspension arms, while elastokinematics describes the behavior of the axle in response to the effect of forces and moments. The characteristics of the wheel suspension are described in the following.

Toe angle
Moving the steering wheel causes the two front wheels to turn in the same direction. This alters the toe angle of the right and left wheels (δ_R and δ_L) respectively. The toe angle is the angle between the vehicle center plane and the wheel center plane when projected onto the x-y plane (roadway, Figure 5). In the case of a positive turn, i.e., in the counterclockwise direction about the wheel's z-axis, the toe angle is also positive.

The difference between the toe angles can amount to several degrees with the steering-wheel angle at maximum. When viewed geometrically, the toe angle of the

Figure 5: Toe angle and axle steering angle
1 Vehicle center plane,
2 Wheel center plane.
δ_L Toe angle of left wheel,
δ_R Toe angle of right wheel,
δ_A Axle steering angle (steering angle), mean toe angle.

inside wheel is greater than the toe angle of the outside wheel.

On vehicles with four-wheel steering the rear wheels also move.

Axle steering angle (steering angle)
The mean toe angle is called the axle steering angle δ_A or simply the steering angle (Figure 5).

Toe-in and toe-out
When the steering wheel is in the straight-ahead position, the toe angles of the front wheels are in the dynamically advantageous range of 0.1 to 0.3°. When the distance of the rim flanges ahead of the wheel centers is smaller than that of the rim flanges after the wheel centers, this is referred to as wheel toe-in (Figure 6). When the situation is reversed, this is referred to as wheel toe-out. Both toe-in and toe-out are given in degrees (°).

The terms toe-in and toe-out are also used to refer to a single wheel. In this case, toe-in means that the wheel has a toe angle in the direction of the vehicle center plane and toe-out that it has a toe angle against the direction of the vehicle center plane.

Camber angle
The camber angle γ is the angle between the vehicle center plane and the wheel center plane when projected onto the z-y plane. The camber angle is positive when the wheels are further away from the vehicle center plane at the top than at the bottom (Figure 7a). On account of the axle kinematics the camber angle relative to the body is dependent on the spring travel. The spring travel is the travel obtained when the wheel rebounds and compresses relative to the body referred to the z-direction.

Further to this definition, the camber angle relative to the road is likewise important to vehicle handling. The camber angle relative to the road is the angle between the wheel center plane and the normal line to the road surface (Figure 7b). The preceding sign is determined according to the rectangular right-handed system. If the vehicle center plane is perpendicular to the road surface, both definitions of the camber angle are equal in terms of amount. Otherwise, it is important to observe the precise definition.

Transverse pole
When the axle is subjected to compression and rebound the position of the wheels is determined primarily by the kinematics and elastokinematics. The wheel moves transversally to the direction of travel about the transverse pole (Figure 8). The speeds for

γ Camber angle.

example at the wheel contact point (v_{RAP}) and at the wheel center (v_{RMP}) are during compression and rebound perpendicular on the connecting line to the transverse pole. The position of the transverse pole changes during compression and rebound.

Roll pole
The vehicle body moves in the case of low lateral accelerations about the roll pole of the respective axle (Figure 8). The roll pole is on the connecting line for wheel contact point and transverse pole in the vehicle center plane, i.e., at half the track width (s/2). The height h_W of the roll pole can thus be easily calculated:

$$h_w = \frac{v_{RAP,y}}{v_{RAP,z}} \frac{s}{2} .$$

The height of the roll pole is typically below 120 mm. In order in the case of high lateral accelerations to avoid the support effect – i.e., the jacking effect – the height of the roll pole decreases with compression.

The roll pole is also known as the roll center or instantaneous center.

Roll axis
The connection between the roll pole of the front axle and the roll pole of the rear axle is called the roll axis (Figure 9). The center of gravity of the body is usually above the roll axis. Center-of-gravity heights for sedans range between 550 and 650 mm. This roll axis applies for lower lateral accelerations. In the case of higher lateral accelerations, both the suspension adjustment and the axle behavior must be taken into consideration. The roll axis is then not inevitably in the vehicle center plane.

Longitudinal inclination at wheel center
The angle between the direction of motion of the wheel center during compression and rebound and the z-axis is called the longitudinal inclination at wheel center ε_V (Figure 10).

Longitudinal pole
When the spring movement of the axle is projected onto the vehicle center plane, the wheel moves about the longitudinal pole L (Figure 10), i.e., the wheel center moves during compression not along the z-axis but along the direction which was rotated about the longitudinal inclination at wheel center relative to the z-axis. The speeds at the wheel contact point (v_{RAP}) and the wheel center (v_{RMP}) are during compression and rebound perpendicular on the connecting line to the longitudinal pole. The position of the longitudinal pole can change during compression and rebound. The angle between the connection of the wheel contact

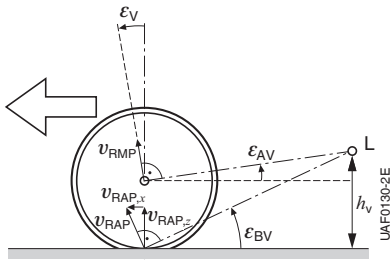
⇦ Direction of travel.



point to the longitudinal pole and the road is called the anti-dive angle ε_B. The angle between the connection of the wheel center to the longitudinal pole and the parallel line to the road is called the anti-lift angle ε_A.

The longitudinal pole of the front axle is behind the front wheels and the longitudinal pole of the rear axle is in front of the rear wheels (Figure 11).

Figure 10: Longitudinal pole, anti-lift angle and anti-dive angle

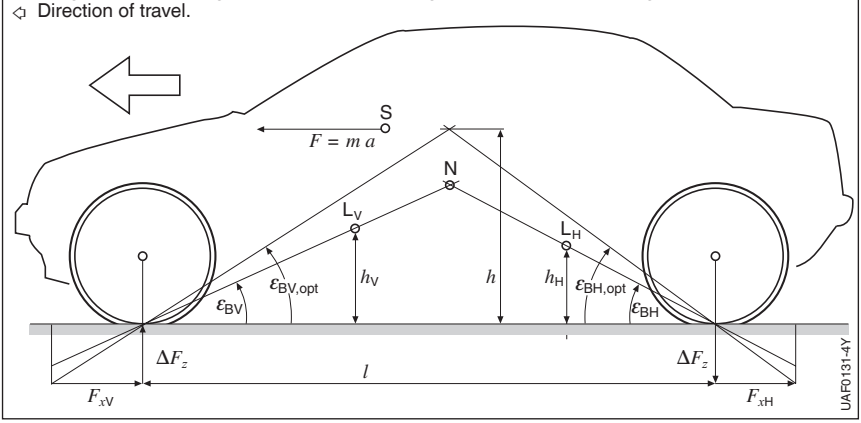
◁ Direction of travel.

When the vehicle is braked, the front axle load is increased by ΔF_z and the rear axle load decreased by ΔF_z. At the vehicle center of gravity the force $F = m\,a$ is applied. With braking-force distribution λ_B the braking forces $F_{xV} = \lambda_B F_x$ and $F_{xH} = (1 - \lambda_B) F_x$ are applied to the front and rear axles respectively. In the optimum case where the resulting force from F_{xV} and ΔF_z on the front axle passes exactly through the longitudinal pole and similarly on the rear axle, no spring movement occurs in the vehicle's body springs. For the optimum anti-dive and anti-rise angles:

$$\tan(\varepsilon_{BV,opt}) = \frac{1}{\lambda_B}\,\frac{h}{l},$$

$$\tan(\varepsilon_{BH,opt}) = \frac{1}{(1-\lambda_B)}\,\frac{h}{l},$$

with wheelbase l and height of center of gravity h.



Similarly, for the case of traction, an optimum anti-lift angle can be calculated in each case on the front and rear axles. In this case λ_A specifies the proportion of tractive force on the front axle. For the optimum anti-lift angle on the front and rear axles:

$$\tan(\varepsilon_{AV,opt}) = \frac{1}{\lambda_A}\,\frac{h}{l},$$

$$\tan(\varepsilon_{AH,opt}) = \frac{1}{(1-\lambda_A)}\,\frac{h}{l}.$$

Figure 11: Longitudinal pole and pitch pole

◁ Direction of travel.

Pitch pole
The two connecting lines between the wheel contact points and the longitudinal pole intersect at the pitch pole N (Figure 11). The pitch pole N is always below the height of the center of gravity so that an expected vehicle pitching motion towards the front can always be effected when braking.

Pitch axis
The pitch axis passes through the pitch pole and is perpendicular to the vehicle center plane.

Braking-torque compensation and starting-torque compensation
Braking-torque compensation X_{BV} and X_{BH} is a measure of how effectively optimum braking compensation has been implemented. The following applies:

$$X_{BV} = \frac{\tan(\varepsilon_{BV})}{\tan(\varepsilon_{BV,opt})}\ 100\ \%\ ,$$

$$X_{BH} = \frac{\tan(\varepsilon_{BH})}{\tan(\varepsilon_{BH,opt})}\ 100\ \%\ .$$

The same applies to acceleration. It is necessary to take into account firstly the type of drive, i.e., four-, front- or rear-wheel drive, and secondly the fact that the tractive force is applied at the wheel center. In the general case of four-wheel drive the following applies to starting-torque compensation X_{AV} (front) and X_{AH} (rear):

$$X_{AV} = \frac{\tan(\varepsilon_{AV})}{\tan(\varepsilon_{AV,opt})}\ 100\ \%\ ,$$

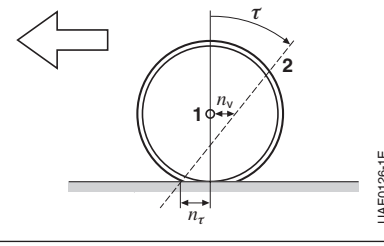
$$X_{AH} = \frac{\tan(\varepsilon_{AH})}{\tan(\varepsilon_{AH,opt})}\ 100\ \%\ .$$

Characteristics of steering kinematics

Steering-wheel angle and steering-wheel torque
The steering-wheel angle δ_H is the turning angle of the steering wheel measured from the straight-ahead position. The angle is positive for a left-hand curve.

The driver must apply a torque when adjusting the steering-wheel angle. This torque is called the steering-wheel torque M_H and is also positive for a left-hand curve.

Steering ratio
Essentially, on account of the steering gear but also on account of the kinematics of the front axle, the toe angle obtained at the wheels is significantly smaller than the steering-wheel angle. In such a case where there are no acting forces or torques and where the vehicle is barely loaded, the steering ratio i_s is governed by the following equation:



$$i_s = \frac{2\ \delta_H}{(\delta_L + \delta_R)}\ .$$

Steering axis (kingpin axis)
During steering the wheels move not about their z-axis, but rather about the steering axis, also known as the kingpin axis. The position of the kingpin axis is essentially determined by the kinematics of the axle (Figures 12 and 13).

Steering-axis spread (kingpin angle)
When the wheel and the kingpin axis are projected onto the vehicle transverse plane (y-z plane), the kingpin axis is inclined by the kingpin angle σ (Figure 13). The kingpin angle (also known as the kingpin inclination) is positive when the kingpin axis is inclined to the vehicle center. Kingpin angles are generally positive.

Kingpin offset at wheel center
The distance between the wheel center and the kingpin axis parallel to the road is called the kingpin offset at wheel center r_σ. The kingpin offset at wheel center is positive when the wheel center is further from the vehicle center plane than the kingpin axis (Figure 13).

Figure 12: Position of kingpin axis when projected onto the vehicle center plane
1 Wheel center, 2 Kingpin axis.
τ Caster angle,
n_v Caster offset in wheel center,
n_τ Caster offset.
◁ Direction of travel.

Deflection-force lever arm
The shortest connection between the wheel center and the kingpin axis is called the deflection-force lever arm r_{st}. The deflection-force lever arm is positive when the wheel center is further from the vehicle center plane than the kingpin axis.

The axes are arranged in such a way that the kingpin offset at wheel center and the deflection-force lever arm are as small as possible. This arrangement prevents deflection forces from being generated in the steering.

Scrub radius
The distance between the wheel contact point and the point where the kingpin axis intersects the road surface is called the scrub radius r_l (Figure 13). The scrub radius is positive when the wheel contact point is further from the center plane than the kingpin axis. When the scrub radius is positive, the wheel moves towards toe-out under braking forces. This behavior is particularly advantageous during the "braking in a curve" maneuver. When the scrub radius is negative, the wheel moves towards toe-in under braking forces. During the "μ-split braking" maneuver with different coefficients of friction on the left and right sides of the vehicle this axle behavior creates the precondition for more stable vehicle handling. On account of these different effects the scrub radius is configured to be as small as possible.

Caster angle, caster offset in wheel center and caster offset
When the wheel and the kingpin axis are projected onto the vehicle center plane, the kingpin axis is inclined by the caster angle τ. It is positive when the top end of the kingpin axis is inclined towards the rear (Figure 12). In this projection the kingpin axis generally does not pass through the wheel center; instead, it is offset by the caster offset in wheel center n_v to the rear.

The distance between the wheel contact point and the point where the kingpin axis intersects the road surface is called the caster offset n_τ. If this point of intersection is located in front of the wheel center (Figure 12), the caster offset is positive. Caster offsets are typically in the range of 15 to 30 mm.

Rack travel
The most widely used type of steering today is rack-and-pinion steering. Here the steering-wheel angle is converted via a pinion into a translational motion of the rack (in the direction of the y-axis). The rack is connected at both ends to the front-axle tie rods and thereby enables the toe angle to be adjusted on both wheels. The

a_c Centripetal acceleration,
v_x Longitudinal velocity,
v_y Lateral velocity.

distance covered by the rack when steering is called the rack travel.

Float angle
In the dynamics of lateral motion the center of gravity of the body does not always move along the x-axis. The angle that forms between the vehicle center plane and the trajectory is called the float angle β (Figure 14). It is counted from the vehicle center plane to the trajectory. The float angle is calculated from the linear velocity v_x and the lateral velocity v_y:

$$\beta = \arctan \frac{v_y}{v_x}.$$

Because linear velocity during forward driving is by definition positive, the sign preceding the lateral velocity in this case also determines the sign preceding the float angle.

Ackermann angle
The Ackermann angle corresponds to the axle steering angle (Figure 5). In the event of very low lateral acceleration a_y, i.e., if virtually no lateral force is built up, the vehicle moves along the Ackermann angle.

Turning circle
The turning circle is described when cornering at full steering lock by the farthest protruding vehicle parts. The radius of the circle formed is the turning circle.

The turning circle is dependent on the wheelbase and the maximum steering lock, i.e., on the maximum toe angle on the front axle.

Basic terms for tires
The most important external forces and moments which act on a vehicle occur during the transmission of force between tire and road surface. Added to this are the wind forces which act on the vehicle special situations.

Footprint
Force is transmitted between tire and road surface by friction in the contact area, also known as the footprint. The two most important types of friction are adhesive friction (intermolecular adhesive force) and hysteretic friction (gearing force).

Lateral force and longitudinal force.
Forces can be generated in the road plane by friction. Lateral force F_S is the force perpendicular to the wheel center plane; longitudinal force F_U runs in the direction of the wheel center plane (Figure 15). The forces are generally not applied exactly at the wheel contact point such that moments are likewise generated in relation to the wheel contact point (tire aligning torque M_R).

Slip angle
When lateral and longitudinal forces occur simultaneously, the forces may be mutually influenced. The situation where lateral and longitudinal forces occur but not combined is considered in the following. The gener-

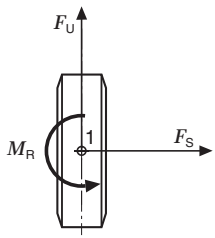

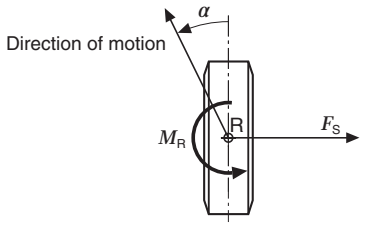

Figure 16: Slip angle
(View from above).
F_S Lateral force,
M_R Tire aligning torque,
α Slip angle.
R Wheel contact point.

ated lateral force F_S is dependent on the wheel load and the slip angle α. A dependence of lateral force F_S on speed can generally be ignored. The wheel load is the force with which the wheel center is pressed towards the road-surface plane. The slip angle α is the angle between the direction of motion of the wheel contact point and the wheel center plane (Figure 16).

When the wheel load is kept constant and the slip angle α is increased, the lateral force initially increases linearly. The lateral force reaches its maximum level at a slip angle of approx. 5° and then decreases slightly (Figure 17).

Tire aligning torque and tire caster offset
With small slip angles the lateral force is applied after the wheel contact point. When the slip angle is increased, the lateral force moves increasingly towards the wheel contact point and can also be located ahead of the wheel contact point. The distance between the lateral application point and the wheel contact point is called the tire caster offset n_R. The lateral force therefore generates a moment about the tire's vertical axis, the tire aligning torque M_R:

$$M_R = F_S \, n_R \, .$$

This produces, at constant wheel load, a curve as shown in Figure 18 for the tire aligning torque.

If the tire aligning torque is positive, it helps to make the slip angle smaller in terms of amount. This behavior helps to make the turned wheels return to the straight-ahead position when the steering wheel is released.

Slip and rolling radius
Similarly to the slip angle α for lateral force F_S, slip λ is the variable which at constant wheel load determines longitudinal force F_U. Slip occurs when the speed v_{xR} at which the wheel center moves in the longitudinal direction differs from the speed v_U at which the circumference rolls. The circumferential speed is calculated from the angular speed ω_R of the wheel and the dynamic rolling radius r_{dyn}:

$$v_U = \omega_R \, r_{dyn} \, .$$

A distinction is made between static and dynamic rolling radius. The static rolling radius is the shortest distance between wheel center and footprint. The dynamic rolling radius r_{dyn} is calculated by means of the circumference U:

$$r_{dyn} = \frac{U}{2\pi} \, .$$

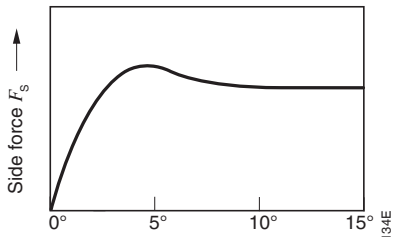
Slip λ_A for tractive forces is defined as:

$$\lambda_A = \frac{\omega_R \, r_{dyn} - v_{xR}}{\omega_R \, r_{dyn}} \, .$$

Similarly, slip λ_B for braking forces is defined as:

$$\lambda_B = \frac{\omega_R \, r_{dyn} - v_{xR}}{v_{xR}} \, .$$

Figure 17: Lateral force at constant wheel load as a function of slip angle



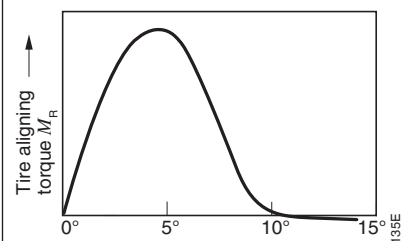


Figure 18: Tire aligning torque at constant wheel load as a function of slip angle

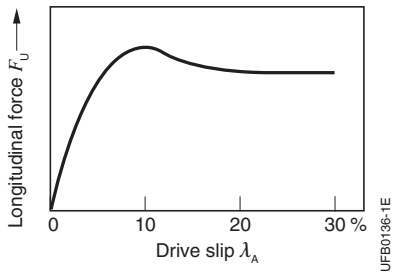
According to this definition, drive slip is always positive and brake slip always negative. These two slip definitions ensure that when a wheel is locked ($\omega_R = 0$, $\lambda_B = -1$) a slip of –100 % is obtained and when a wheel is spinning ($v_{xR} = 0$, $\lambda_A = 1$) a slip of 100 % is obtained.



If the drive slip is increased at constant wheel load, the tractive force (longitudinal force) increases linearly. At approx. 10 % drive slip the longitudinal force reaches its maximum level and then falls again (Figure 19). The same applies to brake slip. Here the maximum braking force is created at approx. –10 %.

Measured variables

In the interests of vehicle development it is sensible to use a special measurement to enable vehicle handling to be measured with greater accuracy. In the dynamics of lateral motion the translational accelerations and the attitude angles are often measured by gyro-stabilized platforms. The absolute positions are recorded with GPS measuring systems. In the dynamics of vertical motion the translational accelerations are measured in each of the three directions in space at different points of the body. From these the most important body accelerations can be determined, i.e., those for lift, pitch and roll.

The linear and lateral velocities are each measured with proximity-type velocity sensors for the float angle.

Figure 19: Longitudinal force at constant wheel load as a function of drive slip

The slip angle α is measured, along similar lines to the float angle, with two proximity-type speed sensors. The wheel speed and the longitudinal velocity are measured for slip λ. The dynamic rolling radius r_{dyn} is determined on test benches.

The tire aligning force M_R, the lateral force F_S, and the longitudinal force F_U can be recorded in mobile operation by multi-component measuring wheels. Because this is very costly, tire forces and tire moments are measured on stationary test benches or determined using special vehicles directly on the road. Up to now, precise measurement of tire forces and tire moments has been accompanied by many systematic failures.

Steering-wheel angle and steering-wheel torque are measured using special measuring steering wheels. If the measuring accuracy is sufficient, the steering-wheel-angle sensor fitted as standard in many vehicles can also be used.

Special measuring devices can be used in both mobile and stationary applications to measure toe and camber angles. These angles are typically measured on special test benches.

Special test benches are also used to measure the axle steering angle and the steering ratio.

The variables for the position of the kingpin axis are generally not measured directly. The axle pivot points are often recorded by means of geometric measurements and the following variables are calculated from them: caster angle, caster offset in wheel center, caster offset, kingpin angle, kingpin offset at wheel center, deflection-force lever arm, and scrub radius.

The roll pole can be determined by measuring the track change during the reciprocal compression and rebound of an axle. The roll axis is obtained from the roll poles of the front and rear axles.

The pitch pole and starting- and braking-torque compensation are usually not measured directly, but rather determined from the measured kinematic points of the axle. The same applies to the longitudinal inclination at wheel center, and the anti-lift/anti-squat and anti-dive/anti-rise angles.

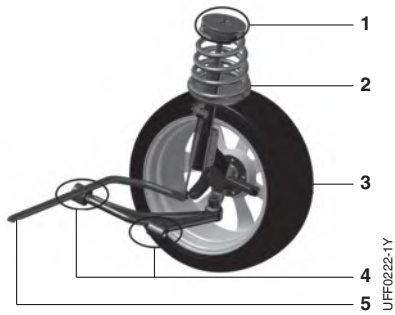
Suspension



Basic principles

The suspension system of a vehicle has a decisive influence on the vibration characteristics and therefore on both comfort and driving safety. Depending on the vehicle category and use case, different solutions have prevailed in the meantime. An overview of the different suspension design elements is shown in Figure 1, using a quarter vehicle as an example.

As a general principle, suspension design elements include all parts of the wheel suspension of a motor vehicle that deliver return forces in the case of elastic deformation. The media that perform the suspension work on the different suspension systems are either steel (spring steel), polymer materials (rubber), or a gas (air).

Tires
As the connecting element between the road surface and vehicle, the tire is the first suspension design element in the transfer chain from excitation to the occupants that has a decisive influence on both the comfort (acoustics, rolling characteristics) and driving safety (longitudinal and lateral force potential). It has both suspension and damping properties, whereby these are not sufficient to eliminate the need for other vibration-absorbing elements in modern vehicles. An exception here is mobile machinery, where changed vertical-dynamics requirements mean that in almost all cases the suspension and damping are achieved by means of the tires.

Figure 1: Suspension design elements within the wheel suspension (McPherson split axle as an example)
1 Dome mount (rubber mount),
2 Body spring, 3 Tire,
4 Rubber mounts, 5 Stabilizer.

Elastomer mounts
Elastomer mounts are rubber elements with different functions and properties that interconnect individual components of a chassis system or secure them to the body.

The rubber mounts are used to provide insulation against vibrations and thus enhance comfort, particularly in the case of higher-frequency excitation (acoustics). At the same time the driving dynamics can be decisively influenced by the elasto-kinematics.

In contrast to series-production vehicles, uniball joints (more rigid connections between wheel suspension and body) are deployed in motor racing; this improves driving dynamics to the detriment of comfort.

In order to reconcile the conflicting objectives of soft mounts for high comfort and rigid mounts for sporty driving dynamics, in the meantime increasing use is made of adaptive or active suspension mounts that are able to adapt their properties to each driving situation.

Body springs
Body springs are parts of the chassis system that provide most of the vertical return forces between the wheel and body. Depending on the use case, various types of spring with very varied properties are used. A summary of the characteristics of suspension design elements used in vehicle construction can be found in Table 1.

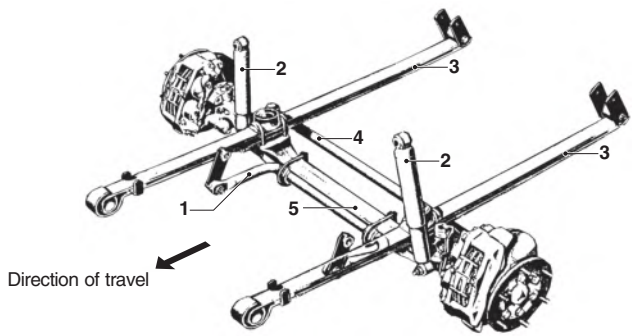


Table 1: Suspension design elements in vehicle construction

Suspension design element	Load influence on body natural frequency	Properties (●), advantages (+) and disadvantages (–)
Steel springs		
Leaf spring	● Natural frequency drops with increasing load ● Characteristic curves are generally linear or progressive	● Assumption of the suspension-linkage function is possible ● Single-layer or multilayer version ● Depending on type, subject to friction (in the passenger car an intermediate plastic layer reduces friction → positive influence on acoustics) + Good transfer of forces to the chassis (on trucks) + Low cost – Maintenance requirement – Friction damping usually inadequate – Acoustic influences
Coil spring		● Arrangement of the shock absorbers within the spring is possible ● Progressive characteristic curve due to corresponding geometry of the spring can be implemented (variable pitch or conical wire) + Great leeway for configuration + Low cost + No intrinsic damping + Low space requirement + Low weight + Maintenance-free – Separate elements required for suspension linkage – Spring characteristic curve is non-variable
Torsion-bar spring		● Made of round steel (for lower weight) or flat steel (with increased stress) + Wear- and maintenance-free + Depending on design, ride-height adjustment also possible – Long springs – Wheel-related spring stiffness depends on suspension-arm arrangement
Stabilizer	● No influence with suspension on the same side ● Half of stabilizer rigidity effective with one-sided suspension ● Entire stabilizer rigidity effective with alternating suspension	● Influence on self-steering effect (oversteer or understeer) ● U-shaped, bent fully round or tube material is usual ● Stub often flat-rolled due to bending stress ● Stabilizer attachment points located far out on the axle to achieve small diameters ● Axes of rotation of suspension arms configured so that stabilizer load is only torsion (not flexion) + Simple possibility to influence driving dynamics of a vehicle + Reduction of the roll angle + With deployment of active systems improved comfort and enhanced driving dynamics – Additional weight – Costs

Table 1: Suspension design elements in vehicle construction (continued)

Suspension design element	Load influence on body natural frequency	Properties (●), advantages (+) and disadvantages (–)
Air springs and hydropneumatic springs		
U-type bellows gas springs and air springs with bellows (air springs)	● Natural frequency remains constant with increasing load ● Characteristic curves depend on gas properties, form of rolling piston shape, and cord angle in the bellows	● Implementation of soft, vertical spring stiffness ● As spring strut or individual spring, can be found above all in commercial vehicles and buses ● Increasingly used in passenger cars for ride-height control of the rear axle + Ride-height control easy to integrate (similar to hydropneumatic spring) + Comfort characteristics independent of payload – Separate elements required for suspension linkage – Low pressure (< 10 bar) requires high volumes
Hydropneumatic spring	● Natural frequency rises with increasing load due to nonlinear spring stiffness	● Gas volume in the spring accumulator determines the suspension properties ● Power flux by means of gas and oil ● Integration of the damper valves in the shock absorber and in the connection between the suspension strut and the accumulator + Hydraulic damping and ride-height control easy to integrate – Maintenance requirement for rubber membrane due to diffusion tendency
Rubber springs		
Rubber spring	● Natural frequency is influenced by increased load due to nonlinear spring stiffness	● Vulcanized rubber shear spring between metal parts ● Used and assembly mountings (engine and transmission), suspension-arm mountings, additional springs, etc. ● Increasingly with integrated hydraulic damping + Design is very freely definable + Low cost – Limited temperature range – Aging

Types of spring

Leaf springs

The oldest types of spring used in vehicle construction are leaf springs, which were even used on horse-drawn coaches (Figure 2). Alongside the suspension functionality, a major advantage of this type of spring is its possible use as a suspension-linkage engineering-design element to connect the body and axle, because, with the appropriate design, it can absorb lateral or longitudinal forces. Multilayer leaf springs also have damping characteristics which, however, can lead to poor response and acoustic influences. The damping forces that can be achieved are not sufficient to completely eliminate the need for conventional shock absorbers.

The influences on comfort and their weight mean that leaf springs in the meantime no longer meet market requirements for personal transportation and they are therefore only used now in a few passenger cars (light utility vans, off-road vehicles). It is still usual to use this type of spring in the commercial-vehicle sector on account of the low costs and high reliability.

Helical springs

The great leeway for configuration with simultaneously low costs means that helical springs are the most frequently deployed type of body springs in the field of passenger cars. On this type of spring, the return forces are generated by the elastic torsion of individual coils during the change in length.

As helical springs are mainly able to absorb forces in the direction of the longitudinal axis of the spring, when they are used as body springs the other force components must be braced by the suspension linkage.

A geometric configuration of the springs that is in line with requirements (wire thickness, coil diameter and spacing, Figure 3) means that not only different design envelopes but also different spring characteristics can be achieved. This can be used in turn to influence the load-dependent body natural frequency and thus the ride comfort.

Torsion-bar springs

This type of spring is encountered mainly in passenger cars and light utility vans. They are bars made of spring steel that are subjected to torsion. The fixed clamping of one end of the bar and the rotatable mounting of the other end means that the shaft is elastically torsioned when subjected to a load in the form of torque applied in the direction of its axis. In the motor vehicle, the elastic twisting of the torsion bar is achieved with the help of a crank secured to the rotatable end of the rod (Figure 4). As a rule, the crank arms are suspension arms of the axle or wheel suspension. The torsion-bar springs are usually arranged in the bearing center of the suspension arms on the body side on the opposite end of which the vertical wheel force F_R takes effect as the external load.

A Area to which gas pressure is applied.

Gas springs

The body springs presented so far are fixed, springing media, whereby the work is performed by the change in shape of the steel springs. In contrast to this, the spring work in the case of gas springs is generated by a change in volume of the gas. The body of the vehicle is decoupled by an effective gas volume (possibly also by an additional fluid, see hydropneumatic springs) from the excitation and it vibrates on the gas cushion within the gas spring (Figure 5). This results in a favorable possibility to integrate a ride-height control function that can be implemented by pumping the intermediate medium (gas or fluid) in or out.

A characteristic parameter of the gas spring is the "theoretical spring length" h_{th}, which results as a quotient from the compression-dependent working volume $V(z)$ (including any additional volume) and the effective piston surface area A to which gas pressure is applied:

$$h_{th} = \frac{V(z)}{A} \qquad \text{(Eq. 1)}$$

where
z Compression path.

The equation for the spring force F:

$$F = (p_i - p_a)\, A \qquad \text{(Eq. 2)}$$

where
p_a Ambient pressure, and
p_i Internal pressure,

generally leads to the following for the spring stiffness of a gas spring with constant effective piston surface area A [1]:

$$c(z) = A\, n\, p(z)\, \frac{1}{h_{th}} \qquad \text{(Eq. 3).}$$

The polytropic exponent for slow and thus isothermic spring movements is $n = 1$ – for fast and thus approximately adiabatic spring movements it is $n = 1.4$. The natural angular frequencies for single-mass oscillators are calculated from

$$\omega_{Gas} = \sqrt{\frac{c}{m}} = \sqrt{\frac{c(z)\, g}{(p - p_a) A}}$$

$$= \sqrt{\frac{g\, n\, p(z)}{(p - p_a)\, h_{th}}} \qquad \text{(Eq. 4).}$$

When the requirement for a relatively small spring diameter is met $p_i >> p_a$. This simplifies the equation for the natural angular frequency to:

$$\omega_{Gas} = \sqrt{\frac{g\,n}{h_{th}}} \qquad \text{(Eq.5)}.$$

However, the above-mentioned theoretical piston cylinder gas spring is only used in vehicles in a modified form, whereby in principle a distinction is made between two types of gas spring, the air spring with bellows and the hydropneumatic spring. The fundamental difference with regard to the vertical dynamics lies in the influence of the load on driving smoothness and in the different effects on the spring stiffness in the level balancing of both systems. Whereas in the case of the hydropneumatic type level balancing is achieved by pumping in fluid or oil (with constant mass of the gas in the spring), level balancing on air springs with bellows takes place by pumping a gas (air) into the spring, thus restoring the original suspension volume. The change in spring stiffness of the hydropneumatic spring type that this causes leads to an increase in the body natural frequency with increasing load. In contrast to this, the air spring with bellows has due to the stiffness change a virtually constant body natural frequency in the entire load range.

To conclude, Figure 6 shows the influence of different suspension systems on the natural frequency, and thus also indirectly on the comfort with rising loads. The reason for the influence of the body natural frequency on comfort lies in the different resonance ranges of different organs in the human body and the consequence that an excitation of human body parts with their natural frequency impairs well-being. This is why a body natural frequency, below the resonant frequencies of the human body, that is as independent as possible of the load is to be ensured.

However, Figure 6 also clearly indicates that an approximately constant natural frequency with rising load is only present in the case of air springs. With steel springs, the natural frequency drops due to the constant spring stiffness.

Figure 6: Comparison of different suspension systems depending on payload

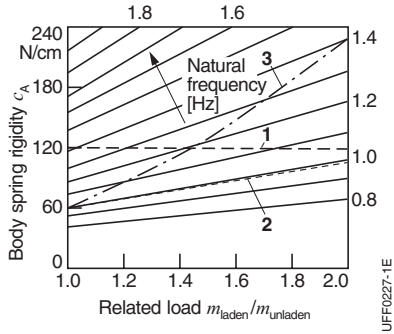
2 Air spring,
3 Hydropneumatic spring.



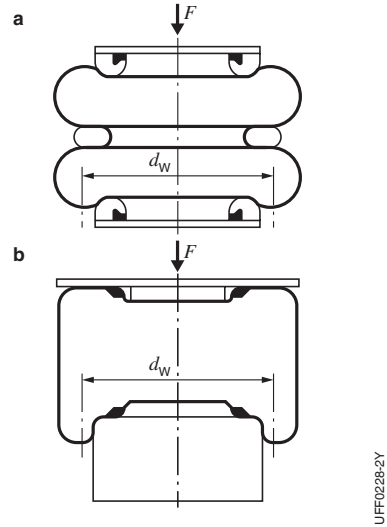


Figure 7: Gas springs with bellows
a) Bellows,
b) U-type bellows.
F Force,
d_w Effective diameter of air spring.

Springs with bellows
Gas springs with bellows with pneumatic ride-height control are suspension systems with constant gas volume (see above), whereby these are in turn divided into two categories. These are firstly gas springs with bellows and, secondly, U-type bellows gas springs (Figure 7) which, in a similar way to pneumatic tires, consist of rubber material reinforced by woven textiles. On these systems, the ride-height control is implemented by pumping gas into or releasing gas from the spring with the suspension volume remaining constant as a general principle. The effective surface area of the air springs (and thus the gradient of the return force) that is affected by the overpressure is not usually constant, rather it changes throughout the stroke. This enables specific influence on the load-bearing capacity by designing the contours of the rolling piston of the U-type bellows gas springs (and thus a change in the effective surface area A in Equation 3 via the range of the spring) accordingly. The effective surface area A of the air spring can be determined via the effective diameter. With integration of an additional volume (increase of h_{th}, see Figure 5), a less progressive and flatter-tending characteristic curve can be achieved.

Hydropneumatic springs
In accordance with the considerations above, hydropneumatic springs (Figure 8) with integrated ride-height control are gas springs with constant gas weight (see above), whereby the power flux is routed not only through a gas but additionally through a fluid or oil. Here, the fluid and gas are separated by an impermeable rubber membrane. It is only when the fluid or oil is placed in between that a wear-resistant and low-friction seal is achieved between the piston and cylinder.

Another advantage of this system lies in the possibility to integrate hydraulic damping in the suspension design element. A disadvantage, on the other hand, is the dependency of the natural frequency on the load (influence on comfort). The reason for this is the pumping in and out of the fluid or oil at a constant gas mass that is required for ride-height control. The load-sensitive volume change of the gas leads to a shift in the spring stiffness in such a way that with rising load there is a fundamental increase in natural frequency (see Figure 6).

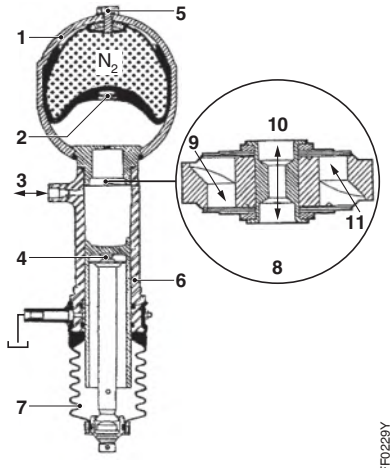

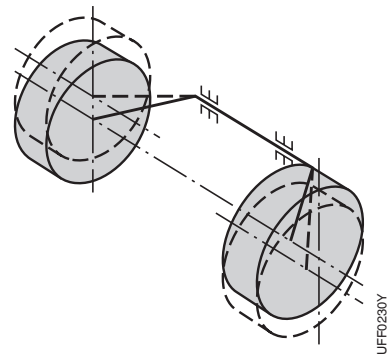

Figure 9: Functioning principle of stabilizer spring

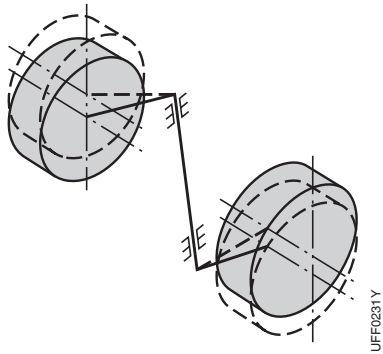


Stabilizers
The suspension systems described above are deployed primarily for the vertical suspension of a vehicle. For the roll suspension, on the other hand, additional passive or active stabilizer springs (under certain circumstances with additional roll damping) are used alongside classical body springs. A diagram of the principle is provided in Figure 9. In the event of a rolling movement of the body, i.e., spring compression of the wheels of one axle in opposite directions, the stabilizer is torsioned and delivers an aligning torque around the roll axis. In the case of in-phase vertical motions of one axle, on the other hand, this has no effect. If the proportions of the rolling moment braced by the stabilizers on the front and rear axles have a different ratio to the proportions braced by the body springs, not only is the roll angle reduced but the breakdown of the differences in wheel load of an axle on cornering and thus the self-steering effect are also influenced.

On a vehicle with a corresponding stabilizer configuration, this can shift the driving characteristics towards understeer (increase in the roll rigidity on the front axle or reduction in the roll rigidity on the rear axle) or oversteer with all other parameters unchanged. In the case of active stabilizers, the stabilizer force can also be actively influenced and adapted to suit the driving status. This enables a reduction in for example copy effects on one axle (due to decoupling between the right-hand and left-hand sides) when the vehicle is driven straight ahead but it also increases the driving dynamics on cornering by minimizing the inclination of the body. Here, the stabilizers do not influence the vertical vibration characteristics of the vehicle.

Compensating springs
Compensating springs have the opposite effect to that of the stabilizer (Figure 10). As a pure stroke element, they have no effect during rolling motions of the body.

The compensating spring was used in the past on axle designs where the wheel suspension kinematics required wheel load differences that were as low as possible to suppress the “resting effect” (stronger rebound of the wheel on the inside of the curve compared to the spring compression of the wheel on the outside of the curve when cornering). The stiffness of the body springs and this braced proportion of the rolling moment on the axle under examination could then be reduced accordingly. Compensating springs are no longer in modern passenger car wheel suspensions.

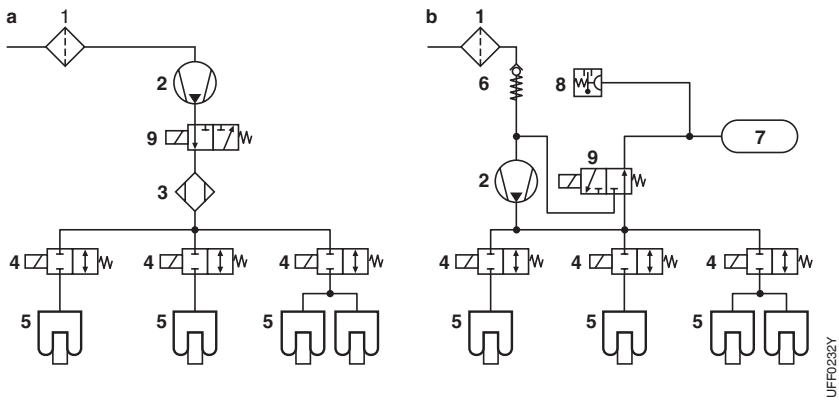
Figure 10: Functioning principle of compensating spring

Suspension systems

Increasing customer requirements (comfort and driving dynamics) with regard to passenger cars and the strongly fluctuating load states of commercial vehicles mean that exclusive deployment of conventional steel springs is often insufficient. In such cases, either partially loaded or fully loaded suspension systems are used.

The integration of the additional functions of partially loaded or fully loaded systems enables increases in both comfort and driving dynamics (for example transverse locking of the springs of one axle to enhance stability on cornering).

Partially loaded systems



These systems are characterized by the fact that the forces to be braced by the suspension system are divided between steel and air springs according to a specified ratio.

In the case of soft body springs (to enhance ride comfort), wide spring ranges occur for example when a vehicle is loaded. In order to prevent the vehicle body from being lowered too much, ride-height control systems with air springs or hydropneumatic springs are used. Here, sensors determine the ride height and provide this information to the control system. By pumping in or releasing air (air springs with bellows) or oil (hydropneumatic springs), the ride height can be then adapted in line with requirements. Depending on the vehicle segment (passenger cars or commercial vehicles), ride-height control systems offer different additional functions.

In the passenger car, for example, a speed-dependent ride-height control of the body in order to save fuel is possible. The adjustable ride height can also be used on poor-quality road surfaces to enhance the vehicle's capability to handle rough terrain.

In the case of commercial vehicles, on the other hand, ride-height control enables variable adaptation of the loading area to different loading ramps. Other functions can also be implemented by networking with other systems. These include, for example, an automatic ride-height increase if the lifting axle is raised, lowering on exceeding the maximum axle load, or brief raising of the lifting axle to increase the wheel load on the driven axle.

Figure 11: System architectures of ride-height control, fully loaded systems

1 Filter, 2 Compressor, 3 Drier, 4 2/2-directional-control valve, 5 Bellows, 6 Non-return valve, 7 Pressure container, 8 Pressure switch, 9 3/2-directional-control valve.

Fully loaded suspension systems

In the case of fully loaded systems, as opposed to partially loaded solutions, the task of suspension is assumed solely by the gas springs and the helical springs are completely eliminated. Depending on the available hardware and control strategy, the ride-height control can be on selected axles or on all axles. Embedding the control system architecture in the global vehicle control architecture ensures that a negative mutual influence of the axles is excluded, thus preventing, for example, the vehicle body from slanting.

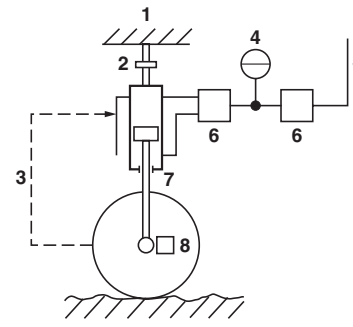
As a general principle, the ride-height control for fully loaded systems can be designed in the form of an open or closed system. In the case of the open system, a compressor draws air from the atmosphere and provides it in compressed form to the air springs if required. The increase in pressure raises the vehicle body. To lower the ride height, air is expelled into the environment, thus lowering the pressure in the springs again. Although this system involves relatively low overhead in construction and has a simple control system, it has the decisive disadvantage that high compressor output has to be provided for the short periods of control operation, which is accompanied by corresponding increased consumption. Moreover, an air drier is required and an acoustic load can be expected when air is drawn in and expelled.

The closed system draws air from a pressure accumulator of the suspension system and feeds this directly to the air springs. When the ride height is lowered, the compressed air is returned to the pressure tank. Although the compressor output requirements for this system are lower and the air drier can be eliminated because the working medium is already dry, other components (accumulator, pressure switch, non-return valve, return line etc.) are required, fundamentally increasing the overhead in construction compared to an open system.

The system architectures of the open and closed ride-height control systems are compared in Figure 11. This clearly illustrates the greater complexity of the closed system.

Active spring systems

Compared to passive systems, active vehicle chassis systems enable optimal adaptation of spring and damper forces to all driving states and road irregularities. With the aid of external sources of energy, forces are generated that stabilize both the axles and the vehicle body. In the meantime, a number of different system architectures have been developed. These differ above all with regard to the overhead involved (design envelope and costs), the energy requirement, and the quality of control operations. A few of these systems are presented briefly below.



Systems with hydraulic cylinders

With this version, the body motion and body position are regulated with quickly adjustable hydraulic cylinders (Figure 12), whereby different items of sensor information (wheel load, range of spring, acceleration etc.) are used as input variables for the control operation.

The control system achieves virtually constant wheel loads while maintaining a constant mean ride height. The static wheel load in this case is carried by steel springs or hydropneumatic springs.

Figure 12: Active chassis system with hydraulic cylinder

1 Vehicle body, 2 Wheel-load sensor,
3 Travel sensor, 4 Accumulator,
5 Pump circuit, 6 Servo valve,
7 Positioning cylinder, 8 Acceleration sensor.

Systems with hydropneumatic suspension system
To stabilize the vehicle, a hydropneumatic suspension system uses specific oil regulation. This is done by pumping hydraulic oil into the suspension struts or draining it off the suspension struts (Figure 13). To limit the energy absorption, the control strategy of this system consists of control operations to eliminate longwave irregularities (low-frequency excitations). In the case of higher-frequency proportions, a gas volume takes effect in the proximity of the suspension strut. Here, the shock absorber is essentially geared to the wheel movements.

Version with spring-mounted point adjustment
In this system, the vehicle body is held horizontally in the low-frequency range in that a conventional helical spring is designed as variable at its mounting point (either against the vehicle body or in relation to the axle, Figure 14). The base is raised for spring compression and lowered for spring rebound. Control operations are continuous by means of a fluid pump and proportioning valves. The helical spring, however, must be longer compared to its original design. In this type of system, the shock absorbers can be fitted with constant adjustment parameters and, above all, they can be matched to the wheel dampers.

Electromagnetic system
In the case of an electromagnetic active chassis system, linear or rotary electromagnetic motors are fitted on each wheel. These are able to actively compensate for the road irregularities. The linear motors are supplied with electrical energy by power amplifiers, whereby as a general principle force control or path control can be implemented. Cross-axle system networking also enables compensation

of rolling and pitching vibrations. In the solution that is currently implemented, the static wheel loads are absorbed via torsion springs at the wheels to limit the electrical energy requirement. A passive shock absorber is also used.

The advantages of the electromagnetic solution lie above all in the high adjustment speed. Despite the low outer dimensions, the electric motors have sufficient power output to ensure driving safety in all driving situations. In comparison with conventional systems, the disadvantages lie in the greater weight and in the increased costs, as an additional, non-electronic damping system is required for safety reasons. As a general principle, however, the electromagnetic motor can also be operated as a generator, which means that damping can also be performed electrically and thereby energy can be recuperated. This enables a lowering of the power requirement of the overall system, which is specified for standard road surfaces as less than 1 kW.

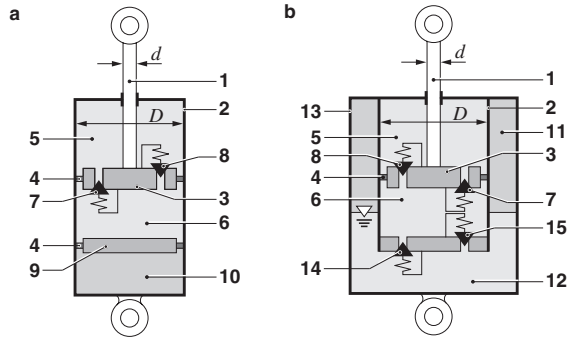
Shock absorbers and vibration absorbers

Shock absorbers

The masses of the vehicle body and wheels connected by the body springs form a system that can vibrate and is excited by irregularities on the roadway and the dynamic movements of the vehicle. Shock absorbers are required to dampen the vibrating system. Nowadays, it is almost exclusively hydraulic telescopic shock absorbers that are used in motor vehicles as body shock absorbers; these convert the kinetic energy of the body and wheel vibrations into heat. The shock absorbers are configured taking account of the partially conflicting requirements for comfort (minimization of body accelerations) and driving safety (minimization of wheel load fluctuations).

Basic principles of hydraulic telescopic shock absorbers

The damper effect of hydraulic telescopic shock absorbers (Figure 1) is based on the movement subject to flow resistance of a shock-absorber piston equipped with throttle elements (damper valves) within an oil-filled working cylinder. In the process, mechanical work is converted into heat that is released into the environment via the shock-absorber surface. The pressure difference Δp between the two working chambers and the effective surfaces caused by the throttle elements on both sides of the shock-absorber piston generates the resulting damping force F_D when the shock absorber moves in or out. The area on which the pressure prevailing in each working chamber is applied corresponds to an annular surface A_{KR} for the working chamber through which the piston rod of the shock absorber runs (see working chamber 1 in Figure 1). The outer diameter of the annular surface corresponds to the diameter D of the shock-absorber piston; the inner diameter corresponds to the diameter d of the piston rod. The following applies:



$$A_{KR} = \frac{\pi}{4}(D^2 - d^2).$$

In the other working chamber (see working chamber 2 in Figure 1), the effective area corresponds to the piston surface A_K which results from the diameter D of the shock-absorber piston.

$$A_K = \frac{\pi}{4}D^2.$$

Figure 1: Structure of single-tube and twin-tube shock absorbers

D Inner diameter of working cylinder and diameter of shock-absorber piston,
d Diameter of piston rod.

When there is a movement of the shock-absorber piston (i.e, an inward or outward movement of the shock absorber), the changes to the volumes in the two working chambers lead to a flowing movement of the incompressible damping fluid between the working chambers of the shock absorber (in the case of twin-tube shock absorbers, additionally between a working chamber and the compensating chamber). The oil volume flows in each case must pass the corresponding valves.

The oil-volume flows through the relevant valves result from the geometry of the shock absorber and the speed of inward or outward movement $\dot{z}$. The following applies to the volume flow $\dot{Q}_1$ between the two working chambers:

$$\dot{Q}_1 = \frac{\pi}{4}(D^2 - d^2)\,\dot{z}.$$

The inward or outward movement of the piston rod on hydraulic telescopic shock absorbers leads to a variable total volume of the working chambers that depends on the retracting or extending state. The incompressibility of the shock-absorber oil means that a possibility to compensate for the oil volume displaced or released by the piston rod is required. The following applies to the volume flow $\dot{Q}_2$ of this compensating volume:

$$\dot{Q}_2 = \frac{\pi}{4}\,d^2\,\dot{z}.$$

The volume flow $\dot{Q}$ through a valve is linked via the throughflow characteristics of each valve to the prevailing pressure difference Δp. The throughflow characteristics of a valve result from the joint effect of the throttle geometry (for example bore diameter of the flow-through channel) and any spring load (i.e., pressure-dependent variation of the discharge opening, Figure 1). The throughflow characteristics can be adapted to the needs of each situation by configuring and coordinating these parameters. The characteristics of the valves are to be designed in such a way that no cavitation whatsoever occurs (formation and implosion of gas bubbles in the working medium due to static pressure fluctuations in the range of the vapor pressure of the working medium) inside the shock absorber. Cavitation leads to acoustic problems and also to damage – ultimately to failure of a shock absorber. The cavitation tendency can also be effectively counteracted by pressurizing the shock-absorber oil.

Types of hydraulic telescopic shock absorbers

Single-tube shock absorbers

To balance out the retracting or extending piston-rod volume, single-tube shock absorbers have an enclosed gas volume which is separated from the working chambers filled with shock-absorber oil with the help of a moving dividing piston (Figure 1a). In the compression phase (moving in) of the shock absorber, the gas volume is compressed according to the volume flow $\dot{Q}_2$; in the rebound phase (moving out), it is relaxed according to the volume flow $\dot{Q}_2$. As a rule, the pressure of the gas volume is between 25 and 35 bar, which means that the maximum occurring retraction forces (compression-stage force) can be absorbed without creating a vacuum at the piston-road seal. The working volume flow $\dot{Q}_1$ flows through each of the piston valves. On moving in, it flows though the compression-stage valve and on moving out through the rebound-stage valve.

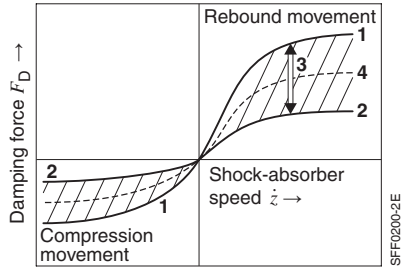
The high gas pressure means that the tendency for cavitation to occur is low in the case of the single-tube shock absorber. The heat that is generated can be released into the environment directly via the outer surface of the working cylinder. The advantages of lean design, the low weight and discretionary installation position of the single-tube shock absorber are offset by the great length, increased friction due to the high internal pressure , and high requirements with regard to sealing the piston rod and gas volume. Furthermore, the single-tube shock absorber is, on account of its more filigree design, not suitable for absorbing considerable lateral forces and bending moments.

Twin-tube shock absorbers

Twin-tube shock absorbers have a compensating chamber resulting from the arrangement of an outer tube around the working cylinder (Figure 1b). The com-

pensating chamber balances out the retracting or extending piston-rod volume. To achieve this, it is connected via bottom valves to the lower working chamber of the shock absorber. The compensating chamber is partly filled with shock-absorber oil and partly with a gas (as a rule, dried air or even nitrogen). The gas volume is at atmospheric pressure or slight overpressure (6 to 8 bar). An overpressure here only serves the purpose of reducing the cavitation tendency; compression-stage-force absorption is not necessary. The piston and bottom valves must be coordinated is such a way that no cavitation occurs. In the compression stage, i.e., when the shock absorber is moving in, the damping work is therefore done at the corresponding bottom valve (compression-stage valve) through which the volume flow $\dot{Q}_2$ flows. On the other hand, the oil volume flow $\dot{Q}_1$ from the lower working chamber into the upper working chamber can only flow through the compression-stage valve in the shock-absorber piston with low flow resistance. This prevents a radical drop in pressure in the upper working chamber. In contrast, in the rebound stage, i.e., when the shock absorber is moving out, the damping work is essentially done by the volume flow $\dot{Q}_1$ from the upper working chamber into the lower working chamber at the corresponding piston valve (rebound-stage valve). The bottom valve only balances out the extending piston-rod volume in that shock-absorber oil flows virtually without resistance from the compensating chamber into the lower working chamber (volume flow $\dot{Q}_2$).

The compensating chamber means that twin-tube shock absorbers have poorer heat dissipation in comparison with single-tube shock absorbers. Furthermore, the installation position of twin-tube shock absorbers is restricted, as it must be ensured at all times that there is compensating fluid at the bottom valves. Advantages compared to the single-tube shock absorber are the lower shock-absorber length and the softer responsiveness due to the seals being subject to less load with correspondingly lower requirements. Furthermore, thanks to its twin-walled structure, the twin-tube shock absorber, with a suitably more solid piston-rod and outer-tube design, can absorb lateral forces and bending moments, meaning that it can be used as a wheel-control element (spring-strut or shock-absorber-strut independent wheel suspension). In the area of passenger cars, the twin-tube shock absorber has prevailed as the standard shock absorber – also due to its lower costs.



Adjustable shock absorbers

The conflict of objectives with regard to the coordination of body shock absorbers between ride comfort and driving safety can be mitigated using adaptive or semi-active shock absorbers. In comparison with passive shock absorbers with fixed shock-absorber characteristics (i.e., defined force-speed characteristics, cf. section “Damping characteristics”), adaptive shock absorbers provide the possibility of discrete to infinitely variable adjustment of the damping characteristics (Figure 2).

Alongside manual adjustment of the shock absorbers (for example soft damping in the comfort mode or hard damping in the sport mode), adjustable shock absorbers can also be activated automatically depending on the driving state in each case (see section “Damping control”). The shock absorbers are as a rule adjusted by the driver by way of controls

Figure 2: Adjustable shock-absorber characteristic curves

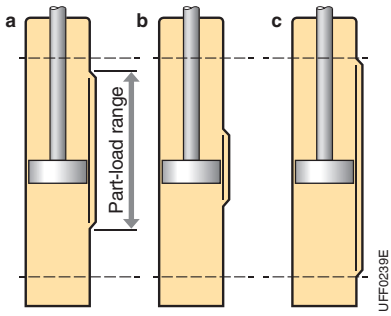
in the instrument panel. Adjustability directly at the shock absorber itself is encountered primarily in motor sport and in sporty retrofit shock absorbers.

Adaptive hydraulic absorbers
In the case of adaptive or semi-active shock absorbers of conventional design, the adjustability of the damping characteristics is implemented by means of adjustable valves, bypass boreholes that can be activated (located on the outside or inside), or with the help of double pistons [1]. As a rule, activation is electronic. Major system features are the adjustment times that can be achieved, the spread of the adjustment range, as well as the number of definable shock-absorber characteristics. It must be mentioned here that the adjustment times should not be shortened arbitrarily in the interests of functionality because changing the flow conditions in the shock absorber too quickly can give rise to noise emissions and possibly wear. Whereas systems of the first generation only permitted adjustment between a few characteristic curves, today's adaptive shock absorbers can usually be set to a large number of characteristics [2]. Newer systems usually even have infinitely variable adjustment between a minimum and a maximum damping-force characteristic (Figure 2).

Rheological shock-absorber systems
The adjustability of the damping characteristics in the case of rheological shock-absorber systems is based on the change in the flow properties of the working medium that is used. Magneto-rheological fluids that change their viscosity under the influence of a magnetic field are used here instead of the usual mineral oils. Electro-rheological fluids have similar properties under the effect of an electric field, but the effect is utilizable to a much lesser extent, which is why primarily magneto-rheological methods have prevailed. The viscosity of the working medium has a direct influence on the flow resistance through the valves. If, for example, creating a magnetic field increases the viscosity of a magneto-rheological working medium, the flow resistance through the valves increases.



Rheological shock-absorber systems not only provide the possibility for infinitely variable adjustment of the damping characteristics but also the implementation of very short adjustment times [2].

Passively adaptive systems
Aside from the mentioned shock-absorber designs with different options for characteristic-curve adaptation by the driver (electronically at the touch of a button or mechanically by hand) or by control electronics, there are also types which are fashioned in such a way that the shock-absorber characteristic is adapted within limits to different driving-dynamic influences. Amplitude-selective, stroke-dependent, and frequency-selective damping are mentioned here by way of example. In the case of amplitude-selective damping a bypass channel with an implemented control piston is usually provided in the shock-absorber piston (Figure 3). In a limited amplitude range the oil flows in part through this bypass and displaces the control piston, increasing the flow cross-section and thus reducing the damping forces. When the control piston reaches its structurally predetermined end stop, the oil now flows only through the piston valve and the damping forces increase. The freely moving section of the control piston determines the amplitude up to which the damping forces are reduced, usually a few millimeters. The result of this is that (depending on the load) smaller road irregularities are damped much less than for example than pitching or rolling of the vehicle, which provides for good comfort and at the same time good driving dynamics.

Figure 4: Stroke-dependent shock absorber
a) Two-stage damping: damping dependent on load/stroke,
b) Two-stage damping: damping dependent on dynamic load (with ride-height control),
c) Hydraulic end-position damping for rebound/compression stage.

Stroke-dependent shock absorbers
In stroke-dependent shock absorbers the operating principle of the partially enlarged flow cross-section is effected by bypass grooves over a predetermined length in the shock-absorber tube (Figure 4). The total flow cross-section is enlarged in the stroke ranges in which the piston passes over these bypass grooves, with the result that the damping forces are lower in this range. The damping force increases in the case of larger strokes outside the bypass-groove range (e.g., towards the end stop). Because of the fixed position of the grooves this system is dependent on the stroke range and the piston position in the shock absorber and less so on the oscillation amplitude.

Frequency-selective shock absorbers
In the case of frequency-selective shock absorbers the cross-section is altered by spring-loaded, oscillatory valves which according to the tunning at predetermined frequencies (e.g. body natural frequency) reduce the flow cross-section and consequently increase the damping forces. Less damping occurs outside the defined frequency range.

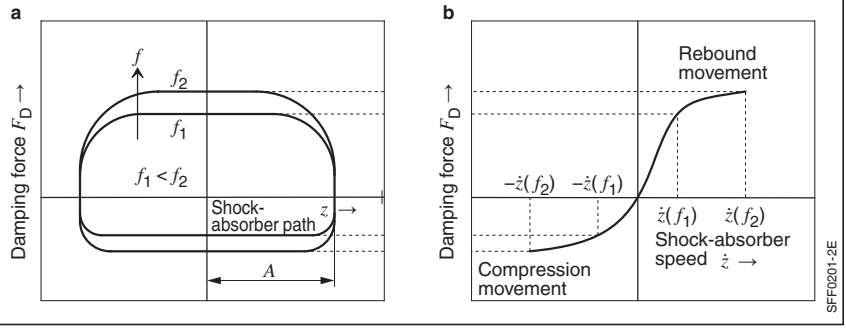
Damping characteristics
Damping force is a function of the speed of the inward or outward movement of the shock absorber, whereby the direction of force is opposed to the direction of speed at all times. It is generally applicable that the damping force F_D and the speed $\dot{z}$ are linked via the damping constant k_D and the damping exponent n. The following applies:

$$F_D = -\text{sign}(\dot{z}) \cdot k_D \cdot |\dot{z}|^n .$$

The damping constant and damping exponent are essentially dependent on the design of the shock absorber (valve characteristics, geometry). With the corresponding configuration of the individual parameters, progressive to degressive damping characteristic curves can be

created. Varying the bore diameter in the shock-absorber piston influences primarily the progression (tube flow), changing the spring load influences first and foremost the degressivity of the characteristic curve (increase in cross-section with increasing pressure difference). Modern body shock absorbers have mainly degressive characteristics. This achieves a high damping effect at low excitation speeds as well as a limitation of the maximum damping forces.

Damping characteristic curves are usually determined with the help of mechanical or servo-hydraulic testing units. A sinusoidal path excitation of constant amplitude and variable frequency or constant frequency and variable amplitude results in various maximum speeds of the inward or outward movement. The recorded path and force signals can be applied in a force-path diagram (work diagram) (Figure 5a). The force-speed characteristic curve of the shock absorber (damping characteristic curve) can be derived from the work diagram by transferring the maximum force and speed values (Figure 5b).



It is mainly for reasons related to comfort that the configurations of the rebound and compression stages differ. The damping forces generated in the rebound stages are for the most part more than twice as high as the correspondingly generated forces during compression (i.e., in the compression stage; ratio for passenger cars is 1:2 to approximately 1:3, for trucks up to 1:9) of the shock absorber (Figure 5). This limits the impact forces on the vehicle body during the compression phase (comfort) and simultaneously ensures the system is strongly dampened (system relaxation) in the rebound phase. In the event of an asymmetrical distribution of the required total shock-absorber work in favor of a high rebound stage there is the danger of the shock absorber contracting with soft springs.

Damping control

In conjunction with electronically adjustable shock absorbers, damping control systems are being used to an increasing degree nowadays. The major component parts of such damping-control systems are the adaptive shock absorbers and sensors (e.g., acceleration sensors on the wheel and body mass) and intelligent algorithms and control strategies. With the help of the sensors and algorithms, the current driving state is continuously determined and evaluated. In accordance with the stored control strategies, this enables the control system to adapt the shock-absorber characteristics to each driving state by activating the shock ab-

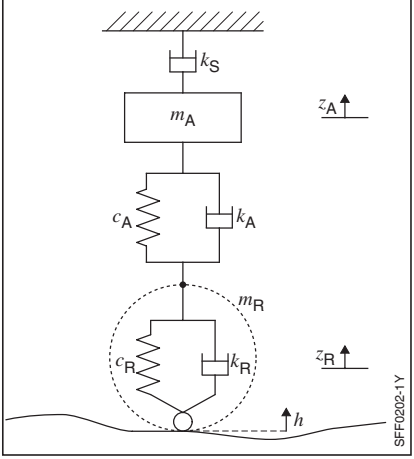
sorbers, thus, for example, influencing and optimizing ride comfort or driving safety. Such systems are often also called semi-active because no active spring adjustment actually occurs, the wheel movement however can be well defined via the adjustable shock absorber within limits.

Control strategies



Threshold-value strategy

Threshold-value controllers compare one or a number of relevant driving-state variables (e.g., body acceleration, steering angle) with the corresponding limit values and initiate defined measures if these values are exceeded or not reached. The damping forces are usually influenced axle by axle simultaneously in the rebound and compression directions. The main focus of threshold-value controllers is on increasing comfort while simultaneously maintaining driving safety.

Alongside purely influencing the vertical vibration characteristics, induced vehicle-body movements can also be optimized. For example, steering angle monitoring can lead to a reduction in the dynamic rolling or hardening the damping depending on the brake pressure can reduce pitching motion caused by braking.

Figure 6: Theoretical principles of the skyhook approach

h Vertical road excitation.

Skyhook

The skyhook control strategy aims to keep the vehicle body calm independently of current driving state and road conditions. This is intended above all to increase ride comfort. In contrast to the threshold-value strategy, the skyhook control strategy regulates the damping characteristics at each individual wheel. The basic principle is to decouple the movement of the vehicle body from the road excitation. To achieve this, it is imagined that the vehicle body is connected by means of a shock absorber to the sky (Figure 6). The damping force F_{DS} of the skyhook shock absorber results from the link of the body speed $\dot{z}_A$ and the damping constant k_S of the imaginary sky shock absorber:

$$F_{DS} = k_S \dot{z}_A .$$

For the conventional vibration system, on the other hand, the damping force F_D would result from the link of the damping constant k_A of the body shock absorber and the difference between the vertical body speed $\dot{z}_A$ and the vertical wheel speed $\dot{z}_R$:

$$F_D = k_A(\dot{z}_A - \dot{z}_R) ,$$

In order to brace the vehicle body against the sky, in the real implementation the additional portion of force F_{DS} of the sky shock absorber must be applied by the body shock absorber. The proportional damping factor k_{AS} this requires is calculated to:

$$k_{AS} = \frac{k_S \dot{z}_A}{\dot{z}_A - \dot{z}_R} .$$

As an adaptive (semi-active) shock absorber is only able to extract energy from the system in the form of heat, but is un-

able to supply heat to the system, a case distinction is required [1], [2]. The following applies:

$$F_{Dtot} = \left(k_S \frac{\dot{z}_A}{\dot{z}_A - \dot{z}_R} + k_A \right) \cdot (\dot{z}_A - \dot{z}_R)$$

where $\dot{z}_A (\dot{z}_A - \dot{z}_R) \geq 0$, and

$$F_{Dtot} = k_A (\dot{z}_A - \dot{z}_R)$$

where $\dot{z}_A (\dot{z}_A - \dot{z}_R) < 0$.

Depending on the amount and direction of the vehicle-body speed and the shock-absorber movement (rebound or compression movement), the control strategy for the skyhook approach shown in Figure 7 is pursued for comfortable damping of the vehicle body. However, specific damping of rolling, pitching, and wheel vibrations is not taken into account by this approach. These movements are also highly relevant with regard to ride comfort and driving safety, which means that the skyhook controller is generally overridden by other controllers.

Groundhook

A groundhook controller aims to improve driving safety by reducing the wheel load fluctuations. In much the same way as the considerations for the skyhook strategy, it is imagined that the wheel is connected

Figure 8: Theoretical principles of the groundhook approach

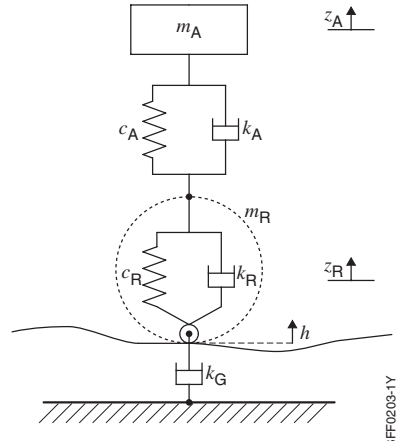
k_G Damping constant of groundhook shock absorber.



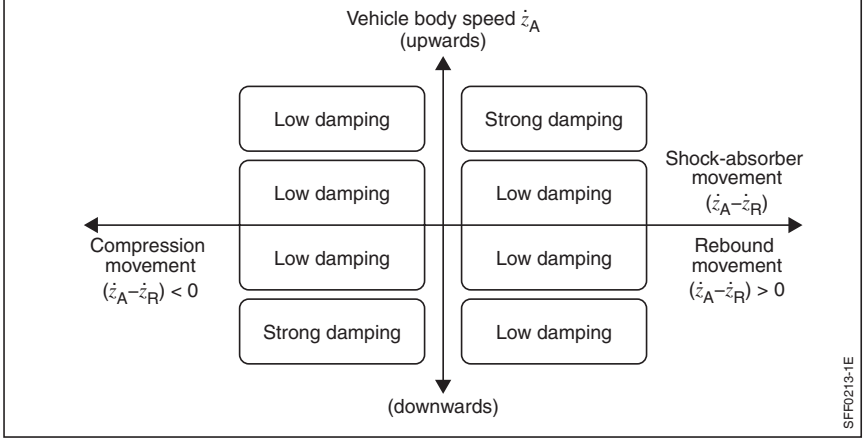


Figure 7: Control strategy of skyhook control (case distinction)

by a shock absorber to the roadway (Figure 8) and a proportional damping factor k_{AG} is derived. The following applies in the same way as the derivations for the skyhook controller:

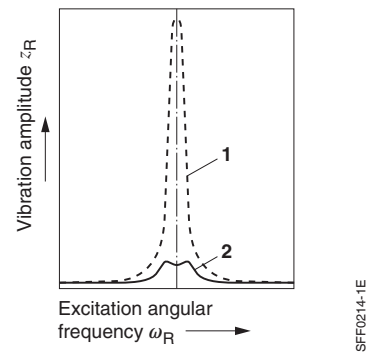
$$k_{AG} = k_G \frac{\dot{z}_R - \dot{h}}{\dot{z}_R - \dot{z}_A}$$

where:
$\dot{z}_A$ Vertical body speed,
$\dot{z}_R$ Vertical wheel speed,
$\dot{h}$ Vertical excitation speed,
k_G Damping constant of the groundhook shock absorber.

Also for the groundhook controller, a case distinction is made depending on the directions of movement of the wheel and vehicle body. This case distinction takes place on the basis of the term:

$$(\dot{z}_R - \dot{h})\ (\dot{z}_R - \dot{z}_A)\ .$$

Huang's algorithm
The aim of Huang's algorithm is shock-absorber control in favor of as low an effective body acceleration as possible as a comfort criterion [3]. With high body acceleration and rectified damping force, damping is set as high as possible. If damping force and body acceleration are opposed, damping is set as low as possible.



$\ddot{z}_A(\ddot{z}_A - \ddot{z}_R) > 0 \rightarrow$ hard characteristic,
$\ddot{z}_A(\ddot{z}_A - \ddot{z}_R) \leq 0 \rightarrow$ soft characteristic.

Vibration absorbers

To specifically influence the vibration properties of the vibration system consisting of the wheel and vehicle-body mass, vibration absorbers (see Vibrations absorption) are deployed in some cases in the area of the chassis.

Depending on the configuration and arrangement of the vibration absorber, the comfort, acoustics, or driving safety can be influenced. A distinction is made between passive and active vibration absorbers. A passive vibration absorber is a mass attached to the chassis by sprung and damped mountings (Figure 10). The absorbing effect is created by the corresponding mass forces and in the case of passive absorbers is restricted to a certain frequency range. The effective range can be enlarged using an active absorber with an actuator that can be activated.

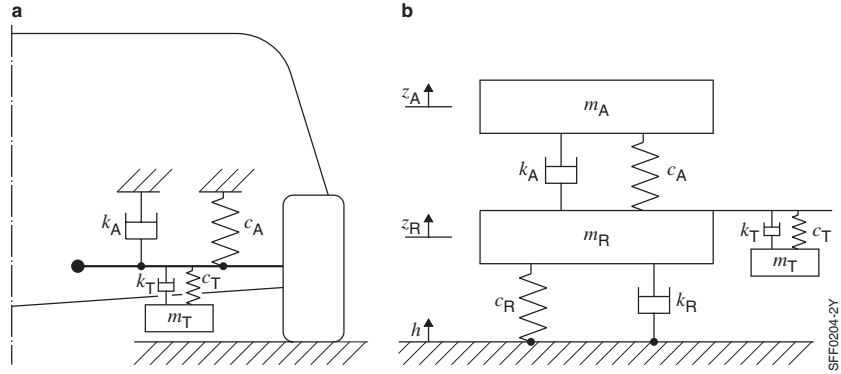


Figure 9: Vibration amplitude of a wheel movement as a function of the excitation angular frequency with and without vibration absorbers
1 Progression without vibration absorber,
2 Progression with vibration absorber.

On excitation of the vibration system, the vibrations and oscillations of the main system are taken over by the appropriately coordinated vibration absorber, i.e., the main system only vibrates very slightly whereas the absorber absorbs a large portion of the energy. Figure 9 shows an example of the progression of the vibration amplitude of a wheel movement with and without vibration absorbers. With the deployment of a vibration absorber geared to the frequency range of the natural wheel frequency, a significant drop in the vibration amplitude can be observed in the corresponding frequency range. However, vibration absorbers have the disadvantage of a (depending on the frequency range to be extinguished) high additional mass.

Wheel suspensions

Basic principles

Vehicle wheels and the vehicle body are connected via wheel suspensions. On the one hand, a wheel suspension has the function of guiding the relevant wheel in relation to the vehicle body in such a way that a movement that is essentially directed vertically relative to the vehicle body remains possible and, on the other hand, that the tire forces exerted in the wheel contact point in the horizontal plane and the torques generated by these forces can be transferred to the body. On the front axle and also on the rear axle of vehicles with rear-axle steering, additional steerability of the wheels is to be ensured.

Alongside the tires, the suspension and shock absorber system, the vehicle body mass, and the individual wheel masses, the wheel suspensions have a major influence on the driving characteristics of a vehicle, as they influence the parameters of the vehicle axle concerned that are relevant to driving dynamics. These are, for example:

- the track width,
- the toe-in or toe-out angle,
- the camber angle,
- the caster angle,
- the caster offset in wheel center,
- the spread angle,
- the spread offset,
- the kingpin offset,
- the disturbing force lever arm,
- the position of the rolling pole of the axle and thus the orientation of the roll axis,
- the location of the pitching pole,
- the braking and anti-squat control,
- the longitudinal and transversal springs.

For the definitions of the individual wheel-suspension and vehicle parameters, refer to the chapter “Chassis systems”, section “Characteristics”:

Kinematics and elastokinematics

During operation of the vehicle, the geometry and kinematics of a wheel suspension lead to changes in the characteristic parameters of the wheel suspension (for example, caster angle, location of the rolling pole) and wheel-position parameters (for example, camber angle and toe angle) of the corresponding wheel. This is the case, for example, as a result of a movement of the wheel within the framework of the vertical degree of freedom permitted by the wheel suspension (i.e., compression or rebound movement of the wheel) or with steerable wheel suspensions as a result of a steering movement. Figure 1 shows examples of the camber- and toe-angle changes of a wheel suspension due to kinematics during compression by the compression path Δz in comparison with the design position. As a rule, the kinematic wheel-position changes are shown with the help of diagrams of the compression and rebound path of the wheel. The so-called “wheel paths” for the camber- and toe-angle changes of the wheel suspension shown in Figures 1a and 1b are shown in Figure 1c.

Due to the fact that the kinematic changes to the wheel-suspension parameters and wheel-position parameters have a great influence on the driving characteristics of a vehicle, correct configuration and coordination of the steering and wheel lift kinematics are of great significance.

Alongside the changes to the wheel-position parameters due to kinematics during compression or rebound movements, the forces and torques affecting the wheel suspension (for example drive and braking forces, lateral and vertical forces in the wheel contact point) in conjunction with the elasticity of the suspension lead to further wheel-position changes. The elasticity of a wheel suspension results from the deformability of the individual wheel suspension components (for example

links) and the bearings used when forces and torques are applied. For reasons related to driving comfort and acoustics, the mounts used in modern wheel suspensions are usually elastic mounts (for example rubber mounts). Figure 2 shows an example of a wheel suspension with two rubber mounts fitted on the vehicle body side; their elasticity when longitudinal force occurs at the wheel contact point leads to an elastokinematic change in the toe angle of the wheel.

Alongside the kinematic wheel-position changes, the elastokinematic effects also influence the driving characteristics of a vehicle. When coordinating the kinematics and elastokinematics of a wheel suspension, this is why it is usually the aim that the kinematic and elastokinematic effects supplement one another when influenced by forces and springs.

For example, elastokinematic steering is used on a number of modern rear-axle suspensions to reduce load change reactions (for example by increasing the toe-in when braking force affects the rear wheel on the outside of the bend) [1]. It is possible to influence the elastokinematic properties of a wheel suspension by, for example, coordinating the individual mount elasticities or adjusting individual mounting points.

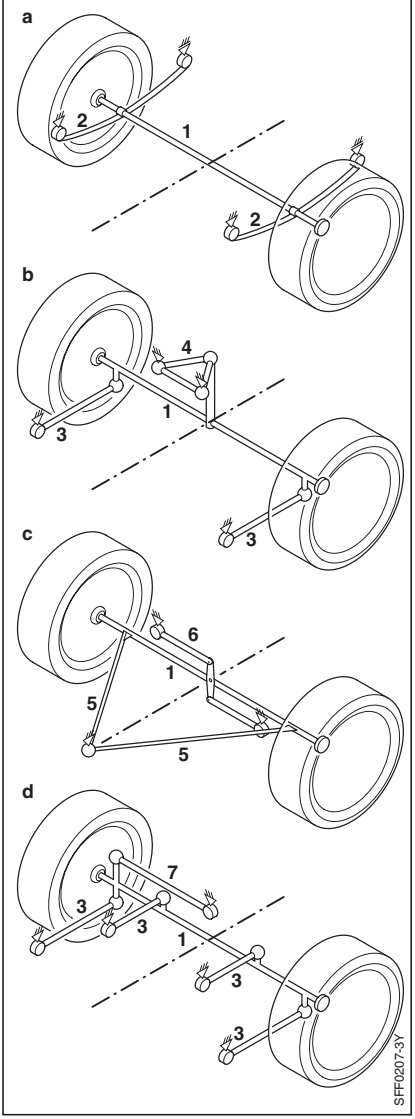
Basic categories of wheel suspensions

There are a large number of different wheel suspensions. They are classified primarily according to the type of suspension concept. An initial distinction is made between rigid axles (dependent wheel control), semi-rigid axles, and independent wheel suspensions (independent wheel control).

Rigid axles

In the case of a rigid axle, the wheels of an axle are firmly interconnected by a rigid axle body, which leads to mutual influences on the wheels. Rigid axles are used as both driven and non-driven rear axles on heavy vehicles (for example off-road vehicles, light utility vans, trucks). Occasionally, however, their sturdy construction and high ground clearance mean that steerable variants are also used as front axles (for example on off-road vehicles or off-road trucks).

Guidance of a rigid axle in relation to the vehicle body can be implemented in different ways. On vehicles with leaf springs, guidance is usually via the spring leaves (Figure 3a). There are also a large number of rigid axle concepts guided by links or coupling shafts (Figures 3b, 3c, and 3d). Where links and coupling shafts are used, statically undefined mounts are selected to make linking at the vehicle body easier and to reduce the required space [3]. Refer to [2] for detailed explanations of the individual axle variants.



The major advantages of rigid axles are the simple and sturdy design, low costs, a high roll center, high maximum wheel lift, and high ground clearance.

However, rigid axles also have a number of disadvantages that are inherent in the design: the mutual wheel influence, high unsprung mass, high installation space requirement, as well as limited possibilities to coordinate the kinematic and elastokinematic factors.

Semi-rigid axles

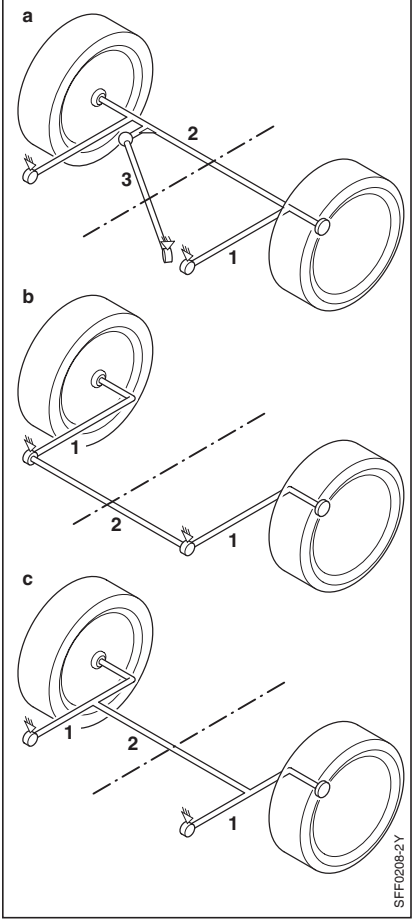
Semi-rigid axles also involve a mechanical coupling of the wheels. In contrast to rigid axles, however, this coupling is not rigid. The elasticity of the coupling profile

Figure 3: Design examples for rigid axles
a) Longitudinal leaf-spring suspension,
b) Trailing and coupling-shaft links,
c) A-bracket with Watt linkage,
d) Trailing link with Panhard rod.
1 Rigid axle, 2 Leaf spring,
3 Trailing link, 4 Coupling-shaft link,
5 Coupling shaft, 6 Watt linkage,
7 Panhard rod.

that is used enables relative movements between the wheels. The coupling profile forms a cross-connection between two trailing links to which it is firmly connected. Longitudinal forces are absorbed via the trailing links. The bracing of lateral forces is supported by the stiffening effect of the coupling profile. In order to guarantee a relative movement between the two wheels of the axle, the coupling profile has to be designed as weak. Depending on the arrangement of the coupling profile, distinctions are made between torsional-link axles, twist-beam axles and semi-independent axles (Figure 4).

Due to their simple and low-cost design, semi-rigid axles are widely used as rear axles on vehicles with front-wheel drive.

The advantages of this axle concept include the low installation space requirement, the low unsprung masses, easy assembly and removal, the stabilizing effect of the coupling profile, the low track width and toe-angle changes, as well as the good anti-dive properties.



These advantages are offset by a number of disadvantages that are inherent in the principle: the mutual wheel influence, the low suitability for driven axles, the high tension peaks at the transition points between the trailing link and coupling profile, the increase in the tendency to oversteer in the event of influencing lateral forces (lateral force oversteer) due to link deformations, as well as limited kinematic and elastokinematic optimization potential.

Torsional-link axles
In the case of torsional-link axles (Figure 4a), the two wheel carriers are connected by means of a coupling profile arranged close to the wheel center. As a rule, the lateral guidance of the axle is supported by an additional guide element (for example a Panhard rod) [2]. There are great similarities to a rigid axle with regard to both the structure and properties.

Twist-beam axles
In contrast, twist-beam axles (Figure 4b) have kinematic properties similar to those of trailing-link wheel suspensions. The coupling profile is arranged at the height of the pivot points of the trailing link. The deployment and arrangement of the coupling profile greatly simplifies the mounting of the trailing links compared to a trailing-link independent wheel suspension.

Semi-independent axles
In comparison with twist beam axles, the coupling profile on a semi-independent

Figure 4: Design examples for semi-rigid axles
a) Torsional-link axle with Panhard rod,
b) Twist-beam axle,
c) Semi-independent axle.
1 Trailing link,
2 Coupling profile,
3 Panhard rod.

axle (Figure 4c) is not at the height of the link pivot points rather is offset towards the rear. This improves above all lateral force bracing in comparison with the twist-beam axle.

Independent wheel suspensions
Alongside semi-rigid axles – as rear axles on vehicles with front-wheel drive – most modern vehicles nowadays have independent wheel suspensions where each wheel is individually connected to the vehicle body according to the desired degrees of freedom of movement. A wheel is connected here with the help of a wheel carrier and a corresponding number of links.

The design (for example two-point links or A-arm links) and arrangement of the links (trailing links, transverse links or diagonal links) and the connecting mounts determine the kinematic and elastokinematic properties of the wheel suspension. The design of the individual links determines the number required to reduce the freedom of movement of a wheel to the desired number of degrees of freedom.

The number of links is frequently used as the classification of suspension types (for example, five-link independent wheel suspension). The resulting type of spatial movement (kinematics) of the wheel during compression and rebound movement is also frequently used for the classification of independent wheel suspensions [1], [3]. Depending on the type of movement of the wheel carrier, distinctions are made here between level, spherical, and spatial independent wheel suspensions [1], [3].

The proportion of independent wheel suspensions in modern vehicles is rising steadily. Compared to rigid and semi-rigid axles, independent wheel suspensions offer a number of advantages. For example, there is no mutual wheel influence, the kinematic and elastokinematic optimization potential is high, and the space requirement and unsprung mass are low in some cases.

However, independent wheel suspensions also have some disadvantages. In some cases, they lead to a complex design, the costs are high, the maximum wheel lift is low, and the configuration and coordination process is more complex in some cases.

There are large numbers of different designs of independent wheel suspensions. The basic principles of selected designs are to be explained briefly in the following section and their structures shown in diagrams. For detailed explanations of the individual designs and of other independent wheel suspensions and specific design examples, refer to [2].

Trailing-link independent wheel suspension
On a trailing-link independent wheel suspension, a wheel is connected to the vehicle body by means of a single link arranged in longitudinal direction (Figure 5a). The trailing link transfers both the longitudinal and lateral forces, which means that high mount forces occur and the mounts have to be designed accordingly.

The axis of rotation of the links runs parallel to the vehicle transverse axis. The advantages of this suspension form are usually low installation space requirement as well as low costs. The disadvantages are the limited kinematic optimization possibilities, the instantaneous center located at road height that causes high roll torque on cornering, as well as the high stresses placed on the links and their mounts.

Diagonal-link independent wheel suspension
In the same way as on the trailing-link wheel suspension, on the diagonal-link wheel suspension the wheel is also connected to the vehicle body by means of a single link. However, to achieve better bracing of the longitudinal and above all lateral forces, the link is arranged diagonally (Figure 5b) and there is more space between the mounting points. To achieve more favorable kinematic properties, on modern suspensions the axis of rotation of the link is arranged diagonally both in the projection to the vehicle lateral plane (roof angle) and in the projection to the road (V-shaped angle) [1].

Double-wishbone independent wheel suspension
A double-wishbone independent suspension is when a wheel is connected to the

vehicle body via two A-arm links. One link is arranged below the wheel center and the other is arranged above it (Figure 6a), which enables the suspension to brace all of the forces and torques that occur at the wheel. As a rule, the high articulation forces mean that the transverse links are not directly connected to the vehicle body structure but rather are secured to a “chassis subframe” that interconnects both wheel suspensions and thus relieves the load of inner forces on the vehicle body.

With adaptation of the mounts and design of the links, double-wishbone independent suspensions provide very high kinematic optimization potential [2]. Depending on the location of the axes of rotation of the links, level, spherical or spatial wheel suspension kinematics are achieved [3]. The disadvantages of double-wishbone independent suspensions are the higher costs as well as the greater installation space requirement.

Figure 5: Trailing- and diagonal-link independent wheel suspension

b) Spring-strut independent wheel suspension,
c) Damper-strut independent wheel suspension.
1 Wheel carrier,
2 Upper A-arm link,
3 Lower A-arm link,
4 Spring damper strut,
5 Tie rod (steering).

Spring-strut independent wheel suspension

The kinematics of a spring strut wheel suspension correspond to those of a double-wishbone independent suspension in which the upper transverse link is replaced by a sliding guide (Figure 6b). This sliding guide corresponds to the spring strut on other suspensions (in the case of a combined spring-shock absorber unit) or the shock absorber strut (in the case of separate spring and shock absorber arrangement) where the housing is rigidly connected to the wheel carrier. With this design, the shock absorber rod also assumes wheel guidance tasks.

The lower link plane of a spring-strut suspension is usually formed by two two-point links (radius links) or an A-arm link. In the case of a suspension using the McPherson principle, originally the lower A-arm link was formed from a transverse link and a stabilizer. Nowadays, however, other spring-strut suspensions are also referred to as McPherson axles.

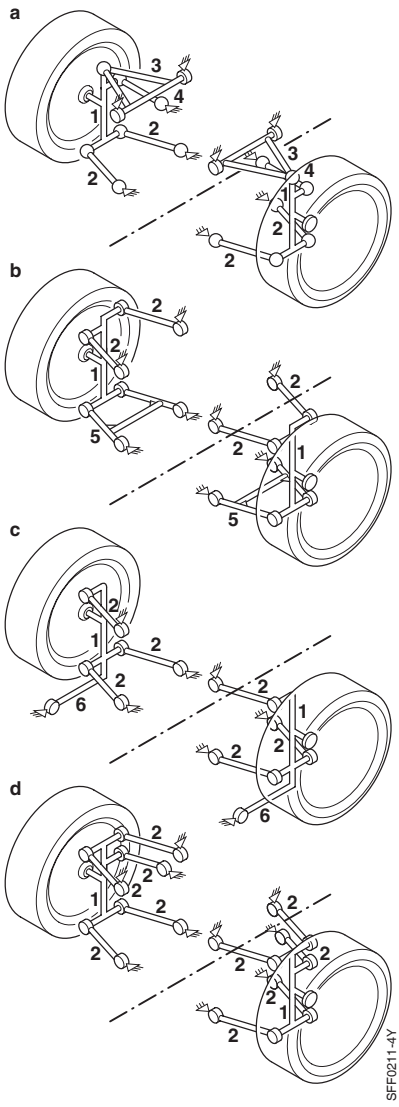
Advantages of the spring-strut wheel suspension are above all the low construction overhead and low amount of space required at the height of the wheel axes which can be used in particular in the case of passenger cars with front-wheel drive with laterally installed engine-transmission units. Other advantages are the cost-saving and weight-saving design, simple installation and assembly, as well as the high degree of integration. On specifying the kinematics, however, spring-strut suspensions offer slightly less leeway for configuration, among others of scrub radius and deflection-force lever arm, in comparison with double-wishbone independent suspensions.

Damper-strut independent wheel suspension

Kinematically similar to the McPherson axle, here too the supension-linkage function is assumed (Figure 6c) and requires a twin-tube shock damper to support the lateral forces. There are advantages in relation to the larger package requirement thanks to the omission of the spring-induced lateral forces on the damper (for improved response), reduced tendency to wear, and easier repair when changing the springs.

Multilink independent wheel suspension

Wheel suspensions with four or five single links are generally referred to as multilink axles. Multilink axles result, for example, from breaking down an A-arm link into two individual two-point links in the case of a double wishbone axle (Figure 7a). Breaking down three-point links and the use of independent two-point links usually result in greater leeway for configuration of the kinematic and elastokinematic properties of the axle. On the one hand, this increases the optimization of the axle with regard to comfort and driving safety requirements. On the other hand, the somewhat complex design increases the overhead involved in the configuration and coordination processes for the wheel suspension.



Trapezoidal-link independent wheel suspension

Trapezoidal-link wheel suspensions (Figure 7b) are a special form of the multilink independent wheel suspension that is mainly used as rear axles. The lower plane is formed by a trapezoidal link that has two connection points on the wheel side and an axis of rotation on the vehicle body side. This means the lower link sets a total of three degrees of freedom of the wheel. Another two degrees of freedom are eliminated by two two-point links arranged accordingly so that only the desired compression degree of freedom of the wheel remains.

Control-blade independent wheel suspension

Another design of multilink independent wheel suspensions is the control blade axle on which the wheel is guided by one trailing link and three transverse links (Figure 7c). The trailing link (control-blade link) is connected to the vehicle body in such a way that it can be rotated and is firmly connected to the wheel carrier. As a rule, it has elastic properties in order to enable kinematic track and camber changes. The lateral forces are braced via three two-point transverse links which are usually arranged in two planes (one above and one below the center of the wheel). The arrangement and orientation of the transverse links determines the kinematic properties of the wheel suspension.

d) Five-link independent wheel suspension.
1 Wheel carrier, 2 Two-point link,
3 A-arm link, 4 Tie rod (steering),
5 Trapezoidal link, 6 Control blade.

Five-link independent wheel suspension
A wheel suspension with completely detached links requires five individual two-point links to reduce the movement of a wheel to the desired vertical degree of freedom (Figure 7d). Five-link rear axles are generally referred to as multilink suspensions, whereby on the front axle this is referred to as a four-link axle plus tie rod [2].

Wheels

Function and requirements

All of the vehicle-specific or axle-specific tasks are performed via the wheel, e.g. transfer of dynamic forces between the vehicle and road surface. These include taking up the vehicle load and the impact forces of the road surface, transferring the rotary motion of the axles to the tires, and taking up and transferring braking and acceleration forces as well as lateral forces when cornering. Wheel size is mainly determined by the space required by the braking system, the axle components, and the size of the tires used.

Wheels have primarily a technical function. But the increasingly booming light-alloy wheel market calls for visually attractive designs.

Figure 1: Structure of a disk wheel
1 Rim inner flange,
2 Rim base,
3 Rim outer flange,
4 Ventilation hole,
5 Wheel disk,
6 Pitch-circle diameter,
7 Center hole,
8 Dish.

Structure

The wheel is a load-bearing, rotating part between the tire and the axle. It usually consists of two main components – the rim and the wheel disk. These two components can be made from a single part, and can also be permanently or non-permanently attached to each other. A permanent connection of a rim with a wheel disk is called a disk wheel.

Figure 1 shows the basic structure of a steel wheel. Here the rim mounts the tire and the wheel disk connects the wheel to the axle.

In daily usage the terms rim and wheel are often interchanged. The term rim is often used when actually the complete wheel is meant. The “wheel” in general usage often also refers to the tire. However, as a technical term in automotive engineering “wheel” generally means the wheel without the tire.

Wheel disk
The wheel disk (wheel nave) is the part that connects the rim to the axle hub. In the case of a steel wheel, the wheel disk consists of a formed steel-sheet blank. This has holes for ventilating the brake system and is usually curved (dish, see Figure 1). The center of the wheel disk contains the center hole and the wheel-bolt or stud holes. The wheel is secured to the axle through these holes. The center hole is provided with a locating bore by means of which the wheel is radially centered on the axle. This bore determines together with the rim bead seat (for the bead ledge) the wheel’s true-running quality (via the radial run-out). The attachment face is, together with the rim flanges, responsible for lateral wheel run-out.

In the case of an aluminum wheel, the wheel disk can, due to its design, have different shapes such that the term wheel disk is no longer applicable.

Rim

The term rim strictly speaking describes only the radially outermost part of the wheel which holds the tire. The rim is therefore the fundamental connecting element between the wheel disk and the tire. In a tubeless tire it provides the air seal and is geometrically matched to the tire. The most commonly used shape of rim is divided into four zones (Figure 2):

– rim flange (inner and outer),
– hump (inner and outer),
– rim bead seat (inner and outer),
– rim base and drop center.

There are also different shapes for passenger cars (Figure 3).

Rim flange

The rim is limited on the inner and outer sides by a rim flange (rim inner flange and rim outer flange). It acts as the side stop for the tire bead (see Tires) and absorbs the forces resulting from the tire pressure and the axial tire load. The rim flange is specified in the guidelines of the ETRTO (European Tyre and Rim Technical Organisation) by, for example, J, K, JK or B. In this way, the geometry of the rim flange and the ratio to the drop center are dimensionally described. This is based on how the wheel is used.

The most common rim-flange shape for passenger cars is the J flange shape. The lower B flange can be found on smaller vehicles and in inflatable spare tire systems. K and JK flanges are rarely used any more; they used to be the domain of heavy, comfortable vehicles of the upper price segment.

Rim bead seat

The rim bead seat describes the contact zone of the tire with the rim. It centers the tire radially. In this zone the tire is given the correct position for radial and lateral true running. All the dynamic driving forces are transferred here. In the tubeless tires mainly used today in passenger cars the wheel/tire system is sealed at the rim bead seat.

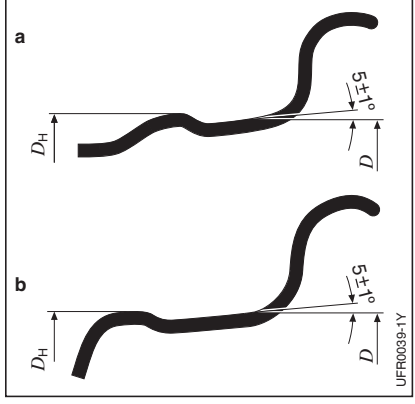
1 Rim flange, 2 Tapered bead seat,
3 Hump, 4 Drop center.
M Flange-to-flange width,
D Nominal rim diameter,
D_H Hump diameter.

Rim base
The rim base connects the inner and outer rim bead seats. The drop-center rim is primarily used in passenger cars. Drop-center rims have a clearly defined shape with a drop-center rim base (drop center). When the tire is mounted on the wheel, the tire is initially positioned with one side of the tire bead in the drop center so that it can be pulled over the rim flange on the opposite side. The drop center is the required shaping of the rim base to mount the tire base (tire bead, tire inner ring) when fitting and removing the tire.



Hump
The hump is the all-round raised bead in the area of the rim bead seat (Figure 4). It is prescribed in many countries for tubeless tires. In the event of low tire pressure the hump is intended to prevent the tire from coming off the rim bead seat. The following hump shapes are customary:
– H: round hump on one side on the outer bead seat,
– H2: round hump on both sides,
– FH: flat hump on the outer bead seat,
– CH: combination hump,
  flat hump on the outer bead seat,
  round hump on the inner bead seat,
– EH2: extended hump on both sides.

Primarily H2 rims are used in passenger cars. H rims (formerly also called H1) are also used in commercial vehicles and older vehicles as well. The major differences are between the standard hump shape (H) and the flat hump (FH). Newly included in the standard is the extended hump (EH2) with slightly larger hump diameter, which is used in some cases, particularly with “run flat” tire systems.

Rim and wheel dimensions
Terms
The most important terms for the function and design of a wheel are (Figure 5):
– rim diameter (nominal diameter, dimension from rim bead seat to rim bead seat),
– rim circumference (measured value, determined with bead tape around the rim bead seat),
– flange-to-flange width (rim width, inside dimension between the rim flanges),
– center-hole diameter (centering diameter, as size of fit),
– rim offset ET (dimension in mm from the rim center to the attachment face of the disk wheel),
– pitch-circle diameter (diameter of the circle on which the center points of the bolt holes are situated),
– flange height (measured from the rim nominal diameter to the saddle point of the flange radius).

The rim offset determines the position of the wheel in the vehicle. The wheel is generally secured to the brake-disk chamber or to the brake drum. With a rim offset ET = 0 wheel attachment is exactly in the middle of the rim width. Changing the rim offset changes the position of the wheel and with it the track width of the vehicle. A smaller rim offset equates to a wider

Figure 4: Hump shapes
a) Hump,
b) Flat hump.
D Nominal rim diameter,
D_H Hump diameter.

track width, a larger rim offset equates to a narrower track width.

Rim size
The basic dimensions of a rim size using a commercial-vehicle disk wheel with 15° tapered bead seat rim by way of example is 22.5 × 8.25 inches. The first value gives the rim diameter in inches, the second value the flange-to-flange width in inches.

Rim designs
Depending on the intended purpose and the tire design, there are a range of different cross-sectional rim shapes available (Figure 6): Rims can be made from a single part or from multiple parts. According to EU standardization single-part rims must be identified with a "x" (e.g. 6J × 15H2) and multiple-part rims with a "-".

Drop-center rims for passenger cars and light utility vehicles
The rim base is recessed for tire mounting. The drop-center rim can be made

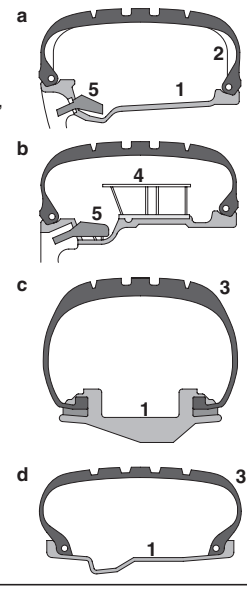
from one part (Figure 6a) or two parts (Figure 6e). The two-part rim is divided into a front half and a rear half which are bolted to each other in the drop center through an all-round pitch circle and to the wheel disk. A sealing ring or a sealing compound is used to provide the seal. The two-part variant traces its origins back to motor sport and offered the advantage of being able to replace one rim half in the event of damage. The tire is mounted in exactly the same way as on the single-part rim.

15° tapered bead seat rim
for commercial vehicles
The 15° tapered bead seat rim (Figures 6b and 6c) is made from a single part. The rim base is for tire-mounting purposes provided with a drop center to which the 15° tapered bead seats are connected. The 15° tapered bead seat rim with drop center is necessary to enable the benefits of the tubeless tire to be exploited on heavy commercial vehicles too.

5° tapered bead seat rim
The 5° tapered bead seat rim (Figure 6d), also called flat-base rim, is made from multiple parts. This is needed to mount the tires. The outer 5° tapered bead seat, which is non-permanently connected to the outer rim flange, can be removed. The outer 5° tapered bead seat is held on the rim base by an all-round sealing ring.

The tire is pushed onto the rim base when the 5° tapered bead seat is removed. The fact that the rim is made from multiple parts means that a tube is required. The two bead seats have a 5° taper.



These rim systems have advantages when it comes to changing tires. However, they are heavier than 15° tapered bead seat rims and do not exhibit the good radial and lateral true-running properties of single-part rims.

Special trims
for special wheel/tire systems
PAX (Pneu Accrochage, X stands for Michelin radial tire technology) and CTS (Conti Tire System) are distinct rim geometries which can only be used with specially developed tires. This design is used primarily on armored vehicles. The complete system is designed to permit continued driving with a punctured tire without the tire coming off the rim. The two systems also prevent the tire from being destroyed by thermal load during driving when punctured. With a conventional rim base the sidewall folds up when the tire is punctured and friction occurs.

In the PAX system (Figures 3c and 7b) from Michelin an additional support ring is mounted on the rim base; the punctured tire rests on this support ring.

The CTS system from Continental does not have an additional support ring. The tire reaches round the rim base and can rest when punctured on the rim base (Figures 3d and 7c). Both run-flat systems are required by law to have a tire-pressure control system.

Design criteria

Passenger-car wheels
Design criteria for passenger-car wheels include:
– High durability,
– Good support for brake cooling,
– Reliable wheel mounting,
– Low radial and lateral run-out,
– Small space requirement,
– Good corrosion protection,
– Low weight,
– Low costs,
– Problem-free tire fitting,
– Good tire seating,
– Good balance-weight seating (see Wheel with tire),
– Appealing design (for aluminum wheels),
– In part requirements to improve vehicle aerodynamics (c_d value).

Special requirements for commercial-vehicle wheels
Wheels for commercial vehicles are technologically highly sophisticated. Whereas racing-car wheels are geared towards maximum speed, commercial-vehicle wheels carry high tonnages at simultaneously – compared with excavators for example – high speed. In Europe, for example, long-distance commercial vehicles travel with a total weight of 40 tons at a speed of 80 km/h. It is essential when establishing the minimum tire size for a commercial-vehicle axle always to start out from the permissible axle load and the top speed dictated by the vehicle design.

The larger the load to be transported and the rougher the terrain to be negotiated, the more important it is to take into account the – sometimes competing – rim-design requirements. High load capacity is to be achieved by designing an appropriate wheel shape and using optimum materials. High fatigue strength is essential to increasing road safety. Low wheel weight optimizes payload and is required because the wheel, as an unsprung, rotating mass, influences the overall vehicle oscillatory system.

Designation for passenger-car wheels

A typical wheel designation for passenger-car wheels is, for example:
6 ½ J x 16 H2 ET30.

6 ½	Dimension of rim width in inches,
J	Rim-flange geometry,
×	Single-part rim base,
16	Dimension of rim diameter in inches,
H2	Rim hump at the inner and outer rim bead seats,
ET	Rim offset,
30	Dimension of rim offset in mm.

The designation and the associated dimensions with permitted tolerances have been prescribed as binding and standardized by worldwide recognized standards organizations such as ETRTO (European Tyre and Rim Technical Organization) or ISO (International Standards Organization) to harmonize rim and tire dimensions.

Materials for wheels

There are basically steel and light-alloy wheels. The material must always be specified in connection with the manufacturing technology. The following overview is intended to simplify systematization.

Classification of wheels

Steel wheel

A steel wheel consists of two parts, the rim and the wheel disk. Steel wheels are made from hot-rolled sheet steel in a forming process under rolling and bending conditions and joined by welding.

Light-alloy wheel

Light-alloy wheels are usually made of aluminum or magnesium alloys. They are produced using a variety of technologies. The aluminum wheel is produced as a cast wheel, forged wheel, sheet-metal wheel, or hybrid wheel. The magnesium wheel is only produced as a cast wheel.

The advantages of lightweight wheels are improved vibrational behavior, responsive suspension, reduced fuel consumption, and higher payloads. Light-alloy wheels are used in commercial-vehicle applications in particular in weight-sensitive transportation jobs. These jobs include the transportation of tanks and silos, where not exceeding the maximum transportation weight is of primary importance. In these situations the higher-cost light-alloy wheels usually pay for themselves within the first year of use.

Plastic wheel

Plastic wheels are made in an injection-molding process from mineral-fiber-reinforced polyamide and with metal inserts.

Materials

Sheet steel

In all the cheapest variant of passenger-car wheels is manufactured from hot-rolled and pickled sheet steel strip unrolled from the coil. The very good mechanical properties of this material provide for thin-walled wheel designed which are manufactured in highly automated, high-precision forming processes under bending conditions to finishing dimensions with close tolerances.

The continuous trend towards lightweight construction particularly since the CO_2 discussion has accelerated the use of high-strength, fine-grained structural steel. Its high tensile strength (600…750 N/mm^2) and very good formability and weldability enable lightweight, and cost-effective wheels to be manufactured efficiently.

Further potential for weight savings can be opened up by the use of “tailored blanks” for rim production. Here the sheet thickness of the starting material is adapted to the stresses in the wheel, in the course of which material strips of sheets of different thicknesses are joined by laser welding to create a blank.

Aluminum sheet

Aluminum sheet as an alternative to sheet steel can be more easily formed and is also – albeit thanks to more expensive methods (MIG welding) – more readily weldable. The manufacturing overhead is greater relative to steel wheels and the material costs are comparatively high, which prevents a wider range of applications. The use of high-strength sheet steels has greatly reduced the original weight advantage of aluminum sheet with the result that a cost/benefit analysis comes out in favor of steel wheels.

Light-metal alloys

Light-metal alloys are based in the main on aluminum alloys and in rare cases (e.g. in motor sport) on magnesium alloys. In the case of aluminum wheels, a distinction is made between cast and forge alloys depending on the manufacturing method used.

Cast alloys
Aluminum cast wheels are manufactured in low-pressure diecasting from aluminum alloys. The cast blank is formed in a steel mold, which is filled with liquid molten mass and cooled under controlled conditions to solidify. Aluminum alloys with a silicon content of between 7 and 11 % are used, depending on whether good castability or high strength is to be achieved.

Two alloys have proven successful. GK-AlSi11 is used for small wheels (up to 16 inches) with low wheel loads. The outstanding castability thanks to the high silicon content provides for highly efficient production with low reject rates due to casting defects. This alloy cannot be hardened by heat treatment. The wheels are therefore designed with greater wall thicknesses, which is reflected in slightly higher weights.

GK-AlSi7Mg is used for large wheels with a higher wheel load and for weight-optimized wheels. Adding 0.2…0.5 % magnesium to the aluminum alloy increases the strength of the cast wheel as a result of subsequent heat treatment (solution heat treatment and aging at warm temperature). This advantage is exploited to meet high load requirements during vehicle operation with a minimum of material usage.

To ensure that the high requirements with regard to strength, tightness and ductility placed on these safety-related vehicle components are met, only pure primary aluminum is used as the starting material. Contamination of the alloy with iron would cause acicular structures to form, which in turn would weaken the mechanical properties (elongation at fracture and tensile strength). Contamination with copper would reduce the chemical stability.

Forge alloy
Aluminum forged wheels are used in passenger cars when light, weight-optimized wheels are required and the target weight cannot be achieved with cast wheels. The increased hardness of the aluminum wrought alloy caused by the forging process (increase in mechanical strength due to plastic deformation) enables the wheel to be designed with a thinner wall, which means that less material needs to be used and thus the wheel is lighter.

The starting material takes the form of round continuously cast bars of AlSi1Mg which are sawn into precisely “portioned” disks. These are subjected to a three- to four-stage forging process to create the visible side (design side, disk, spider) and a flow-forming process to create the rim. As well as being hardened by plastic deformation the material is modified by a heat-treatment process.

Magnesium alloys
Whereas magnesium alloys have been unable to establish themselves in volume production – due to higher production costs in view of special safety precautions (risk of fire during cutting) – they are used in individual cases for special-purpose vehicles and racing cars.

Plastics
The use of plastic as a material for wheels is still in the developmental stage due in particular to insufficient high-temperature strength and difficult wheel mounting and manufacture. In particular the insufficient impact strength and thermal load capability as well as the incalculable long-term properties mean that plastic currently appears to make little sense as a material for a safety component such as the disk wheel in automobile construction.

Manufacturing processes

Steel wheels
When the text refers to passenger-car and commercial-vehicle steel wheels, exclusively sheet-steel wheels are what are meant. Other manufacturing processes such as casting and forging are not used for this material to manufacture wheels.

Passenger-car steel wheels consists of two parts: the wheel disk and the rim. They are welded to each other at the end of the production process. Both the wheel disk and the rim are manufactured in volume production on fully linked, highly automated production lines by means of forming processes under bending conditions. Smaller quantities can be produced more economically on individual presses.

Manufacturing the wheel disk
To manufacture the wheel disk the material required is unrolled directly from the coil, straightened flat and fed to a large transfer press with a force of pressure of approx. 40,000 kN. The press is equipped with a nine- to eleven-stage follow-on composite tool, in which the sheet blank is automatically routed with each press stroke from station to station.

A square blank with rounded corners is punched in the first machining step. Then in three to four stages the wheel disk and the center-hole area are formed by deep-drawing and stamping operations. In the next two or three stations the ventilation holes are punched with wedge driving tools and then stamped on the tool outlet side. The stamping replaces deburring of the pointed cutting edges and reduces the wheel's susceptibility to cracking under load.

Finally, the wheel designations are stamped on the reverse side and the calotte- or cone-shaped wheel-stud attachment faces are formed. In the last stage the wheel disk is calibrated to the finishing dimension for joining with the rim.

Manufacturing the rim
The rim material is likewise unrolled from the sheet coil, straightened and cut to length. The strips are stacked and forwarded to the automated rim production line. Here the sheet strip is shaped in a bending machine between three cylinder rolls into a ring and joined at the junction point in a butt-seam welding machine. The upsetting flash created in the process is then planed away on the inside and outside and the weld seam is smoothed by rollers. The unavoidable upsetting flash also on the side edges is then deburred and rounded.

The final rim contour is created on roller-burnishing machines by three consecutive forming steps, each with three profile rollers. The contour of the tool rollers is transferred to the rim here.

Where necessary, flow-forming is used to adapt the wall thickness and material distribution in the rim profile to the loads involved, thus saving more weight.

In the next operation the valve bore is produced on a rotary table. In the first station a flat attachment face is struck, from which the bore is punched in the second cycle. The cutting edges are then rounded on both sides by stamping.

Finally, the rim is drawn in a press onto a gage with the exact finishing dimension in order to create the tight concentricity and lateral-running tolerances (calibration).

Joining the wheel disk and rim
The process of joining the wheel disk to the rim creates the steel wheel. The two wheel parts – wheel disk and rim – are routed to a fully automated welding installation. On a small press they are aligned to each other and then joined to each other in a precisely specified position.

In the next station the assembly is connected by shielded arc welding with four to eight weld seams. These are deslagged and cleaned by rotating brushes adapted to the wheel. Then the wheel is calibrated to the finishing dimensions and made available for surface treatment.

The manufacturing process for steel wheels is so precise that the blank wheel is able to move on to the painting plant without any mechanical reworking. There, as a general principle, it runs through cathodic dip coating and, if stipulated, is given an additional visually appealing finishing coat.

Sheet-steel wheels are characterized in particular by their robustness and, thanks to their low manufacturing costs, are offered in the entry-level equipment specs of vehicle models.

Aluminum wheels

Aluminum-sheet wheels

For the most part, the basic manufacturing process is identical to that of the sheet-steel wheel. In view of the lower strength, the wall thickness must be greater compared with the sheet-steel wheel. Despite engineers having full mastery of the technology, aluminum-sheet wheels have not gained acceptance because steel wheels as a whole are the more economical wheel variant and the design options are very limited.

Aluminum forged wheels

As the name suggests, a forged wheel is created by the hot forming of an aluminum round blank between two forming tools. The forming process takes place in two stages – the forging of the wheel front and rear sides between two defined tools and the flow-forming of the rim contour.

The starting material for aluminum forged wheels takes the form of 6 m long continuously cast bars of AlSi1Mg with a diameter of 200…300 mm, depending on the planned wheel size. After an ultrasonic test the cavity-free bar sections are sawn off to a predefined length. The saw support – a cylinder approx. 250 mm in diameter and 150 mm high – is fed to the automated forging line. This consists of a heating furnace and up to four consecutive forging presses with forces of pressure of 8,000…40,000 kN. Parts are handled between the presses by robots. The result of this first forming process is blank with the finished design of the wheel disk, a punched-out center hole and a ring-shaped material reservoir positioned around the circumference with the material scheduled for the rim.

In flow-forming operation involving three rollers the ring-shaped disk is split open (hence the term “split wheel”) and rolled out on a bell-shaped tool to make the rim.

Before being machined, the forged blank is subjected to heat treatment to improve the mechanical properties. The complete wheel contour is turned on two consecutive lathes (i.e. machined to finishing dimension). Then the bolt holes and the valve hole are drilled and milled on a machining center. The concluding polishing process gives the wheel its reflecting luster.

This high-precision machining ensures that every wheel runs absolutely true. There is no radial or lateral run-out.

If small batch sizes do not justify the manufacture of a forging tool, a special form of forged-wheel production is used. This involves the manufacture of a forged blank in the shape of a thick-walled cylinder whose base is a disk representing the rotation contour of the design and of the inner side of the wheel. With high machining overhead, the wheel design is usually 100% milled and the rim base first flow-formed and then turned.

Aluminum cast wheels

The most common method used is low-pressure mold casting. In the casting machine the aluminum molten mass tempered under controlled conditions is located in a crucible underneath the mold. The mold and crucible are connected by means of a feed tube. Once the mold is closed, the pressure in the crucible is increased to approx. 1 bar, causing the molten mass in the feed tube to rise and fill the mold.

Fusion heat is drawn off during the solidification process through precisely defined cooling channels in the mold. The specific cooling and heat removal during the solidification process and the casting parameters in their entirety (pressure, temperature and time) are decisive factors for the casting quality.

The production process is completely automated from the casting stage. The cast blanks removed by robot arms pass via linked conveyors through the following machining stages until they are automatically stacked and packed as wheels in the dispatch area:
– casting,
– removal of riser bore,
– X-ray test,
– heat treatment,
– machining,
– brushing and deburring,
– leak test,
– painting,
– dispatch.

In the X-ray test all the blanks are tested for casting defects according to specifications stipulated by the customer. The defective parts with casting defects that are not visible from the outside, e.g. porosity or shrink holes (cavities, material breaks) and inclusions or contaminants, are separated out and returned to the melting furnace.

The automated run is interrupted only before the painting stage so as to form production batches which are painted the same color.

Flow-forming process
Where necessary, it is possible to use a modified, slightly more sophisticated process to manufacture weight-optimized cast wheels, so-called “flow-forming wheels”. This produces a weight saving of around 0.9 kg for a 19″ wheel. For the flow-forming process, the cast blank is made in a similar way to that used in forging. A ring is provided around the design surface instead of the formed rim contour as a material deposit for the rim. This ring is processed in a specially designed machining cell as follows:
– preturning for rolling,
– heating,
– rolling out of the rim (flow-forming).

The blank formed in this way is returned to the “normal” manufacturing process prior to heat treatment.

Another way of manufacturing weight-optimized wheels is to insert lost cores in zones of the wheel subject to less stress. Thus, aluminum is replaced by cavities, for example in the spoke, but also much more rarely in the hump. Accordingly there are hollow-spoke wheels and hollow-hump wheels.

Squeeze-cast process
The squeeze cast process attempts to exploit the advantages of diecasting for aluminum wheels. An exactly portioned amount of molten aluminum is pressed under high pressure into a diecasting mold under exactly defined casting parameters. The great advantage lies in the high solidification speed with positive effects on the material structure. Other advantages are the significantly lower machining overhead – and thus less material usage – and the relatively high output and longer mold service life. This casting process is used in individual cases, but it requires special, relatively complex casting machines and molds. This process has yet to gain acceptance.

Wheel design variations

Single- or multiple-part design variation

Sheet-steel and aluminum-sheet wheels consist of two parts. In this design wheel disk and rim are welded to each other. In the case of forged light-alloy wheels and cast wheels, the one-piece version dominates.

Multiple-part versions, even those which are made of different materials (e.g. magnesium wheel disk and aluminum rim), are available mainly for tuning applications and for sports vehicles. Multiple-part wheels trace their origin back to motor sport. Mechanics exploited the advantage of being able to replace the damaged parts. In tuning applications, for example, the possibility of standardized rim rings and disks is used to create a large number of different wheel dimensions. For the most part, however, multiple parts no longer have a technical background and are now only used for visual reasons. Multiple-part wheels are subdivided into two- and three-part wheels.

Wheel spider

The wheel spider on cast wheels refers to the area of the spokes, which is represented in a steel wheel as the wheel disk and is for the most part provided with openings. Ventilation holes, slits and openings in the wheel disk or the wheel spider serve on the one hand to reduce weight, and on the other hand to ventilate the brake system and to enhance the visual design of the wheel. Set against this is the present-day requirement also to optimize the effects of the wheel with regard to the entire aerodynamics of the vehicle. Depending on the dynamic behavior of the body, a positive effect can be achieved here by keeping the area of the openings small and fashioning the geometry of the spokes as flat as possible. This measure has a more negative impact on the weight of the wheel such that it is now more common to find plastic parts on an aluminum wheel which are intended to aerodynamically optimize the wheel.

Rim variants

Rims used for passenger cars, vans and light utility vehicles are almost always drop-center rims with H2 double humps (rarely with FH or FH2 flat humps), tapered bead seats, and J section rim flange. Less common on smaller vehicles is the lower flange shape B, which today is used primarily in compact spare wheels. The higher flange shapes, JK and K, are rare on modern vehicles, and then only on heavy vehicles.

Lightweight-construction technologies

Hollow-spoke technology with sand casting cores or ceramic cores remaining (lost) in the wheel also provides good possibilities to reduce weight, but it requires a suitable design and special manufacturing equipment. This process is also associated with higher costs.

More widely used today is the flow-forming process for cast wheels, in which the rim base is only partly precast and then rolled out by machine to the corresponding rim width. The compressed material provides for thinner wall thicknesses with reduced weight in the rim base.

"Structural wheels" are used, among other things, as spare wheels or as road wheels with plastic wheel covers. Unrestricted by design conditions, the aim here is to use the minimum quantity of material possible to guarantee operating and functional safety, as well as streamline production costs for these wheels.

Wheel mounting
The design of the wheel and the mounting elements must meet safety requirements in all vehicle operating conditions. The wheel forces resulting from motive force, brakes, wheel load and wheel location must be supported by the overall mounting system (wheel bolt, wheel hub, brake-disk chamber, wheel-bolt holes, possibly coatings of parts) without impairing fatigue limits or the function of the wheel and axle components. Careful coordination of the friction parameters and geometry at the wheel bolts or the wheel nuts and contact zone of the wheel (bolt head to wheel-bolt hole) is essential when specifying the tightening torques in engineering design and in practice.

The geometric configuration of the wheel mounts in pitch diameter, number and dimensioning of the mounting elements are subject to the needs and requirements of each vehicle manufacturer. The wheel on a passenger car is secured to the axle hub by three to five wheel bolts or wheel nuts inserted through the mounting holes. Off-road vehicles and light utility vehicles often have six wheel bolts or wheel nuts. Commercial vehicles as a rule have ten wheel nuts, but this number can sometimes be even higher (e.g. tractors and excavators). The design of the contact surface of the nuts varies, depending on the vehicle manufacturer (e.g. calotte, cone, flat head). The longitudinal bolt forces that are decisive for the durability of the bolted connection must be reached and adhered to, both when new and used, in all dynamic operating states.

The high degree of true-running is achieved by means of a central wheel mount at the wheel hub with a precise alignment shoulder.

At present, wheels mounted with a central nut and interlocking driving pins are used almost exclusively on racing cars.

Wheel trims
Wheel trims (wheel caps) are mainly used for visual reasons on steel wheels and are affixed to the wheels using elastic retaining-spring elements which are easily detachable. But today aluminum cast wheels also feature wheel trims, which are often intended to improve aerodynamics. The design of aluminum wheels is for the most part kept simple and the weight kept low. Bolted solutions are also used in rare cases. The material used most often for wheel caps is heat-resistant plastic, e.g. polyamide 6. However, in some cases, aluminum and stainless pressed steel are also used.

Special wheel/tire systems
TRX rim
More recent rim developments, which have produced in limited series, are the TR rim (in metric dimensions). They were developed by MICHELIN for use with matching TRX tires and provide more room for the brakes.

Rims made by DUNLOP with a Denloc groove also require special tires; at low tire pressure and also in the case of pressure loss, the system is supposed to prevent the tire from coming off the rim, enhancing safety and mobility.

The TD system (TRX-Denloc) brings together both wheel/tire systems. As opposed to common practice, the two above designs are have rim and tire matched to each other and are unable to combine rim and tire with other tire versions, or only to a very limited extent.

CTS and PAX systems
The CTS/CWS and PAX systems were able to dispense with the need for a spare wheel. The original idea behind using these two systems to save on the spare wheel failed to catch on in the market and today these are used primarily on armored vehicles (see Rim designs).

Compact spare wheels
For space-saving reasons a compact spare wheel (mini spare) is often used as the spare wheel. This can be stowed in combination with a collapsible spare tire in an even smaller space (e.g. in roadsters, convertibles). All compact spare wheel systems are equipped with a specially designed tire where the driving properties are only suitable for emergency operation and limited top speed (approx. 80 km/h). Its benefits are the subject of debate, but it is becoming increasingly popular compared with a full-size spare wheel.

In many countries it is no longer required by law to carry a spare wheel. Instead, vehicles are equipped with a puncture kit (Tire-Fit) to repair any tire damage. The puncture kit consists of an electrically driven compressor and a sealant, which is pumped into the tire through the valve.

Stress and testing of wheels

The extremely varied and complex stress conditions in the wheel as a component in conjunction with a wide variety of operating conditions in the vehicle require specific endurance tests in order to be able to confirm the durability of a wheel with acceptable overhead. In general, the dynamic tests are run in test laboratories on standardized testing units, whereby a simulation of road operation that is close to reality is simulated and a good correlation of the test results to pure road operation is achieved. Country-specific legal requirements make special tests necessary, e.g. in the case of light-alloy wheels the simulation of a side curb impact (impact test).

Testing of sheet-steel wheels
The critical zones on a sheet-steel wheel are in particular the zones around the weld seams, mounting boreholes, dish (curvature of the wheel disk, see Figure 1), and ventilation holes. The operating conditions in each case, for example straight-ahead driving and cornering, generate different damage patterns in the area of the welding seam on the drop center well and in the wheel disk. Tests of the material quality and of the welded joints as well as surface tests are backed up by the endurance tests and indicate the need to optimize wheel manufacturing.

Testing of light-alloy wheels
Light-alloy wheels run through a similar testing process whereby, unlike sheet-steel wheels, the more varied influencing parameters of material, manufacturing, and design mean that the test requirements are at a significantly higher level. This ensures that fluctuations in material and manufacturing are unable to lead to premature failure. The maximum stresses occur mainly on the back of the wheel in the supporting structure of the ribs and spokes, in rare cases on the visible side.

The material quality and processing have a great influence on the durability of aluminum cast wheels. Inadequate physical values such as elasticity (during expansion) and tensile strength can be caused by poor heat application during casting or during heat treatment. This leads to porosity and shrink holes and deficient structural formation. The burrs that occur in high-stress zones during machine-cutting represent preliminary damage similar to notches and are often the starting point for incipient cracks. Careful machine deburring of these zones or specific constructive countermeasures, e.g. generously molded radii, are essential.

Testing of wheel with tire
Concentricity and lateral running
To assess the concentricity (true running) quality of a wheel on a vehicle, it is necessary to assess the wheel with the tire fitted, i.e. as a wheel with tire. During the manufacture of a wheel for concentricity the hub centering is in proportion with the two areas for the inner and outer tire seats. Likewise the contact face on the wheel hub and the inner areas of the rim flanges are responsible for the lateral running of the wheel. As a result of production these areas are endowed with tolerances (0.3 mm is usually given for concentricity and lateral running for passenger-car wheels), with which the tolerances of the tire now overlap. This can positively or negatively influence the concentricity of the wheel with tire. “Matching” is used to facilitate optimum concentricity of a wheel with tire. In this process the wheel and the tire are positioned during fitting in relation to each other in such a way that the “concentricity high point” of the wheel matches up with the “low point” of the tire.

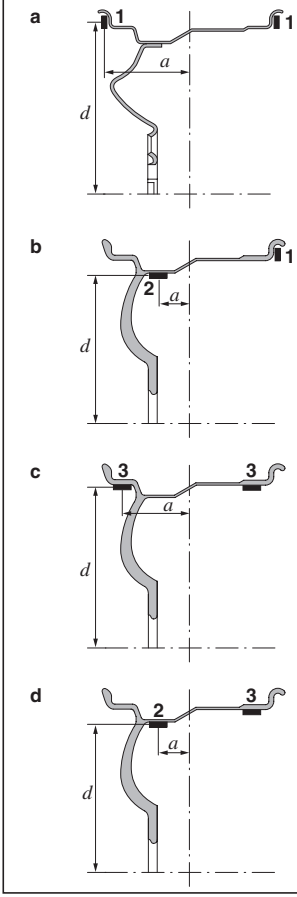
On the wheel the high point is determined from the concentricity measurements of the two tire-seat areas. For each area an individual high point is obtained with different angular positions on the circumference of the wheel. These two values produce through vector addition a common value with a resulting angular position. This position is marked on the wheel with a colored dot or an adhesive dot.

On the tire the low point corresponds to the position where it reaches the lowest force variation while rolling. It is also marked with a colored dot. From a technical viewpoint the tire can also be compared with a spring that exhibits a radial stiffness. Based on production the tire can never be manufactured to such precision that it exhibits a uniform stiffness over its entire circumference. Wheels with tires with poor concentricity make themselves felt on the vehicle not only through a radial movement of the body (i.e. in the z direction). In the direction of travel a minimal variable force from acceleration and braking is also experienced with each wheel rotation.

Good wheel centering is extremely important for commercial vehicles that travel at higher speeds, but also when the wheels in question are large and heavy. On commercial vehicles that travel at higher speeds in particular, the lowest possible radial and lateral run-out on both rim bead seats and flanges is essential to ensuring smooth running. This increases safety and fuel economy.

Imbalance
Just as important as concentricity and lateral running to a smooth-rolling wheel with tire is compensation of the differently distributed masses on the wheel and tire. To this end it is necessary to minimize the influences of the masses on the rotating

wheel with balance weights by balancing. Normally passenger-car wheels are dynamically balanced due to the rim width, i.e. measurements are taken on two planes (inner and outer tire seats) and the required compensation mass is determined. This is then applied with balance weights at the point indicated by the balancing machine. Adhesive, clip-on or drive-on balance weights are used for this purpose (Figure 8). The ideal position for the balance weights on the wheel for dynamic balancing is the maximum distance to the rim center at as large a diameter as possible.



An imbalance, referred to as “residual imbalance”, of 5 g per balance plane depending on the vehicle type and suspension is not discernible in the majority of vehicles. For each balance plane a balance weight should be attached at one position only. If a relatively high balance mass (over 80 g) is required in a balance plane, it is recommended to turn the tire on the wheel and repeat the balancing process. The lower the balance-weight mass on the wheel, the lower the residual-imbalance potential also.

Narrow wheels for two-wheeled vehicles are balanced on one plane only (with a balance weight in the rim center). This method is called static balancing.

Wheels for commercial vehicles and compact spare wheels with a restricted top speed are not balanced.

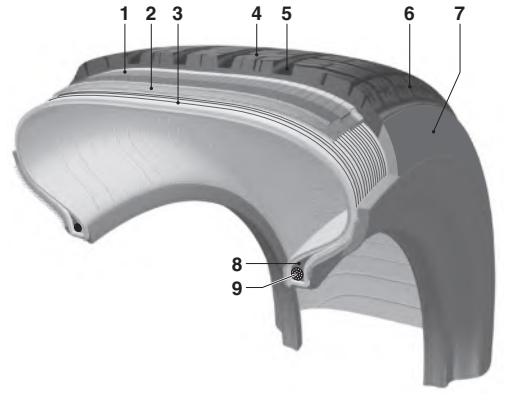
Tires

Function and requirements

The tire is the only component of a vehicle that comes into contact with the road. It thus assumes a key driving-dynamics position. Downstream driving-dynamics control systems such as the Antilock Braking System, the Traction Control System and the Electronic Stability Program are only ever as effective as the tire allows within the framework of its instantaneous power-transmission potential. When it comes to the tire, ultimately the crucial factor is the active safety of the vehicle.



Tires perform a variety of functions in everyday driving applications: They cushion, damp, steer, brake, accelerate, and simultaneously transmit forces in all three dimensions – at high and low temperatures, in the wet, on dry roads, on snow, mud and ice, on asphalt, concrete and pebble stones. They are meant to roll straight, permit precise steering, absorb road irregularities, bring the vehicle safely to a stop, and be quiet and comfortable. They are also meant to last, retain their characteristics with increasing age and decreasing tread depth, and produce as little rolling resistance as possible. Furthermore, an inflated tire performs supporting, vibration-damping and comfort-giving functions, and is therefore an active and fully integrated suspension element. The requirements resulting from these functions to be met by tires can be summarized as follows:

– high-speed resistance,
– durability,
– abrasion resistance (mileage),
– low rolling resistance,
– good properties in the wet (aquaplaning, wet braking, wet handling),
– good tire comfort, quiet rolling noise,
– good running characteristics in the limit range,
– resistance to aging,
– precise steering properties (handling),
– short braking distances,
– simple installation and assembly,
– true running and uniformity,
– economy,
– resistance to damage,
– resistance to chemicals.

The fundamental and visible material of a tire is rubber, an elastic to viscous material to which a tire owes the majority of its typical properties that are so important to the vehicle.

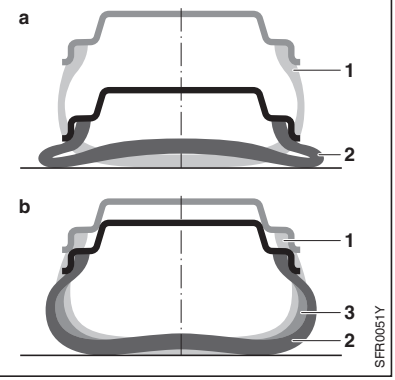
Tire construction

Design and components
Tires are a complex construction of different, mutually influencing raw materials, components and chemicals. A standard passenger-car tire consists of up to 25 different components and up to 12 different rubber compounds.

Today, only the tubeless, radial-ply steel-belted tire constructed in two stages satisfies the stringent demands imposed by the automotive industry and consumers.

Ingredients
The ingredients of a radial tire are:
– natural and synthetic rubber (approx. 40 %),
– fillers such as e.g. soot, silica, silane, carbon, and chalk (approx. 30 %),
– strength members such as e.g. steel, aramide, polyester, rayon, and nylon (approx. 15 %),
– softeners, e.g. oils and resins (approx. 6 %),
– vulcanization accelerators, e.g. sulfur, zinc oxide, stearin (approx. 6 %),
– anti-aging agents, e.g. UV and ozone blockers (approx. 2 %).

Since 2010 the toxicologically serious softeners and paraffined oils have been subject to particularly stringent limits values in the EU. For this reason manufacturers are increasingly using uncritical natural oils (e.g. sunflower oil).



Casing
The casing is stretched over a thin inner liner of airtight butyl rubber (Figure 1). Around 1,400 rubberized cords of rayon, nylon or polyester are combined in one or more casing plies to form the decisive strength member, the elastic “shell” of the tire. The cords run radially, i.e. at right angles to the tire plane from bead to bead – hence the designation radial tire. Cross-ply tires, in which casing cords are placed diagonally to the tire plane, in practical terms no longer play a role in modern-day applications.

Bead
The bead performs the important function of ensuring that the tire is securely and tightly seated on the rim. Driving and braking torques are transmitted via this crucial connecting point from the rim to the tire tread and thus to the road surface. Seated in the bead core is a cable of numerous steel wires, each of which can bear a load of up to 1,800 kg [1].

Sidewall
A thin and highly flexible rubber flank forms the sidewall and thus the flexible zone of the tire. The sidewall (tire flank) is however also the area of the tire that is most sensitive to damage.

Trouble-proof run-flat tires on the other hand have much thicker sidewalls than conventional designs (Figure 2). In the event of a blow-out the rim does not slump onto the tire casing and thus cannot damage it. In addition, fully deflated run-flat tires ensure a certain degree of steerability and directional stability for a further 80 km at speeds of up to 80 km/h.

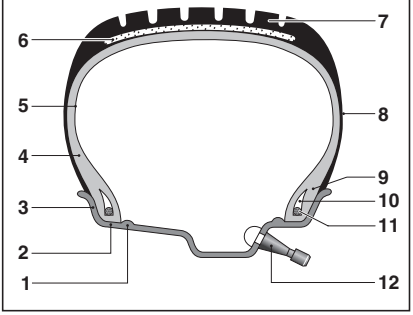


Figure 2: Comparison of run-flat tire with standard tire
a) Standard tire,
b) Run-flat tire.

Cambering to blank
The finished, cylindrical combination of casing, inner liner, bead and sidewalls is pushed over a drum, the outside diameter of which corresponds to the inside diameter of this preliminary tire stage and to that of the subsequent tire. On this drum the cylindrical combination is cambered into the "real" tire shape (inflated and fixed) and then built further.

Because the casing cords run radially, i.e. transversely, to the rolling direction, the casing on its own would not be able sufficiently to transmit lateral forces when cornering and peripheral forces when accelerating and braking. It therefore needs support. This job is performed by the steel-belt assembly placed on top. Two or more plies of twisted and brass- and rubber-coated steel wires (steel cord) run not in the peripheral direction, but alternately at acute angles of between 16° and 30° to each other. High-speed-resistant tires are additionally stabilized by a nylon or aramide binding which suppresses a peripheral increase caused by centrifugal force. The tread surrounds the casing.

From blank to finished tire
The tires in this penultimate stage is called a blank and is now placed in a heating press. Inside this press is an exchangeable recess – an exactly shaped negative mold of the later finished tire. In this heating mold the tire blank is "baked" under steam pressure (approx. 15 bar) and heat (to 180 °C) for up to 30 minutes and acquires its final, typical appearance. The tread rubber creeps on heating exactly and without cavities into the tire negative mold of the heating press, thus creating the tread pattern and the sidewall markings. As a result of sulfur added in a previous process the hitherto plastic rubber vulcanizes into elastic rubber and acquires its desired operating characteristics.

The tread pattern ensures low rolling resistance, water expulsion, good grip, and high mileage.

A finished tire of the standard size for the medium-size car class 205/55 R 16 91 H weighs around 8.5 kg. A commercial-vehicle tire of the standard size 385/65 R22.5 weighs around 75 kg.

Tire with wheel
Together with the rim, the tire valve and the balance weights the tire forms the car's operational wheel (Figure 3). The rubber-elastic tire is inflated with compressed air, at which point it is able to absorb and transmit forces. Tire inflation pressure is usually 2…3.5 bar for a passenger car and 5…9 bar for a commercial vehicle. It is not the tire itself but rather the inflation air that supports the weight of the vehicle.

Differences between commercial-vehicle and passenger-car tires
Commercial-vehicle tires and generally similar in design to passenger-car tires, but are bigger, wider and heavier. Tire inflation pressure at 5…9 bar is much higher than approx. 2…3.5 bar for passenger-car tires.

The primary development objective is, as with passenger-car tires, to have all the parameters in proper proportion and above all the mileage. Commercial-vehicle tires therefore have comparatively hard, low-wear treads which are also regroovable and retreadable. Retreading of a bald tire identified as such is possible if the tire casing is undamaged.

Although the rolling resistance of a truck tire is lower than that of a passenger-car tire, its influence on the truck fuel consumption is greater due to the higher vehicle weight and the number of axles. In addition to high load capacity (up to 3…4 t per tire), other important tire characteristics include good straight-running stability, good cornering stability and traction. The trend in truck tires is towards increasingly smaller tire dimensions. This increases the useful load height and thus the transport volume.

Tire inflation pressure

Motor-vehicle manufacturers specify two values for tire inflation pressure for every vehicle – the part-load air pressure for a partly laden vehicle and the full-load air pressure for a fully laden vehicle or high driving speeds. The values are based first and foremost on the vehicle weight, on its top speed, on the tire design, and on the tire size. As a rule, the front and rear axles are subject to different desired pressures. The tire inflation pressure may only be measured and adjusted on a tire that is cold, i.e. that has not been heated up by vehicle operation.

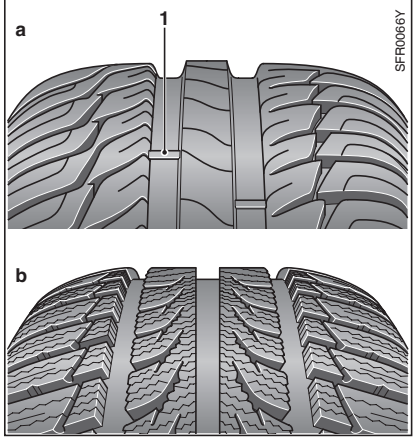
A correct tire inflation pressure is important for
– optimum tire contact patch and optimum ground contact,
– shortest possible braking distance,
– optimum wet grip,
– balanced cornering stability,
– low rolling noises,
– low rolling resistance,
– low flexing work and heat production.

An excessively low tire inflation pressure will result in each case in the opposite end of the above parameters and in
– reduced service life,
– increased and sometimes uneven abrasion,
– progressive structural damage,
– danger of sudden tire blow-out,
– increased risk of accident,
– increased fuel consumption.

An excessively high tire inflation pressure (much less critical compared with low pressure)
– results in impaired tire comfort,
– reduces the ground contact patch (tire “stands”) and thus diminishes cornering-stability and braking-force potential,
– causes increased central abrasion,
– but only reduces the rolling resistance slightly.

Tire tread

A tire is provided over its entire circumference with geometrically shaped tread grooves, ribs and channels as well as additional notches forming gripping edges (sipes) (Figure 4).



The most important function of the integrated tread (not cut, but heated) is to adequately absorb and disperse water on the road surface (also snow and mud in the case of winter tires), since wet and even surface moisture alone have a negative effect on grip characteristics. The braking distance is therefore dependent not only on the effects of interlocking and adhesion produced by the two friction partners tread rubber and road surface (see Tire grip). The braking distance on wet roads increases as tire wear increases.

Minimum tread depth

Summer tires

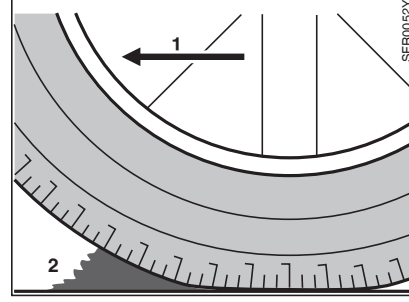
The minimum tread depth prescribed by law (EU Directive 89/459 of 1989 [2]) is established in most European countries at 1.6 mm (for passenger cars).

Figure 4: Tire tread
a) Typical tread of a summer tire,
b) Typical tread of a winter tire.
1 Wear marker.

Winter tires

The minimum tread depth for winter tires varies greatly from country to country. In Austria, for example, winter tires for passenger cars are required to have a minimum tread depth of 4.0 mm.

Wear-detection aid



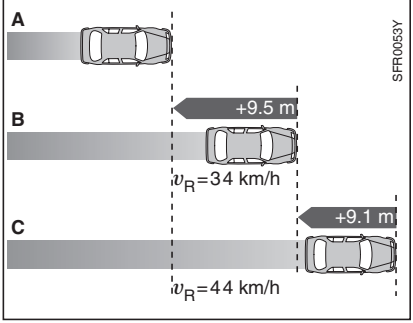
The main tread-groove base features several rubber bumps exactly 1.6 mm high spread across the entire tread for the purpose of checking the minimum tread depth prescribed by law of 1.6 mm. If such a wear marker (TWI, tread wear indicator) on the tire makes contact with the road surface, the tire may no longer be used in road traffic.

Truck tires bearing the wording "Regroovable" on their sidewalls may be regrooved by the regrooving depth approved by the tire manufacturer (depending on the tire version 2…4 mm), ideally when the remaining tread depth is still 2 to 4 mm. Essentially, passenger-car tires are not permitted to be regrooved.

Aquaplaning

At higher speeds or when there is an enclosed layer of water on the road the tread the tread is no longer able to absorb sufficient water in itself and disperse it to the sides and to the rear. A wedge of water forces its way between the tires and the road, the tires lose contact with the road, and the vehicle loses its controllability – aquaplaning occurs (Figure 5).

Figure 5: Aquaplaning
1 Driving direction,
2 Splash area.



The tire loses contact at precisely the stage when the pressure of the wedge-shaped splash water in front of the tire exceeds the pressure of the tire on the road. This pressure is squared as the driving speed increases. Because the critical pressure at which the tire aquaplanes is approximately equal to the internal tire pressure, passenger-car tires with an inflation pressure of approx. 2.3 bar aquaplane at a much lower speed than truck tires with 8 bar. Driving with a lower inflation pressure than prescribed decreases the already low speed from which aquaplaning occurs, once again significantly in passenger-car tires.

Tire contour, tread design and tread depth can defer the speed from which the risk of aquaplaning arises. Narrow tires, due to the higher pressure on the road (surface pressure, weight per contact patch), essentially aquaplane at higher speeds than wide tires, and they also heave to channel a much smaller volume of water. Drainage channels and rounded contact surfaces on wide tires reduce their risk of aquaplaning to an acceptable level. To compare: A tire with a nominal width of 220 mm must at 80 km/h and a rainwater height of 3 mm disperse roughly 15 liters per second so as not to aquaplane. This figure is 10 liters for a 140 mm “narrow” tire.

Figure 6: Braking distance from 80 km/h to a step on a wet road with new tires and with bald tires [3]

A Braking distance with 8 mm tread depth: 42.3 m.
B Braking distance with 3 mm tread depth: 51.8 m.
C Braking distance with 1.6 mm tread depth: 60.9 m.
v_R Residual speed.

Wet braking

Figure 6 shows the further point at which the tread depth is of crucial importance to road safety: The braking distance on a road wet with rain is roughly 50% longer with an almost bald tire (tread depth 1.6 mm) than with a new tire of identical size (tread depth 8 mm).

The residual speed v_R denotes the speed of the worse braking vehicle at the moment when the vehicle with better tires comes to a stop. It is calculated as

$$v_R = \sqrt{v_0^2 \cdot \left(1 - \frac{s_1}{s_2}\right)} \text{ in m/s,}$$

where
v_0 Driving speed at start of braking in m/s,
s_1 Braking distance with vehicle 1 (with better tires) in m,
s_2 Braking distance with vehicle 2 (with bald tires) in m.

The residual speed is a measure of the theoretical accident severity to be expected in the event of a collision.

These calculated differences however can in practice only be effected by highly experienced drivers with extremely fast reactions. Many car drivers are not accustomed to ABS full braking; the total braking distance is lengthened significantly. Potentially shorter-braking tires only get a look-in if the vehicle is fitted with a brake assistant.

Force transmission

The four tire contact patches (footprint) are the direct and sole interface between the road surface and the vehicle.

Slip angle and slip
Only the tires rolling under an angle to the wheel rolling plane (slip angle α, Figure 7) and in the process deforming and constantly more or less slipping (see slip) transmit simultaneously and within physical limits the forces requested by the driver through steering, braking and accelerating. Conversely: A tire that does not roll or slip at an angle does not transmit any forces.

The tire transmits ever higher forces as the slip angle and slip increase. This relationship however is not linear. The effect is reversed after a relevant maximum value is reached (Figure 8). For passenger-car tires this reversal point for the slip angle is roughly 4…7°, corresponding to a pronounced steering-wheel angle. The reversal point for slip is 10…15 % (on snow up to 30 %). Excessive slip is a consequence of excessive acceleration or excessively heavy braking. If the steering angle or brake pressure is increased further, the wheels lock if the vehicle is not fitted with an antilock braking system. The slip is then –100 %.

Longitudinal and lateral forces
If a force F_x in the peripheral direction and a side force F_y occur simultaneously (e.g. when braking while cornering), the resulting transmitted horizontal force

$$F_h = \sqrt{F_x^2 + F_y^2}$$

cannot exceed the value $\mu_h F_z$. This situation can be explained by reference to the Kamm (friction) circle (Figure 9). The radius of the Kamm circle is equal to the maximum horizontal force $\mu_h F_z$ that can be transmitted via the tire. The maximum side force F_y is therefore smaller is at the same time a force F_x occurs in the peripheral direction. With the forces F_x and F_y marked in Figure 9 the wheel is exactly at the limit of the maximum horizontal force that can be transmitted.

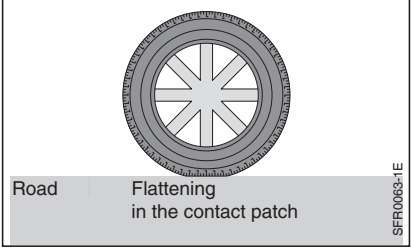
Tire grip

Generation of grip

Tires must transmit all the dynamic forces to only four roughly postcard-sized areas. The grip required for this purpose between the tire contact patches and the road surface is generated by several simultaneously occurring phenomena. These are essentially positive locking (also referred to in this context as the interlocking effect) and adhesion by molecular forces of attraction.

When a vehicle driving past at a constant speed is considered from the outside, as the tire rolls the continuously changing ground contact patch remains apparently fixed in relation to the vehicle (Figure 10) – while each individual rubber block of the tire tread runs into this forcibly flattening contact patch, deforms, and is "ejected" again at the other end. Relative movements and thus slip are generated in this contact patch: Each individual rubber block more or less slips during the dwell time in the contact patch.

Figure 10: Flattening in the contact patch between tire and road surface



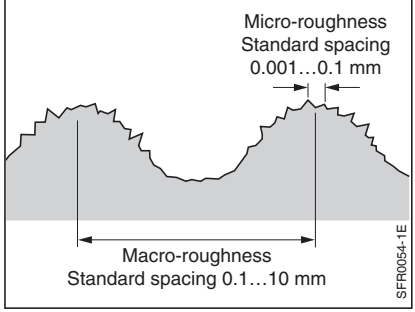


Figure 11: Micro- and macro-roughness of a dry road surface

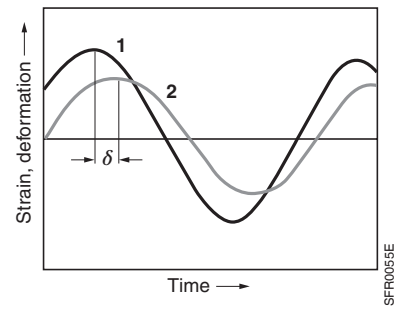
Viscoelasticity



Viscoelasticity describes the time-, temperature- and frequency-dependent elasticity and the viscosity of polymer and elastomer substances (e.g. of plastics, rubber). Internal damping, molecular interlocking and creeping processes prevent the two extreme states "fully elastic" (e.g. like an elastic spring) and "highly viscous" (like a solid body). Deformation and the force that causes it as well as the mechanical strain pass off at different times.

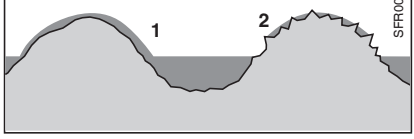
Interlocking effect

The interlocking effect is created by the direct and intensive contact of the tire with the road, depending on the micro- and macro-roughness of the road surface (Figure 11). In the passage of the contact patch the tread block under consideration comes up against a bump in the asphalt, is upset, and slips off again on the other side of the bump at accelerated speed. Only when it produces slip in the process can it build up in the tangential direction a counterforce contrary to the rolling direction which counteracts the sliding and thus permits the transmission of steering, drive or braking forces.

Figure 12: Load application and load removal of a viscoelastic substance

1 Strain, force per unit of area,
2 Deformation, elongation or upsetting relative to output variable.
δ Phase lag.

On account of its viscoelastic properties a rubber block does not revert immediately to its original shape after deformation; the strain follows on from the deformation that causes it (Figure 12). This effect typical of rubber of hysteresis results, on account of the cyclic deformation of the viscoelastic rubber, in a loss of energy in the form of non-utilizable heat and thus in a contribution to friction (hysteresis friction). The component of the friction force parallel to the road surface thus facilitates the transmission of drive or braking forces.



The principle of positive-locking grip also functions on damp and wet micro- and macro-rough road surfaces, but with limited effectiveness. Figure 13 shows that microfine asphalt points can penetrate the layer of moisture and thus the interlocking effect is maintained. However, an enclosed layer of water forms over the more rounded local bumps.

Essential to the interlocking effect is the presence of micro- and macroscopically small road irregularities. On a completely smooth surface (the coefficient of friction μ approaches zero) there would be no interlocking effect at all.

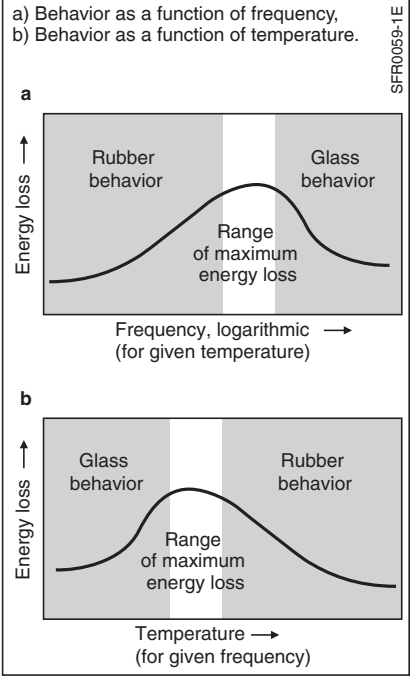
The interlocking effect and inner-molecular friction cause the tire to heat up. The resulting loss of energy is jointly responsible for the tire's rolling resistance, which makes up around 20…25 % of a vehicle's fuel consumption.

Figure 13: Micro- and macro-roughness on a damp or wet road surface

1 Macro-roughness channels and stores the water, but cannot penetrate the water layer.
2 Micro-roughness generates local pressure peaks and can thus penetrate the residual layer.

Adhesion

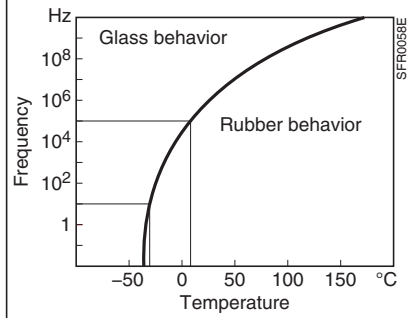
Molecular adhesion is created by the interaction and intensive contact between tire and dry road. The creation and subsequent breaking up of adhesive connections at the contact points result in a contribution to the coefficient of friction (adhesion friction). On a wet road molecular adhesion fails while the interlocking effect remains effective.



The frequency range of molecular adhesion, excited by the micro-rough road surface during drastic braking and extreme cornering, encompasses the spectrum of 10^6…10^9 Hz.

Load frequency and temperature

Two further important influencing factors on the quality of grip must be mentioned: If the tire when rolling is only excited with a low frequency (exposure frequency), the rubber behaves elastically (low energy loss, Figure 14a). In this low frequency range the rolling resistance is very low, the tire is relatively cold, and the grip is weaker. If, on the other hand, the frequency increases due to the excitations caused by micro- and macro-roughness, a viscoelastic behavior is manifested – the ideal range for tire grip (energy loss has its maximum). If the frequency continues to increase, viscosity (flowability) and energy loss decrease again, the is barely able to be deformed and hardens (glass behavior).



In parallel, rubber part exhibits pronounced heat-dependence behavior: In the glass-temperature range – when for example winter ambient temperatures cause the rubber compound to harden and become brittle (hence the analogy to glass) – the coefficient of friction of the tire rubber and with it the energy loss decrease markedly as a result of the rubber's molecular immobility (Figure 14b). Conversely, higher forces can be transmitted when the tire is moved in its optimum operating-temperature range.

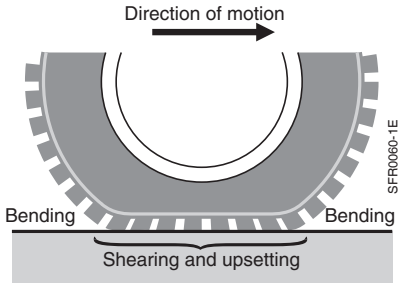
Figure 14: Energy loss in the tire as a function of frequency and temperature
a) Behavior as a function of frequency,
b) Behavior as a function of temperature.

For rubber, therefore, an inversely proportional dependence between temperature increase and exposure frequency can be ascertained. Thus the glass temperature of an elastomer rises from –20 °C at only 10 Hz to +10 °C at 10^5 Hz (Figure 15). Compound developers are able to design rubber compounds with a glass temperature of between –60 °C and 0 °C at a frequency of 10 Hz.

Figure 15: Rubber behavior as a function of frequency and temperature

Special case: Rubber friction
Coulomb's classic law of friction ($F_R = \mu m g$) does not apply to vulcanized tire rubber. Its coefficient of friction μ (also called friction value or friction factor) is not constant, but
– increases with decreasing surface pressure (force per contact patch, given in N/mm^2),
– decreases with increasing surface pressure,
– depends on the sliding velocity,
– depends on the temperature and exposure frequency.

The phenomenon of increased grip with decreasing surface pressure explains the importance of very wide (and thus low-surface-pressure) tires in motor sport.



Rolling resistance

Definition of terminology
Tractive resistances inhibit the forward movement of the vehicle and must be overcome by motive means. In addition to the aerodynamic drag, the frictional resistances in moving engine, transmission and chassis/suspension components, the climbing resistance, and inertia forces, the rolling resistance of tires is classed as one of the main tractive resistances. It contributes to approx. 20 % of the fuel consumption on expressways/interstates, approx. 25 % on orbital roads and approx. 30 % on urban and ordinary roads [4].

Rolling-resistance decreases thus result directly in consumption and emission reductions. Rolling resistance (RR) corresponds to the energy loss per unit of distance and is given like every force in N (newtons). The dimensionless rolling-resistance coefficient c_{RR} denotes the ratio of rolling-resistance force to vehicle weight.

Example: Assuming a rolling-resistance force F_{RR} = 120 N and a vehicle weight G = 10,000 N ($G = mg$; vehicle mass m in kg, gravitational acceleration $g \approx 9.81$ m/s^2) c_{RR} amounts to 0.012 = 1,2 %. Standard values for c_{RR} for passenger-car tires on asphalt amount to 0.006 to 0.012, the (lower) value for truck tires to 0.004 to 0.008.

Figure 16: Shearing, upsetting and flexion in the contact lead-in

The "unit" kg/t (kilogram per ton) is occasionally used. In the example above the result 0.012 is 12 kg/t. This means in the case of a wheel load of 1 t = 1,000 kg that the rolling-resistance force F_{RR} assumes a value of 120 N.

Rolling-resistance-optimized tires have additional designations such as "Eco", "Green" or "Energy". Tire designers could indeed immediately and quite significantly reduce the rolling resistance by choosing rubber grades with low hysteresis and thus a low energy loss, but, as already explained, this would reduce the grip values to unacceptable levels. In other words, lower fuel consumption comes at the expense of less grip.

Generation of rolling resistance
With each wheel rotation the tire is deformed during the forcible flattening in the contact patch by flexion, upsetting and shearing of the rubber blocks and of the proportional tire casing (Figure 16). The fabric plies of the tire rub against each other (flexion), during which the tire performs flexing work. This produces a viscoelastically caused energy loss in the form of non-utilizable heat. This heat loss makes up 90 % of the rolling resistance.

Narrow tires and higher tire inflation pressure do increase the rolling resistance because contact patch and flexing work are reduced. However, designers are subject to very tight limits in terms of their scope of action in that the catalog of requirements with regard to handling performance, grip level and comfort are in direct conflict. Nevertheless, the technical specifications of the tire industry for future tire generations already feature tire dimensions such as 115/65 R 15 for subcompact-size cars and 205/50 R 21 for medium-size cars. Further drastic rolling-resistance reductions are not achievable with the requirements still standard today with regard to vehicle size, weight, maximum speed, sportiness, and comfort.

Even increasing the tire inflation pressure by 1 bar above the recommended value will only deliver a rolling-resistance reduction of 15 %. In a vehicle with an assumed fuel consumption of 10 l/100 km this would only produce a saving of 1.6 %. But because drivers still neglect to check tire pressure, the rolling-resistance reductions achieved in the most recent development cycles are not always implemented in real driving conditions. In addition, there is a direct conflict of aims between rolling-resistance optimization and the wet grip essential to road safety.

Conflict of aims between rolling resistance and grip

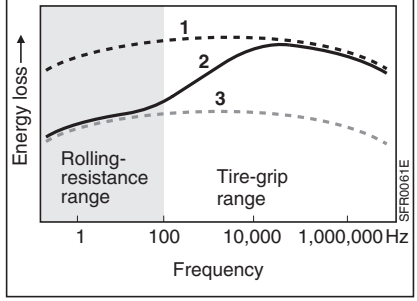
Frequency ranges

The deformations of the tread and rubber blocks caused by micro- and macro-roughness in the contact area between road surface and tire surface which generate the grip potential due to viscoelasticity occur in the very high frequency range of $10^3 \ldots 10^{10}$ Hz. The energy loss caused by hysteresis is high here, resulting in the creation of high grip values.

However, the frequency spectrum which is important to rolling resistance is much lower at 1…100 Hz – precisely the range in which the inner tire structure is excited with each wheel rotation. At a driving speed of 100 km/h a passenger-car tire is deformed roughly 15 times per second, equating to a load frequency of 15 Hz. Tire designers nonetheless refer here to low-frequency excitation of the tire structure, particularly the casing.

Optimization incompatibility

These greatly differing frequency ranges explain the basic optimization incompatibility of simultaneously high values for grip and low rolling resistance. In conventional tires using industrial soot as the primary filler (up until the mid-1990s) a rubber compound with high hysteresis in the high-frequency grip range automatically results in a high energy loss in the tire components subjected to low-frequency load and thus in high rolling resistance.

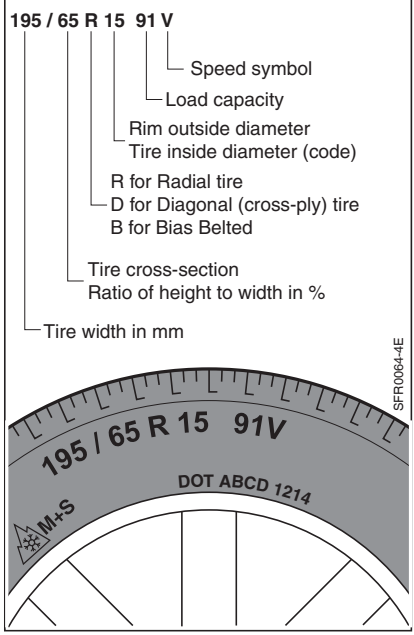


Silica to resolve the conflict of aims

The solution in the late 1990s involved the introduction of silica (trade name for refined silicate) as a gray-powdered filler, which increasingly replaced the standard industry soot used up that point. Together with auxiliary binding materials, or silanes, the conflict of interests between rolling resistance, grip and abrasion resistance can be elevated to a high level of compromise.

Silica-based rubber compounds exhibit low energy losses in the low-frequency range relevant to rolling resistance, but high energy losses in the high-frequency rubber-grip range (Figure 17). The curve for energy absorption has this rise steeply and thus advance in frequencies of $10^2 \ldots 10^4$ Hz. This results in tires which have low rolling resistance but nevertheless very good grip.

Figure 17: Frequency dependence of energy loss



1 Rubber compound with distinct hysteresis (high tire-grip values),
2 Latest-generation rubber compound (combines low rolling resistance, good grip and high abrasion resistance),
3 Rubber compound with weak hysteresis (low rolling resistance, poor grip).

Rolling resistance and air pressure
Reduced tire pressure means increased flexing work and thus higher rolling resistance and impaired steering precision and braking stability.

Safety checks carried out in 2009 by the tire industry (Goodyear, Dunlop, Fulda) on 52,400 vehicles in 15 EU countries established that 81 % of all car drivers drive with excessively low tire pressure. Of these, 26.5 % were driving with clearly (down to 0.3 bar) and 7.5 % with significantly reduced pressure (0.75 bar and higher). The upshot of excessively low tire pressure is that fuel is wasted.

Figure 18: Tire designation (example)

Tire designation

Definition of terminology
According to EU Directives ECE 30 (for passenger cars, [5]), ECE 54 (for trucks, [6]) and ECE 75 (for motorcycles, [7]) tires must be provided with internationally agreed, standardized tire designations. This applies in particular to the tire sidewall (Figure 18). Tires tested in accordance with ECE (mandatory since October 1998) carry a burned-in circle with a capital “E” or a lower-case “e” and the code of the approving authority, e.g. E4, and followed by a release number (homologation number, see Figure 20).

The lettering, codes and symbols on the sidewall indicate, as well as the tire manufacturer and the type designation, the origin, the production date, the dimension, the load capacity, the maximum permissible speed, the tire design, and the ratio of tire width to tire height (tire cross-section).

Reading the information is made more difficult by the fact that units of measurement of the metric system standard in Central Europe (mm, bar) and of the British imperial system (1 inch = 25.4 mm) are jointly used.

The service description must feature near the size specification. This consists of the load index (LI, Table 1) and the speed symbol (SSY; also used is SI, speed index, Table 2) and provides information about the maximum load capacity of the tire in question for the top speed corresponding to the speed symbol. This regulation is binding in all EU member states and in Switzerland.

On tires with directional treads (often on winter and summer tires with V-shaped treads) an arrow on the sidewall indicates the prescribed rolling direction. If the tires are already mounted on the rim, they can only be mounted on one side of the vehicle and may not for example be exchanged cross-wise (diagonally) together with the rim.

Example: A 205/55 R 16 91 H size tire has a nominal width of 205 mm, the height of the sidewall is 55 % of the nominal width, which in this case in roughly 112 mm. The diameter of the matching rim to be mounted is 16 inches, i.e.

406 mm. The load capacity corresponds with a load index LI = 91 to the table value 615 kg – the vehicle axle load therefore according to the certificate of registration must not exceed 2 x 615 kg, i.e. 1,230 kg. With the speed index SI = H the vehicle may be driven with this tire at a speed not exceeding 210 km/h, even if the vehicle is designed to reach an higher final speed. Load-capacity reductions must be taken into account from speed index V and upwards.

Production date

There is usually a pressed-in four-digit number in an oval field on at least one of the two sidewalls next to the acronym DOT (US Department of Transportation) and a sequence of letters (code for manufacturing plant). This number denotes the production date. The first two digits indicate the calendar week, the last two digits the final digits of the production year (Figure 18).

Table 2: Speed index SI (speed symbol)

A1	up to 5 km/h	L	up to 120 km/h
A2	up to 10 km/h	M	up to 130 km/h
A3	up to 15 km/h	N	up to 140 km/h
A4	up to 20 km/h	P	up to 150 km/h
A5	up to 25 km/h	Q	up to 160 km/h
A6	up to 30 km/h	R	up to 170 km/h
A7	up to 35 km/h	S	up to 180 km/h
A8	up to 40 km/h	T	up to 190 km/h
B	up to 50 km/h	U	up to 200 km/h
C	up to 60 km/h	H	up to 210 km/h
D	up to 65 km/h	V	up to 240 km/h
F	up to 80 km/h	W	up to 270 km/h
G	up to 90 km/h	ZR	over 240 km/h
J	up to 100 km/h	Y	up to 300 km/h
K	up to 110 km/h	(Y)	over 300 km/h

Table 1: Load index LI (values up to 3,350 kg, table open in upward direction)

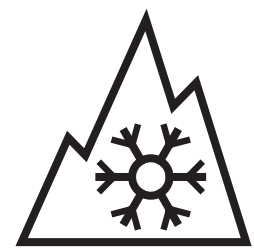
20	80	45	165	70	335	95	690	120	1,450	145	2,900
21	82.5	46	170	71	345	96	710	121	1,500	146	3,000
22	85	47	175	72	355	97	730	122	1,550	147	3,075
23	87.5	48	180	73	365	98	750	123	1,600	148	3,150
24	90	49	185	74	375	99	775	124	1,650	149	3,250
25	92.5	50	190	75	387	100	800	125	1,700	150	3,350

Example: 1214 means the 12th week of the year 2014. Prior to the year 2000 the designation of the production date had only three digits.

Special case:
Winter-tire designation
M+S tires
Winter tires must carry the M+S symbol (Mud and Snow) (see Figure 18). EU Regulation No. 661/2009 [8] denotes as an M+S tire a tire whose tread pattern, tread compound or construction is designed first and foremost "to achieve compared with a summer tire better values for winter handling performance and traction on snow" – an extremely woolly definition.

To compare: The previously applicable EU Regulation from 1992 [9] stated that "M+S tires" are such tires "on which the pattern of the tread and the structure are designed in such a way that they guarantee above all in mud and fresh or melting snow better handling performance than normal tires. The pattern of the tread of M+S tires is generally characterized by larger tread grooves and lugs which are separated from each other by larger spaces than is the case on normal tires".

"M+S" is to date not a protected or precisely defined designation and for this reason may also be used on tires not suitable for winter driving conditions (i.e. also on summer tires). The M+S symbol no longer has any significance with regard to suitability for winter driving conditions.



Snow-flake symbol
A revision of the M+S designation was called for in response to the widespread traffic chaos in the USA in 1995. A winter tire should satisfy certain criteria with regard to its suitability for winter driving conditions and verify this by way of appropriate tests. This gave rise to the designation 3PMSF (Three Peak Mountain Snow Flake), which today is firmly established in North American legislation.

This designation has also be used voluntarily for a few years in Europe. This is intended to verify to the consumer suitability for winter driving conditions substantiated by tests. The test criteria are defined by the European Union in UN-ECE R 117 [11].

Amendment of StVZO §36 section 4 [12]
With the 52nd Regulation to amend road-traffic legislation of 18 May 2017 the definition of tires for winter weather conditions was adapted and consequently a new winter-tire regulation came into force. By force of this regulation the snow-flake symbol for winter tires is already mandatory for the winter season 2017/2018 in Germany and consequently replaces the M+S marking. In a transition phase lasting until 30 September 2024 tires which only have an M+S marking which continue to be classed as winter tires provided there date of manufacture is before 31 December 2017. M+S tires which are manufactured from 2018 onwards and only have an M+S marking will no longer be classed as winter tires.

For truck and bus tires on the steering axle the introduction of this regulation will be deferred until no later than 1 July 2020. This time will be used to check as part of a study the necessity of the new winter-tire regulation for the steering axle of these vehicle categories. The deferment of the winter-tire regulation does not apply to the permanently driven axles of these vehicles.

Figure 19: Snow-flake symbol (3PMSF) in acc. with UN-ECE R117

Sound identification
Tires featuring this marking comply with Directive ECE 2001/43 [10], which lays down the maximum values for rolling noise. This marking has been mandatory since 1 October 2009, is featured next to the UN/ECE approval mark, and can be recognized by the code letter “s” after the homologation number.

With the introduction of the tire label on 1 November 2012 this designation for new tire types was extended by a capital “S” and by the letters “W” for wet grip and “R” for rolling resistance (Figure 20). Additional code numbers (1 and 2) after the letters S and R denote the limit values which must be adhered to for the prescribed time phases (periods) (regulations, see UN/ECE Regulation No. 117 [11]).

Figure 20: E designation
Example of a homologation number acc. to ECE R 117 for complying with rolling noise.

EU tire label

Definition of terminology
Since November 2012 new tires sold in the EU which were produced from July 2012 onwards must be provided with a standardized tire label (7.5 cm × 11 cm) (Figure 21). This label is meant to provide the buyer with quick and unmistakable information on the three tire properties of rolling resistance, wet grip (restricted to wet braking distance) and pass-by noise (not passenger compartment), thereby helping them to make a more informed decision to purchase. The winter properties of winter tires are currently not recorded by the EU tire label.

The tire label records tires in the categories C1 (passenger cars), C2 (light utility vehicles) and C3 (heavy commercial vehicles) as set out in Table 3. Excluded from the regulation are retreaded tires,

Figure 21: EU label

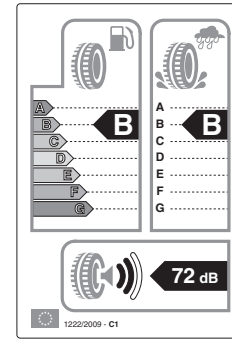


Table 3: Energy-efficiency classes of the different tire categories

Class C1 tires (passenger cars)		Class C2 tires (light utility vehicles)		Class C3 tires (heavy commercial vehicles)	
c_{RR} in kg/t	Energy-efficiency class	c_{RR} in kg/t	Energy-efficiency class	c_{RR} in kg/t	Energy-efficiency class
$c_{RR} \le 6.5$	A	$c_{RR} \le 5.5$	A	$c_{RR} \le 4.0$	A
$6.6 \le c_{RR} \le 7.7$	B	$5.6 \le c_{RR} \le 6.7$	B	$4.1 \le c_{RR} \le 5.0$	B
$7.8 \le c_{RR} \le 9.0$	C	$6.8 \le c_{RR} \le 8.0$	C	$5.1 \le c_{RR} \le 6.0$	C
not assigned	D	not assigned	D	$6.1 \le c_{RR} \le 7.0$	D
$9.1 \le c_{RR} \le 10.5$	E	$8.1 \le c_{RR} \le 9.2$	E	$7.1 \le c_{RR} \le 8.0$	E
$10.6 \le c_{RR} \le 12.0$	F	$9.3 \le c_{RR} \le 10.5$	F	$c_{RR} \ge 8.1$	F
$c_{RR} \ge 12.1$	G	$c_{RR} \ge 10.6$	G		
Example: c_{RR} = 10.5 kg/t (label class E) corresponds to c_{RR} = 0.0105 or F_{RR} = 105 N.					

professional off-road tires, racing tires, spikes, compact spare-wheel tires, vintage-car and modern classic-car tires (for vehicles first registered before 1 October 1990), tires for top speeds below 80 km/h, tires with inside diameters of less than 254 mm or more than 635 mm, and motorcycle tires.

Naturally, the tire label cannot show all the tire criteria (there are up to fifty), but the criteria selected do represent a certain combination of many other linked properties.

Fuel consumption
Letters from A (highest efficiency) through G (lowest efficiency) and the traffic-light colors green, yellow and red in the EU label denote the efficiency of the tire with regard to rolling resistance and thus fuel consumption. The range for rolling resistance from class A through G represents a difference in fuel consumption of up to 7.5 % [13]. The potential for savings is even higher, depending on the driving situation. The difference between the individual stages of the tire classes with regard to rolling resistance is clearly defined: for instance 0.11 *l* / 100 km for a vehicle with an average consumption of approx. 6.6 *l* / 100 km. The difference between an A-rated tire and a G-rated tire adds up to approx. 0.5 *l* / 100 km (in each case provided a consistent driving style and identical tire inflation pressure).

Wet grip
Letters A (shortest braking distance) through G (longest braking distance) provide information on the tire's wet grip when braking. The difference in wet grip between a particularly good tire and a poor tire when applying full brakes from 80 km/h to zero produces an 18-meter shorter braking distance.

Tire noise
Pass-by noise is depicted in the EU label by a symbol together with an indication of the dB value. The symbol is based on the binding noise-emission limit values. The more sound waves are shaded black in the EU label, the louder the tire.

Winter tires

Technical characteristics
Passenger-car winter tires exhibit no or only slight differences in structural design from summer tires. They are characterized by good force transmission (traction) on snow and mud, satisfactory grip on ice, good adhesion on wet and dry road surfaces, safe handling, comfortable rolling, and low noise.

The feature that is unique to them is primarily the softer and elastic-when-cold rubber compound with high natural-rubber content. Unlike the summer rubber compound, it does not become brittle and harden ("vitrify") at minus temperatures (which results in reduced adhesion because the interlocking effect can no longer occur).

Added to this are increased tread area (thus a greater positive proportion) and, as a conspicuous external identifying feature, a multidimensional superfine tread (design shapes: zigzag, spheres, honeycombs, and mixed shapes, see Figure 4) in the rubber blocks themselves. These sipes (up to 2,000, depending on tire size) offer additional gripping edges in the snow and increase both traction and braking performance noticeably.

As the tread depth decreases, but also with increasing age (hardening caused by among others the influence of UV and ozone) the winter properties diminish: Traction and cornering-stability potential deteriorate, the braking distance is extended, and the risk of aquaplaning increases. Winter tires identified for example in Austria under a remaining tread depth of 4 mm are always classed as summer tires.

Standard winter tires customary in Europe are offered in speed ratings up to speed index W (maximum speed 270 km/h).

Development of a tire

The tire is always a compromise product: If a particular property (e.g. rolling resistance) is predominantly developed, this is inevitably at the expense of other properties (e.g. with the upshot of reduced wet grip) and thus of balance. This is only desirable or permissible in special cases (motor sport, special tires, industrial requirements). There is a conflict of aims when on principle contrasting properties are to be simultaneously optimized. Modern rubber compounds with a high silica filler content and optimized ground contact patches raise this balancing act to a higher level, but this does not eliminate the conflict.

The conflicting development aims which can negatively influence each other include grip potential and rolling resistance, dry braking and wet braking, aquaplaning and dry handling, and grip and abrasion.

Tire tests

Tire manufacturers conduct around fifty objective laboratory tests and subjective road tests on in-house test and racing circuits. The most important tests are:

Handling on a dry road
Criteria are directional stability, steering precision, straight-running stability, noise, and tire comfort.

Properties in the wet
Criteria are handling on a wet course with bends, braking, aquaplaning, longitudinal and lateral, and circular-course driving.

Machine tests
Criteria are top speed, continuous running, and abrasion.

Winter properties
Criteria are snow handling, driving on passes, traction measurement, accelerating performance, and braking.

Tire-pressure monitoring systems

Application

Tire-Pressure Monitoring Systems (TPMS) are used to monitor the tire pressure on vehicles to prevent tire defects due to insufficient tire pressure, thus reducing the number of accidents resulting from defective tires.

If a vehicle is operated with insufficient tire pressure, this leads to increased flexing energy on the tire sidewalls and thus to increased wear of the tire. When operated at full load or at high speed, the greater flexing energy results in increased thermal load, which can even cause tire bursts. Following a spate of severe fatal accidents in the USA due to tire bursts caused by insufficient inflation pressure, legislation was passed (NHTSA Tread Act) to regulate the nationwide introduction of tire-pressure monitoring systems in the USA in order to warn drivers about low tire inflation pressure at an early stage in the future. Since September 2007, all new cars have been required to be fitted with tire-pressure monitoring systems which detect both tire damage and slow pressure losses through the tire rubber caused by gas diffusion.

The tire inflation pressure, however, is not only an important variable for traffic safety. Ride comfort, tire service life, and fuel consumption are also significantly influenced by the inflation pressure. Inflation pressure reduced by 0.6 bar can increase fuel consumption by up to 4 % in urban traffic and shorten the service life of the tire by up to 50 %. In the European Union (EU), the decision has been taken to prescribe the fitting of tire-pressure monitoring systems in all new cars as from October 2012 in order to help reduce CO_2 emissions.

Already today the rising proportion of tires with run-flat properties necessitates the deployment of tire-pressure monitoring systems, as the car driver is no longer able to detect a tire with a considerable pressure deficiency (“flat”) on the basis of the drivability. In order to prevent the driver from inadvertently exceeding the speed and range limits that apply in this case, run-flat tires may only be used in conjunction with tire-pressure monitoring systems.

As a general principle, two different types of tire-pressure monitoring system are used: directly measuring and indirectly measuring systems.

Directly measuring systems

In directly measuring systems, a sensor module with a pressure sensor is installed in each tire of the vehicle. This transfers data such as the tire pressure and tire temperature from inside the tire across a coded high-frequency transmission link to a control unit. The control unit evaluates these data in order to detect not only pressure losses in individual tires (“puncture detection”) but also slow pressure losses in all the tires (“diffusion detection”). If the tire pressure falls below a specified threshold or if the pressure gradient exceeds a certain value, the driver is warned by a visual or acoustic signal.

The sensor modules are usually integrated into the tire valve. As a rule, they are supplied by a battery. In comparison with other applications, this results in additional requirements with regard to power consumption, media resistance, and sensitivity to acceleration. Micromechanical absolute-pressure sensors are used as sensor elements.

The data measured with the pressure and temperature sensor in the tire are processed in the sensor module, modulated on a HF carrier signal (433 MHz in Europe, 315 MHz in the USA), and emitted via an antenna. This signal is either detected via individual antennas on the wheel arches or in a central receiver (e.g. in the control unit of existing Remote Keyless Entry systems).

Directly measuring systems do not need a reset function if they have a fixed, constant pressure-loss warning threshold. For such a system to work, the vehicle must only have one prescribed inflation pressure, regardless of vehicle load and tire size. As soon as different inflation pressures have to be set in the vehicle, a directly measuring system also needs a reset function to be able to adapt the warning threshold accordingly.

The advantages of directly measuring systems are that they provide precise,

real measurement of the tire pressure and temperature, and their functioning is not dependent on specific tire types, vehicle conditions and road conditions. The disadvantages of direct systems compared with indirect systems are the much higher system costs, the additional logistical costs in the field of maintaining the availability of all the design variants, the follow-up costs for each new rim, and their battery-dependent, limited service life.

Indirectly measuring systems

In indirectly measuring systems, pressure loss in the tires is not determined directly, but rather by means of a derived variable. To achieve this, these systems perform a mathematical-statistical evaluation of the speed differences of all wheels for "puncture detection", and if necessary also an evaluation of a wheel natural-frequency shift for "diffusion detection". In vehicles with antilock braking or driving-dynamics control systems, the wheel speed required for this is determined by sensors that are already present and transferred to the control unit. Speed differences occur when pressure loss reduces the rolling circumference of the corresponding tire, thus increasing its speed relative to the other three wheels. The subtraction, which can be implemented using a low-cost extension of the software algorithms in the antilock braking or driving-dynamics control system, enables detection of high pressure losses on up to three tires. The wheel natural-frequency spectrum of the individual wheels is evaluated to enable a simultaneous pressure loss at all four wheels to be detected. Typically, the maximum wheel natural frequency shifts at a pressure loss of 20% from 40 Hz to approximately 38 Hz.

Indirectly measuring systems must necessarily be calibrated to the nominal pressure. A calibration is initiated by operating the reset button. When the reset function is activated, the system stores the current learning values on the next few kilometers as new reference values, based on the current rolling circumferences and wheel natural-frequency characteristics. The warning capability takes effect after approx. ten minutes of driving time. The driver is required to activate the reset function to recalibrate the system when one or more tires are changed, the tire positions are changed (e.g. switching the front and rear wheels), the tire pressure is altered (e.g. when the vehicle is fully laden), or work has been carried out on the wheel suspension (e.g. adjustment work, shock-absorber replacement).

Advantages of indirectly measuring systems are their lower system costs and their robustness over the service life of vehicles, since no additional components are required. Because the system is linked to the vehicle and not to the wheels, no further costs are incurred in the field for logistics and spare parts. A disadvantage is the system's dependence on the specific tire, resulting in a wider variation of the detection times and in higher costs for adapting the system's function to the tire dimensions permitted for a particular vehicle. The system's dependence on mileage and road surface also influences the detection times.

Fulfillment of statutory requirements

As things stand, both systems satisfy the statutory requirements in North America and Europe with regard to "puncture detection" and "diffusion detection". Statutory provisions for tire-pressure monitoring systems are also being drafted in China and Korea.

Rotary seal for tire-pressure control

Function

The Turcon PTFE rotary seal (Turcon Roto L, Figure 1) was developed for tire-pressure control purposes in order to seal around the axle of the central tire-pressure system only when required and always when the tire pressure is increased or decreased. In conventional seal concepts the seal remains in permanent contact with the axle that bears the seal. This causes friction, which in turn leads to increased fuel consumption. By avoiding friction in pressureless operation this rotary seal necessarily reduces fuel consumption.

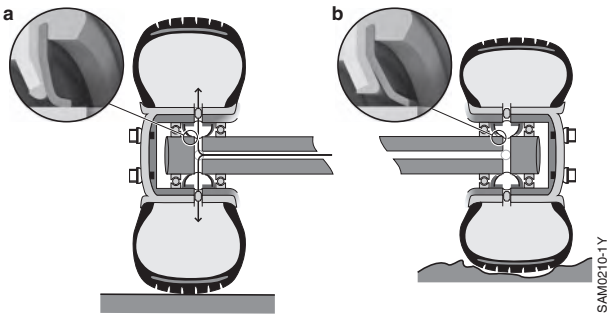
Application

The Turcon Roto L was originally developed primarily for off-road vehicles to adapt the tire inflation pressure to the ground. On asphalt surfaces a high tire inflation pressure is required, whereas on dirt tracks a low tire inflation pressure is advantageous.

The use of this tire-pressure control can also produce benefits for trucks. It facilitates the extension of tire-pressure control systems and produces benefits for trucks with long loading areas or different semi-trailers in which the tire pressure could be optimized for the respective road and load conditions. This would increase traction and safety and help to deliver significant fuel savings to transport companies.

Performance and passenger cars are a further target market. When sports cars are driving at low speeds the tire pressure should be kept low. At high speeds the handling performance is improved if the tire pressure can be set to high or, depending on the road surface, set differently at each wheel. Furthermore, it can be used as a safety system in the event of a blow-out in order to inflate the system with air until the driver reaches the nearest repair shop.

Design



The Turcon Roto L combines a polytetrafluoroethylene (PTFE) sealing lip with an elastomer seal body and a stable, shape-forming metal ring (Figure 2). The seal's design ensures that during pressure build-up the sealing lip is pressed against the mating sealing surface. As the pressure decreases, the relaxing elastomer area, which acts like a spring, returns the sealing lip to its neutral initial position.

Seal wear

A further important effect on the performance of the Turcon Roto L with regard to the service life of the overall system is the significantly reduced shaft run-in. This is due on the one hand to the use of a special seal material which is filled with a complex mixture of non-abrasive mineral fibers and on the other hand to the low friction when the seal is not activated.

A conventional standard seal used today in a tire-pressure control system already exhibits a shaft run-in of around 10 µm after 168 hours. In comparison, the Turcon Roto L has a shaft run-in of around 4 µm after 780 hours (Figure 3). In other words, the service life of a sealing system with this rotary seal is at least four times longer.

Figure 1: Turcon Roto L sealing system
a) Setting a high tire inflation pressure,
b) Setting a low tire inflation pressure.

Seal seat
Rotary seals for tire-pressure control need to be well seated in the groove to ensure tightness, even when the system is pressurized. In this way, a relative movement of the body is also prevented when the shaft is subject to axial movement. The groove should have a diameter tolerance of H8 (according to DIN 3760 [1], ISO 6194-1 [2], and ISO 16589-1 [3]). It is important that the seal has not been subjected to load by other components beforehand (for example, by bearings).

The shaft should have a diameter tolerance of h7. The surface should be ground to a perfectly flat finish. A surface with Ra = 0.2 to 0.4 µm and a maximum Rz value of 1.5 µm is recommended for this rotary seal.

Benefits
One benefit of this concept is that it extends the seal life. If the seal in a vehicle is only used for around 10 % of the axle system's service life, it remains operational and fit for use over the system's entire service life.

Even more important, however, is the elimination of friction when there is no pressurization. This means considerable fuel savings for the vehicle operator. Because the seal generates less than half the friction of conventional seal solutions, the tire pressure can also be reduced or increased during driving. In the case of large commercial-vehicle tires it can take 20 to 30 minutes to adjust the tire pressure. If this can be done en route while the vehicle is driving, the vehicle can be active for up to 30 minutes instead of standing idle. This means a reduction of overall costs for the operator.

Steering

Purpose of automotive steering systems

The direction of vehicles of any kind is changed with the steering. In single-track vehicles, for example motorcycles, steering is performed by turning the pivoted front fork in the steering head (steering-head steering). In two-track vehicles kingpin steering as described in the following is used.

In road vehicles the wheels on the front axle are steered; in some vehicle models the wheels on the rear axle also steer. Rear-axle steering reduces the turning circle at low speeds and increases the driving dynamics at high speeds.

Kingpin steering

In a kingpin-steering system the two wheels are each secured to a pivoted steering knuckle (Figure 1). The rotary movement is introduced via the steering arms rigidly connected to the steering knuckle by the two tie rods actuated by the steering box. The casing of the steering box is permanently connected to the vehicle. The rotary movement is introduced via the steering column, at the upper end of which the steering wheel is located.

Aside from the vehicle weight and the friction coefficient of the wheels on the road surface, the axle kinematics affect the steering behavior and the forces to be applied by the steering. As a result of the toe-in (see Fundamentals of automotive engineering) the two front wheels are not parallel but instead are slightly inclined towards each other in the direction of travel in order to improve straight-running stability. As a result of the camber the wheels are not exactly vertical on the road but instead are slightly inclined inwards. This results in a side force on the wheels acting towards the inside of the vehicle. This force pretensions the bearings in the straight-ahead position and provides a better steering response and greater directional stability. The kingpin inclination influences the steering forces. In the transverse direction the swivel axis of the steering knuckle is inclined inwards, equating to a positive kingpin angle. A small kingpin angle reduces the steering

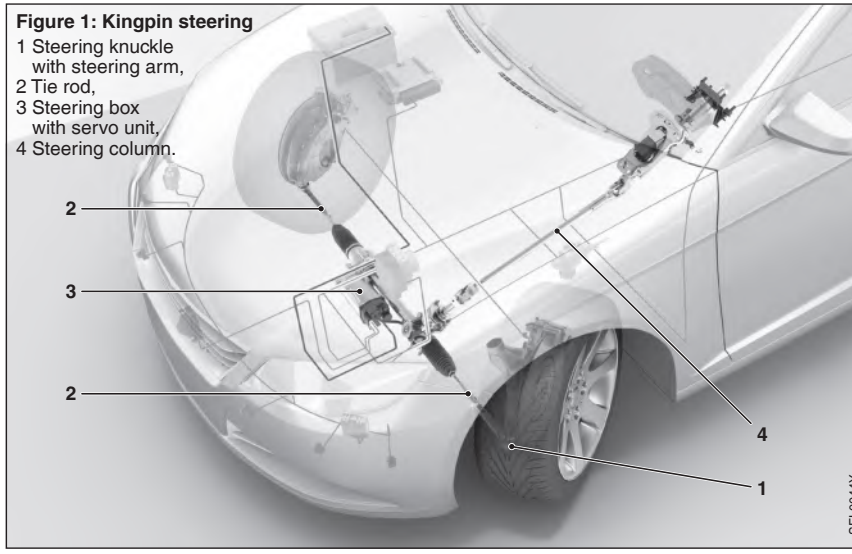

Figure 1: Kingpin steering
1 Steering knuckle with steering arm,
2 Tie rod,
3 Steering box with servo unit,
4 Steering column.

forces, whereas a large kingpin inclination assists the automatic return to the straight-ahead position.

The automatic return to the straight-ahead position is achieved above all by the caster offset. Inclining the swivel axes in the direction of travel towards the rear moves the piercing point of the swivel axis through the road surface in the direction of travel ahead of the wheel contact point and consequently the wheels are pulled in the direction of travel.

Classification of automotive steering systems

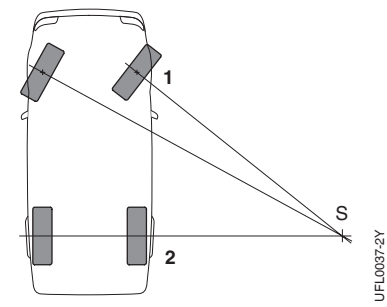
Muscular-energy steering system
The required steering forces are generated exclusively by the muscular energy of the driver. These steering systems are currently used in the smallest vehicle categories.

Power-assisted steering system
The steering forces are generated by the muscular energy of the driver and by an additional auxiliary force hydraulically and increasingly electrically. This steering system is currently the type typically used in passenger cars and commercial vehicles.

Power-steering system
The steering forces are generated exclusively by non-muscular (external) energy (e.g., in machinery).

Friction steering system
The steering forces are generated by forces which act on the tire contact patch. The trailing axles in trucks are an example of this type. The transmissions for the steering and auxiliary forces are effected by mechanical, hydraulic or electrical means or by combinations of the three.

Steering-system requirements



General requirements
To ensure that the road wheels roll cleanly and are thereby not subjected to excessive tire wear, the entire steering kinematics must satisfy the Ackermann condition. This means that the extensions of the wheel axes of the steered wheels intersect at the same point on the extension of the wheel axis of the non-steered wheels (Figure 2).

Steering kinematics and axle design must be such that, although the driver receives feedback on the adhesion between wheels and road surface, the steering wheel is not subjected if possible to any forces from the spring motion of the wheels or from motive forces (front-wheel drive). Furthermore, damping properties must be utilized to ensure that no vibration, caused by road irregularities for exampled, occurs in the steering train.

Jolts from irregularities in the road surface should be damped as much as possible during transmission to the steering wheel. But, in the process, the required haptic feedback from the road to the driver must not be lost.

The steering-angle requirement for turning the steering wheel from lock to lock should, for comfort reasons, be as small as possible when parking and driving at low speed. However, the direct

Figure 2: Ackermann condition
1 Front axle,
2 Rear axle.
S Point of intersection of extension of wheel axes.

steering ratio should not make the vehicle susceptible to instability at medium and high speeds.

Statutory requirements

Displacement and time synchronization when the steering system is operated is required by law. A rigid, zero-play configuration of all the components in the steering train helps to achieve this and causes the slightest steering-wheel movements by the driver to be translated into changes of direction at the steered wheel. This property is particularly important in the range of the straight-ahead position. This makes possible safe, precise, and fatigue-free vehicle guidance.

A further statutory requirement is the tendency of the steering to return automatically to the straight-ahead position. This is achieved by appropriate axle kinematics and a low-friction design of the components in the steering train.

The statutory requirements imposed on steering systems in motor vehicles are described in the international regulation ECE-R79 [1]. These requirements include, as well as the basic functional requirements, the maximum permissible control forces for an intact steering system and for a faulty steering system. These requirements govern, above all, the behavior of the vehicle and the steering system when driving into and out of a circle. Owing to different requirements, vehicles are divided in ECE-R79 into different categories, to which different stipulations then apply (Table 1).

For vehicles of all categories: After the steering wheel is released when the vehicle is driven on a circular course at half lock and at a speed of 10 km/h or faster, the driven radius of the vehicle must become larger or at least remain the same.

For M1 category vehicles (passenger cars with up to eight seats in addition

Table 1: Categorization of vehicles in ECE-R79

Vehicle category	
M1	Vehicles for the carriage of passengers comprising no more than 8 seats in addition to the driver's seat
M2	Vehicles for the carriage of passengers comprising more than 8 seats in addition to the driver's seat and having a maximum mass not exceeding 5 tons
M3	Vehicles for the carriage of passengers comprising more than 8 seats in addition to the driver's seat and having a maximum mass exceeding 5 tons
N1	Vehicles for the carriage of goods and having a maximum mass not exceeding 3.5 tons
N2	Vehicles for the carriage of goods and having a maximum mass exceeding 3.5 tons but not exceeding 12 tons
N3	Vehicles for the carriage of goods and having a maximum mass exceeding 12 tons

Table 2: Regulations for steering operating force when driving into a circle at a speed of 10 km/h

Vehicle category	Intact system			Faulty system		
	Maximum operating force in daN[1]	Time in s	Turning circle radius in m	Maximum operating force in daN[1]	Time in s	Turning circle radius in m
M1	15	4	12	30	4	20
M2	15	4	12	30	4	20
M3	20	4	12 [2]	45	6	20
N1	20	4	12	30	4	20
N2	25	4	12	40	4	20
N3	20	4	12 [2]	45 [3]	6	20

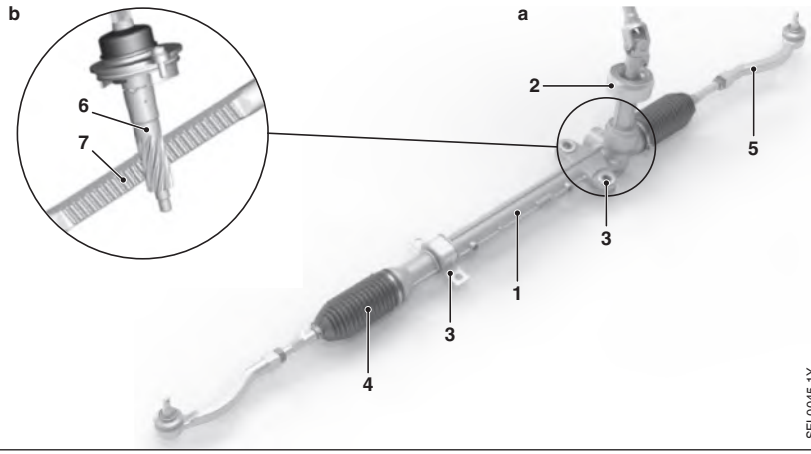
[1] 1 daN = 10 N.
[2] Or steering lock in case this value is not reached.
[3] 50 daN for non-articulated vehicles, with two or more steered axles, excluding friction-steered axles.

to the driver's seat): When the vehicle is driven tangentially out of a circle with a radius of 50 m at a speed of 50 km/h, no unusual vibrations may occur in the steering system. In vehicles of the other categories, this behavior must be substantiated at a speed of 40 km/h or, if this value is not reached, at top speed.

This behavior is also prescribed in the event of a fault in vehicles with power-assisted steering systems. For M1 category vehicles, it must be possible in the event of a steering-servo failure to drive at a speed of 10 km/h within four seconds into a circle with a radius of 20 m. The control force at the steering wheel must not exceed 30 daN in the process (Table 2). The same applies to the behavior with an intact system.

Types of steering box

The specified steering-system requirements have given rise above all to two fundamental types of steering box. Both types can be utilized in pure muscular-energy steering systems or, in combination with appropriate servo systems, as power-assisted steering systems.



Rack-and-pinion steering

Rack-and-pinion steering is by far the most commonly used type and consists essentially of steering pinion and rack (Figure 3). The steering pinion is driven by the steering wheel and the steering column (Figure 1). The steering ratio is defined by the ratio of pinion revolutions (steering-wheel revolutions) to rack travel.

As an alternative to a constant reduction ratio on the rack, suitable toothing of the rack allows the ratio to be varied as a function of travel. In this way, the straight-running stability of the vehicle can be improved by a suitably indirect

Figure 3: Rack-and-pinion steering

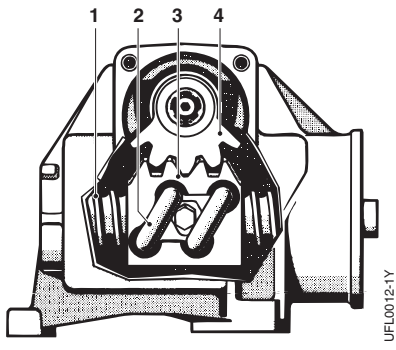
7 Rack with toothing.



ratio around the center of the steering. At the same time, it is possible with a direct ratio arrangement in the range of medium and large steering angles (e.g., when parking) to reduce the necessary steering-angle requirement when turning from lock to lock.

Recirculating-ball steering
The forces generated between steering worm and steering nut are transmitted via a low-friction row of recirculating balls (Figure 4). The steering nut acts on the steering output shaft via gear teeth. A variable ratio is also possible with this type of steering box.

The increasing performance of rack-and-pinion steering has meant that recirculating-ball steering is practically no longer used in passenger cars.

Figure 4: Recirculating-ball steering
1 Steering worm,
2 Recirculating balls,
3 Steering nut,
4 Steering output shaft with toothing segment.

Power-assisted steering systems for passenger cars

The upshot of the increasing size and weight of vehicles and the heightened comfort and safety requirements involved is that in the last few years power-assisted steering has gained acceptance in all vehicle categories down to the compact-car segment. These steering systems are, but for a few exceptions, already installed as standard. The steering forces exerted by the drive are boosted by a hydraulic or an electric servo system. This servo system must be such that the driver receives good feedback on the adhesion conditions between the tires and the road surface at all times, and yet negative influences caused by road-surface jolts are effectively damped.

Hydraulic power-assisted steering
Combining the mechanical type of steering box with a hydraulic servo system produces rack-and-pinion power steering (Figure 6) and ball-and-nut power steering.

Control valve
The control valve provides the working cylinder with an oil pressure that corresponds to the rotary force of the steering wheel (Figure 5). For this purpose, a torsion-bar spring is used to convert the operating torque into proportional actuator travel inside the valve. The actuator travel changes opening cross-sections inside the valve and thereby control the oil and pressure ratios in the working cylinder.

Control valves are built according to the "open center" principle, i.e., when the control valve is not actuated, the oil delivered by the pump flows back to the oil reservoir at zero pressure.

Power-assisted steering systems with modulation capability
Increasing demands regarding user-friendliness and safety have resulted in the introduction of power-assisted steering systems with modulation capability. An example of this is the rack-and-pinion power-steering system operating in response to driving speed. An ECU evaluates the driving speed and controls,

via an electrohydraulic control valve, the hydraulic feedback in the system and consequently the operating force at the steering wheel.

This produces in the parking range and when driving slowly low operating forces, which then increase as the speed increases. In this way, precise and accurate steering is possible at high speeds.

Working cylinder

The double-action working cylinder integrated in the steering box converts the applied oil pressure into an assisting force which acts on the rack and intensifies the steering force exerted by the driver. As the working cylinder has to have extremely low friction, particularly high demands are made on the piston and rod seals.

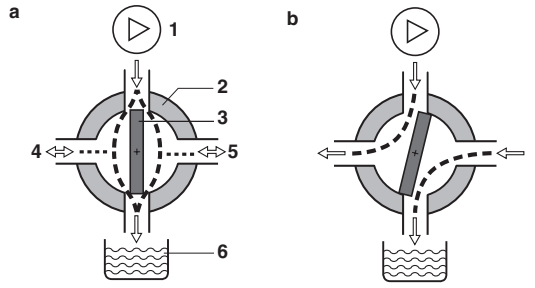

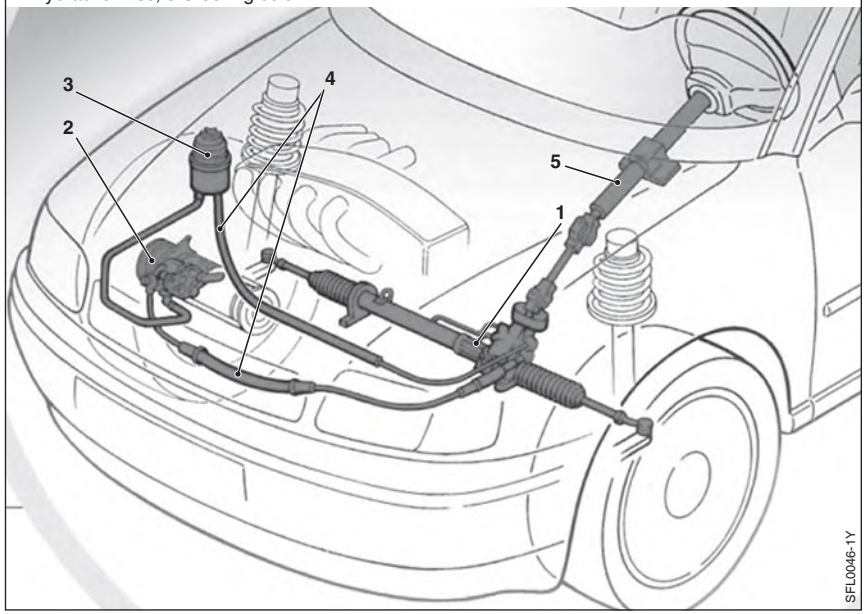

Figure 6: Rack-and-pinion power steering

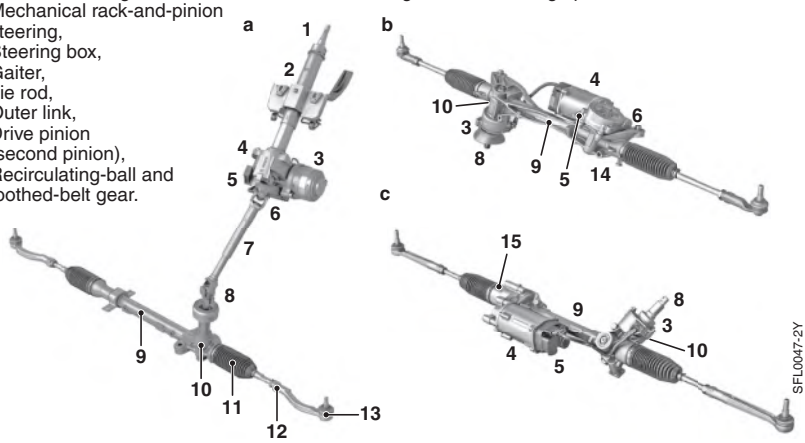
1 Hydraulic steering box, 2 Power-steering pump, 3 Oil reservoir,
4 Hydraulic lines, 5 Steering column.



Energy source
The energy source consists of a vane-type supply pump (generally driven by the internal-combustion engine) (power-steering pump) with an integrated oil-flow regulator, an oil reservoir, and connecting hoses and pipes. The pump must be dimensioned so that it makes available the required oil pressure and the required oil quantity for parking maneuvers, even when the engine is just idling.

To provide protection against overload, steering systems contain a pressure-relief valve which is usually integrated in the pump. The pump and the components in the hydraulic working circuit must be designed so that no offending noise is generated and the operating temperature of the hydraulic fluid does not rise to an excessive level.

Alternatively, the pump for the energy supply of the steering can also be driven by an electric motor. The pump is usually designed as a gear or roller-cell pump. The pump can be mounted in a variety of locations due to the omission of the belt drive for the internal-combustion engine. Thanks to an electronic control module which evaluates signals like the vehicle or steering speed, the pump's rotational speed can be adapted to the steering's current energy demand and to the driving situation, and consequently greater energy efficiency can be achieved.

Electric power-assisted steering
Hydraulic power-assisted steering has been replaced in the passenger-car sector in the last few years almost exclusively by electromechanical power-assisted steering (EPS, Electric Power Steering). Introduced in micro and compact cars in around 1990 and then in the compact class in around 2000, ever more powerful electric ECUs and motors enable such systems to be used even in the upper passenger-car and SUV sectors. Electromechanical power-assisted steering is characterized by an electric drive unit consisting of an ECU and an electric motor powered by the vehicle electrical system which delivers the required servo force. The system consists of the following components (Figure 7):
– Steering column that connects the steering pinion with the steering wheel inside the vehicle.
– Steering pinion that converts the rotating steering movement into the linear movement of the rack.

Figure 7: Variants of electromechanical power-assisted steering
a) Servo unit on the steering column,
b) Servo unit on a second pinion,
c) Paraxial servo unit.

– Rack connected to the wheels via the tie rods and links.
– Sensors to record the information required to calculate the necessary supporting steering torque.
– Servo unit, consisting of an electric ECU with microprocessor, electric motor and reduction gear which generates the assisting steering torque and links into the steering train.

Variants
The mechanical coupling of the motor to the steering box can be set up as a steering-column, steering-pinion or rack drive.

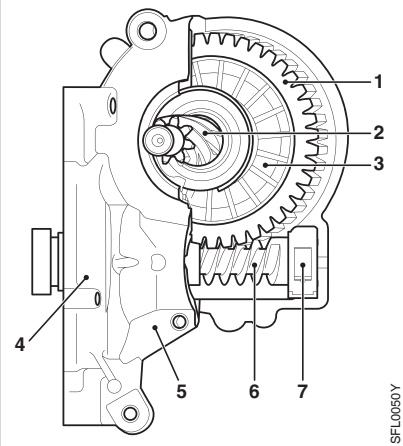
Servo unit on the steering column
The servo unit is integrated along with its electronics in the steering column (Figure 7a). It is connected via the intermediate steering shaft with universal joints to the mechanical rack-and-pinion steering. The torque generated by the electric motor is converted via the helical-gear drive (Figure 8) into an assisting torque and transmitted to the steering column. The sensor technology and the torsion-bar spring are located next to the helical-gear drive.

This system is used in vehicles with low steering forces (micro and compact cars).

Servo unit on a second pinion
The servo unit is mounted on a second pinion (Figure 7b), meaning that the sensor unit and drive unit can be separate. The helical-gear drive (Figure 8) converts the torque provided by the electric motor into the servo assisting torque and transmits it to the rack. The drive-pinion ratio is not dependent on the steering ratio; this makes possible a power-optimized design with 10 % to 15 % more system power.

This system is used in mid-size vehicles.

Paraxial servo unit
To convert the rotary movement of the steering wheel into a linear motion of the rack, this system uses a gear concept consisting of toothed belt and recirculating-ball gear. A system with ball recirculation is used in the ball-and-screw spindle drive. The ball chain is returned through a channel integrated in the recirculating-ball nut. The slip-free toothed belt is able to transmit the torque reliably.



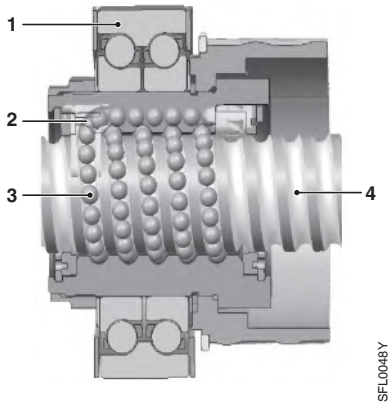
This system is used in vehicles with high steering forces (sports cars, upper mid-size, off-road vehicles, light commercial vehicles).

Servomotor
Brushed or brushless DC motors are used as servomotors. Depending on the required performance capability of the steering the design of the reduction gear, the torque generated by these motors is 3 to over 10 Nm.

Activation of the motor and hence the power consumption itself are demand-oriented; in other words, only when assisting power is actually required is the vehicle electrical system subjected to load extending beyond the stand-by power input.

Reduction gear
Primarily two principles are used in the reduction gear.

Figure 8: Helical-gear drive
1 Helical gear,
2 Drive pinion,
3 Overload safety,
4 Locating bearing,
5 Housing,
6 Worm,
7 Spring-damper element.



Helical-gear drive
When a helical-gear drive is used (Figure 8), the motor drives a worm which engages a helical gear and thereby acts on the steering output shaft, the steering pinion or a separate drive pinion (Figure 8). It is important to ensure in the design of the helical-gear drive that there is no tendency to self-lock when turning back as a result of the rack force.

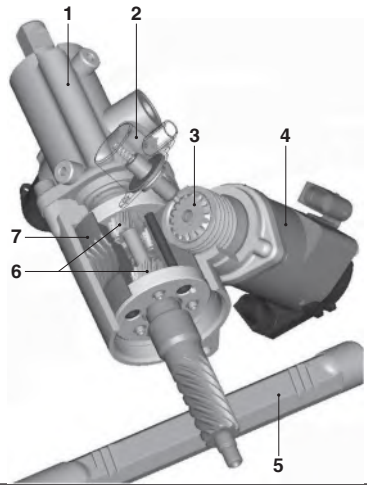
Recirculating-ball gear
When a recirculating-ball gear is used (Figure 9), the motor drives, either directly or additionally reduced by an upstream belt-transmission stage, a ball-and-screw spindle drive, which converts the rotary movement into linear motion of the rack.

Torque sensor
To deliver the assisting force in line with demand, the driver manual torque is measured by the torque sensor integrated in the steering system, the required servo force is calculated in the electric ECU, and the motor is activated accordingly. The assisting force is delivered by the motor on the basis of torque control (see Torque sensor).

Figure 9: Recirculating-ball gear
1 Ball bearing,
2 Return channel,
3 Ball chain,
4 Rack.

Functions
Further functions are executed in the ECU software to optimize the steering behavior. The ECU evaluates further signals from the vehicle or the steering (e.g., driving speed, steering angle, steering torque, and steering speed) for this purpose. Thus, for example, the resetting movement of the steering wheel is optimized as a function of the steering angle and the driving speed by an additional motor torque. Likewise, a damping function is implemented with the information on driving speed and steering speed; this function supports the straight-ahead stability of the steering and hence of the vehicle at high driving speeds.

By networking the steering ECU with other ECUs in the vehicle network, it is possible to realize assistance functions with the electromechanical power-assisted steering to enhance comfort and safety.



Demand-oriented control of the electric motor leads to considerable fuel savings of 0.3 *l*/100 km on average compared to hydraulic power steering with a pump driven by the vehicle engine. In urban driving, the fuel savings increase to 0.7 *l*/100 km.

In the event of a failure of the energy supply or steering assistance, the driver can continue to steer mechanically, but with higher manual steering torque.

Superimposed steering
With a superimposed-steering system, an additional steering angle can be added to or subtracted from the steering-wheel angle set by the driver at the steering wheel. This system is usually combined with a parameterizable hydraulic or an electric power-assisted steering system. Superimposed does not facilitate autonomous driving, but it does provide for a steering characteristic optimally adapted to the driving situation, and thus maximum comfort and directional stability. When networked with driving-dynamics control systems, it can further increase safety in critical driving situations by means of driver-independent steering adjustments. Such steering systems are already in series production, known as Active Steering at BMW and Dynamic Steering at Audi.

Technical solution
The angle superimposition independent of the driver's steering angle is currently effected by two different technical solutions.

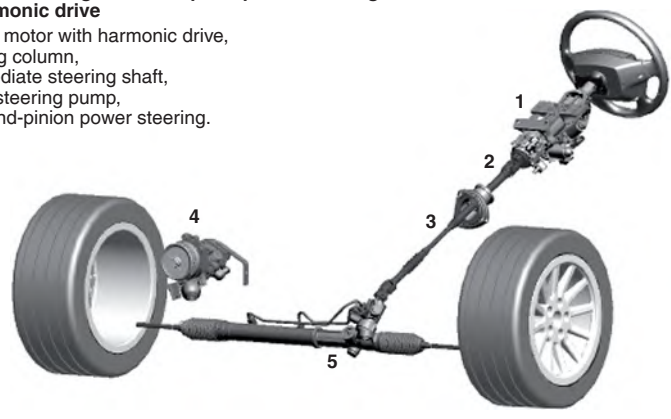


Figure 10: Planetary-gear set of superimposed steering
1 Valve,
2 Electromagnetic lock,
3 Worm,
4 Electric motor,
5 Rack,
6 Planetary gear,
7 Worm gear.

Planetary-gear set
A twin planetary-gear set with different gear ratios of the gear stages is integrated into a common planetary-gear carrier in the steering train (Figure 10). This means there is always a mechanical link between the steering wheel and the steered wheels. The different gear ratios of the gear stages mean that turning the planetary-gear carrier sets the additional steering angle. The angle setting is made by a electric motor that drives the worm gear of the planetary-gear carrier.

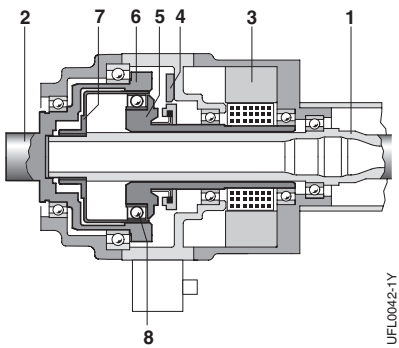
Harmonic drive
The steering-angle superimposition unit consists in this case of a harmonic drive and an electric motor with a hollow shaft (Figure 11). The highly compact design enables it to be integrated into the steering column without compromising the requirements with regard to installation space and crash behavior. The shaft at the steering-wheel end (input shaft) is positively connected (Figure 12) to a flex spline. The rotary movement of the steering wheel is transmitted via the toothing of the flex spline (teeth in the region of the flexible ball bearing point outwards) to the toothing of the internal gear (circular spline, teeth point inwards in the direction of the axle) for the output shaft. An elliptical inner rotor (shaft generator) located in the flex spline, which is driven by the electric motor, generates the superimposed steering angle via the different number

Figure 11: Steering train of superimposed steering with harmonic drive
1 Electric motor with harmonic drive,
2 Steering column,
3 Intermediate steering shaft,
4 Power-steering pump,
5 Rack-and-pinion power steering.

of teeth between the flex spline and the circular spline. The races of the flexible ball bearing follow the shaft motion of the elliptical inner rotor and transmit this shaft motion to the flex spline. Here, too, there is always a mechanical link between the steering wheel and the steered wheels via the toothing of the harmonic drive.

In the passive state, the electric motor is blocked by an electromechanical lock, thereby ensuring direct mechanical through-drive for the steering movement.

Activation concept
The superimposed-steering ECU checks the plausibility of the required sensor information and evaluates this information. It calculates the setpoint angle for the electric motor and generates via an integrated driver stage the pulse width-modulated signals for activating the electric motor. This is implemented as a brushless DC motor with integrated rotor position sensor. The maximum motor current is 40 A at a vehicle system voltage of 12 V. The rotor position sensor enables the control unit to control the electronic commutation and thus the direction of rotation of the motor. It also calculates and checks the total set additional steering angle using a summation algorithm in the control unit software.



The effective steering angle, the sum total of the steering-wheel angle and the superimposed angle of the electric motor, is calculated by the ECU, and made available on the vehicle communication bus to the partner ECUs.

Setpoint value
The setpoint value for the effective steering angle formed in the superimposed-steering ECU is made up of the partial setpoint value for steering comfort and the partial setpoint value for vehicle stabilization. The signals required to calculate these variables are read in by the control unit via the CAN bus.

The partial setpoint value for the steering comfort is implemented as a speed-dependent, variable steering ratio. The value is calculated from the input variables of steering angle and driving speed. When the vehicle is stationary and at low driving speeds, an angle is added to the steering angle set by the driver. This makes the steering ratio more direct. The driver can turn the wheels fully with less than one complete steering wheel revolution. This steering-angle addition is continuously reduced as driving speed increases. From speeds of roughly 80 – 90 km/h, a proportion is subtracted from the driver's steering angle and steering becomes more indirect. This ensures straight-running vehicle stability at high speeds and at the same time prevents the driver from losing control of the vehicle due to excessively fast steering movements.

For the calculation of the partial setpoint value for vehicle stabilization – in addition to the steering angle and the driving speed – the vehicle movement is measured using the sensors for the vehicle yaw rate and lateral acceleration. The superimposed steering uses the driving-dynamics control sensors for this purpose. In the same way as the driving-dynamics control, a calculation model that runs in the ECU software calculates the reference vehicle movement. In the event of a deviation of the actual vehicle movement from the reference movement, the steering is activated to stabilize the vehicle. The two systems continuously

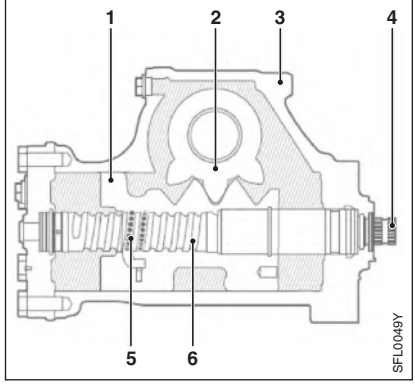
6 Internal gear (circular spline),
7 Flex spline,
8 Flexible ball bearing.

exchange information so that the controllers of the driving-dynamics control and the superimposed steering cooperate to optimal effect.

Safety concept
All of the internal and external signals that are used are continuously monitored in the control unit and their plausibility checked. If a sensor signal is no longer plausible, the additional steering function on which it is based is first disabled. For example, if the yaw-rate sensor that measures the rotation of the vehicle around its vertical axis (yaw rate) fails, the yaw-rate control of the superimposed-steering system is disabled. The variable steering ratio remains active.

If safe activation of the electric motor is no longer possible due to a fault, the system is completely shut down and direct steering-wheel through-drive is ensured by self-locking of the gear stage and by an electromechanical lock. This fallback level is always automatically active when the internal-combustion engine is not running or even if there is no electrical supply voltage.

Power-assisted steering systems for commercial vehicles



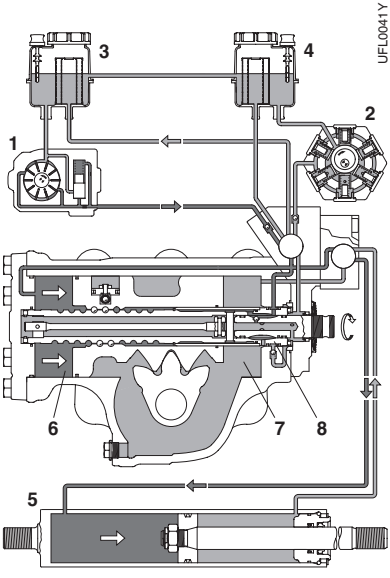
Power-assisted steering with all-hydraulic transmission

Hydrostatic steering systems are hydraulic power-assisted steering systems. The steering force of the driver is hydraulically boosted and transmitted exclusively by hydraulic means to the steered wheels. Because there is no mechanical connection, the maximum permissible speed is limited by national regulations. In Germany, this is 25 km/h. Depending on the system configuration and emergency steering properties, approval up to a speed of 62 km/h is possible. Use of these systems is therefore confined to machinery and special vehicles.

Single-circuit power-assisted steering system for commercial vehicles

Commercial vehicles are usually equipped with ball-and-nut power steering (Figure 13). The control valve is integrated into the steering box and together with the steering worm forms a single unit. The rotary movement of the steering wheel is transmitted via an endless ball chain to

Figure 13: Ball-and-nut power steering
1 Piston,
2 Steering-sector shaft,
3 Housing,
4 Steering-spindle connection,
5 Ball nut with ball chain,
6 Steering worm.



the ball-and-nut. Short toothing on the ball-and-nut meshes with the toothing on the segment shaft. The generated rotary movement of the segment shaft is transmitted via a steering arm to the steering linkage and the steered wheels.

The servo force is applied, as with rack-and-pinion power steering, by a rotary-slide valve. The working cylinder is formed by a sealing surface between the ball-and-nut housing and the steering box. Because no additional lines are required outside the housing, a robust and compact steering box with high power output is created.

Dual-circuit power-assisted steering system for heavy-duty commercial vehicles

Dual-circuit steering systems (Figure 14) are required when the operating forces needed at the steering wheel exceed the statutory requirements in ECE-R79 [1] if the power-assistance system fails. These steering systems feature hydraulic redundancy. Both steering circuits in these systems are functionally tested by means of flow indicators and a fault is indicated to the driver. The pumps for supplying the independent steering circuits must be driven in various ways (e.g., engine-dependent, driving speed-dependent, or electrically). If a circuit fails, caused for example by a fault in the steering system or engine failure, the vehicle can be steered with the still operational redundant circuit in accordance with the statutory requirements.

Dual-circuit systems take the form of ball-and-nut power steering with an integrated second steering valve. This second valve controls an additionally externally installed working cylinder and thereby provides the redundancy in relation to the existing servo system in the ball-and-nut steering.

Brake systems

Definitions and principles

(based on ISO 611 [1] and DIN 70024 [2]).

Brake equipment
All the vehicle brake systems whose functions are to reduce vehicle speed or bring the vehicle to a halt, or to hold the vehicle stationary if already halted.

Brake systems
Service brake system
All the elements, the action of which may be regulated, allowing the driver to reduce, directly or indirectly, the speed of a vehicle during normal driving or to bring the vehicle to a halt.

Secondary brake system
All the elements, the action of which may be regulated, allowing the driver to reduce, directly or indirectly, the speed of a vehicle or to bring the vehicle to a halt in case of failure of the service brake system.

Parking brake system
All the elements allowing the vehicle to be held stationary mechanically even on an inclined surface, and particularly in the absence of the driver.

Continuous-operation brake system
System of components which allows the driver to reduce the vehicle's speed or descend a long downhill gradient at a virtually constant speed with practically no wear to the friction brakes. A continuous-operation brake system may incorporate one or more retarders.

Automatic brake system
All the elements which automatically brake the trailer as a result of intended or accidental separation from the tractor vehicle.

Electronic brake system (ELB, EHB)
Brake system controlled by an electrical signal generated and processed by the control transmission system. An electrical output signal controls components which generate the application force.

Component parts
Energy-supplying device
Parts of a brake system which supply, regulate and, if necessary, condition the energy required for braking. It terminates at the point where the transmission device starts, where the various circuits of the brake systems, including the circuits of accessories if fitted, are isolated either from the energy supplying device or from each other.

The energy source is that part of an energy-supplying device which generates the energy. It may be located remotely from the vehicle (e.g. in the case of a compressed-air braking system for a trailer) or may be the muscular force of the driver.

Control device
Parts of a brake system which initiate the operation and control the effect of this brake system. The control signal can be conveyed within the control device by, for example, mechanical, pneumatic, hydraulic or electrical means, including the use of auxiliary energy or non-muscular force.

The control device is defined as starting at the component to which the control force is directly applied. It can be operated:
– By direct application of force by the driver by hand or foot,
– by indirect action of the driver or without any action (only in the case of trailers),
– by varying the pressure in a connecting line, or the electric current in a cable, between the tractor vehicle and the trailer at the time when one of the brake systems on the tractor vehicle is operated, or if it fails,
– by the inertia of the vehicle or by its weight or of one of its main component parts.

The control device is defined as ending at the point at which the braking energy is distributed, or where part of the energy is diverted to control braking energy.

Transmission device
Parts of a brake system which transmit the energy distributed by the control device. It starts either at the point where the control device terminates or at the point where the energy supplying device terminates. It terminates at those parts of the brake system in which the forces opposing the vehicle's movement, or its tendency towards movement, are generated. It can, for example, be mechanical, hydraulic, pneumatic (pressure above or below atmospheric), electric, or combined (for example hydromechanical, hydropneumatic).

Brake
Parts of a brake system in which the forces opposing the vehicle's movement, or its tendency towards movement, are developed, such as friction brakes (disk or drum) or retarders (hydrodynamic or electrodynamic retarders, exhaust brakes).

Auxiliary device of the tractor vehicle for a trailer
Parts of a brake system on a tractor vehicle which are intended to supply energy to, and control, the brake systems on the trailer. It comprises the components between the energy supplying device of the tractor vehicle and the supply-line coupling head (inclusive), and between the transmission device(s) of the tractor vehicle and the control-line coupling head (inclusive).

Brake-system types relating to the energy supplying device
Muscular-energy brake system
Brake system in which the energy necessary to produce the braking force is supplied solely by the physical effort of the driver.

Energy-assisted brake system
Brake system in which the energy necessary to produce the braking force is supplied by the physical effort of the driver and one or more energy supplying devices.

Non-muscular-energy brake system
Brake system in which the energy necessary to produce the braking force is supplied by one or more energy-supplying devices excluding the physical effort of the driver. This is used only to control the system.

Note: A brake system in which the driver can increase the braking force, in a state of totally failed energy, by muscular effort acting on the system, is not included in the above definition.

Inertia brake system
Brake system in which the energy necessary to produce the braking force arises from the approach of the trailer to its tractor vehicle.

Gravity brake system
Brake system in which the energy necessary to produce the braking force is supplied by the lowering of a component part of the trailer (e.g. trailer drawbar) due to gravity.

Definitions of brake systems relating to the arrangement of the transmission device
Single-circuit brake system
Brake system having a transmission device embodying a single circuit. The transmission device comprises a single circuit if, in the event of a failure in the transmission device, no energy for the production of the application force can be transmitted by this transmission device.

Multi-circuit brake system
Brake system having a transmission device embodying several circuits. The transmission device comprises several circuits if, in the event of a failure in the transmission device, energy for the production of the application force can still be transmitted, wholly or partly, by this transmission device.

Definitions of brake systems relating to vehicle combinations

Single-line brake system
Assembly in which the brake systems of the individual vehicles act in such a way that the single line is used both for the energy supply to, and for the control of, the brake system of the trailer.

Dual- or multi-line brake systems
Assembly in which the brake systems of the individual vehicles act in such a way that several lines are used separately and simultaneously for the energy supply to, and for the control of, the brake system of the trailer.

Continuous brake system
Combination of brake systems for vehicles forming a road train. Characteristics:
– From the driving seat, the driver can operate a directly operated control device on the tractor vehicle and an indirectly operated control device on the trailer by a single operation and with a variable degree of force.
– The energy used for the braking of each of the vehicles forming the combination is supplied by the same energy source (which may be the muscular effort of the driver).
– Simultaneous or suitably phased braking of the individual units of a road train.

Semi-continuous brake system
Combination of brake systems for vehicles forming a road train. Characteristics:
– The driver, from his driving seat, can gradually operate a directly operated control device on the tractor vehicle and an indirectly operated control device on the trailer by a single operation.
– The energy used for the braking of each of the vehicles forming the road train is supplied by at least two different energy sources (one of which may be the muscular effort of the driver).
– Simultaneous or suitably phased braking of the individual units of a road train.

Non-continuous brake system
Combinations of the brake systems of the vehicles forming a road train which is neither continuous nor semi-continuous.

Brake-system control lines
Wiring and conductors: These are employed to conduct electrical energy.

Tubular lines: Rigid, semi-rigid or flexible tubes or pipes used to transfer hydraulic or pneumatic energy.

Lines connecting the brake equipment of vehicles in a road train
Supply line: A supply line is a special feed line transmitting energy from the tractor vehicle to the energy accumulator of the trailer.

Brake line: A control line is a special control line by which the energy essential for control is transmitted from the tractor vehicle to the trailer.

Common brake and supply line:
Line serving equally as brake line and as supply line (single-line brake system).

Secondary-brake line: Special actuating line transmitting the energy from the tractor vehicle to the trailer essential for secondary braking of the trailer.

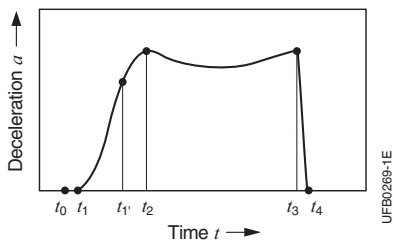
Braking mechanics
Mechanical phenomena occurring between the start of actuation of the control device and the end of the braking action.

Gradual braking
Braking which, within the normal range of operation of the control device, permits the driver, at any moment, to increase or reduce, to a sufficiently fine degree, the braking force by operating the control device. When an increase in braking force is obtained by the increased action of the control device, an inverse action must lead to a reduction in that force.

Brake-system hysteresis: Difference in control forces between application and release at the same braking torque.

Brake hysteresis: Difference in application force between application and release at the same braking torque.

Forces and torques
Control force F_c: Force exerted on the control device.



Application force F_s: On friction brakes, the total force applied to a brake lining and which causes the braking force by the effect of friction.

Braking torque: Product of frictional forces resulting from the application force and the distance between the points of application of these forces and the axis of rotation of the wheels.

Total braking force F_f: Sum of the braking forces at the tire contact patches of all the wheels and the ground, produced by the effect of the brake system, and which oppose the movement or the tendency of the vehicle to move.

Braking-force distribution: Specification of braking force according to axle, given in % of the total braking force F_f. Example: front axle 60 %, rear axle 40 %.

Figure 1: Times and deceleration during braking to a stop

before t_0: Reaction time,
t_0: Initial application of force on control device,
t_1: Start of deceleration,
t_1': End of pressure build-up time,
t_2: Fully developed deceleration,
t_3: End of maximum retardation,
t_4: End of braking operation (vehicle stationary),
$t_1 - t_0$: Initial response time,
$t_1' - t_1$: Pressure build-up time,
$t_3 - t_2$: "Mean maximum retardation" range,
$t_4 - t_1$: Active braking time,
$t_4 - t_0$: Total braking time.

Brake coefficient C^*: Defines the relationship between the total peripheral force of a given brake and the brake's application force.

$$C^* = \frac{F_u}{F_s} .$$

F_u Total peripheral force,
F_s Application force.
The mean is employed when there are variations in application forces at individual brake shoes (i number of brake shoes):

$$F_s = \Sigma \frac{F_{si}}{i} .$$

Time periods
Reaction time (see Figure 1): The time that elapses between perception of the state or object which induces the response, and the point at which the control device is actuated (t_0).

Actuating time of the control device: Elapsed time between the moment when the component of the control device (t_0) on which the control force acts starts to move, and the moment when it reaches its final position corresponding to the applied control force (or its travel). (This is equally true for application and release of the brakes).

Initial response time $t_1 - t_0$: Elapsed time between the moment when the component of the control device on which the control force acts starts to move and the moment when the braking force takes effect.

Pressure build-up time $t_1' - t_1$: Period that elapses between the point at which the braking force starts to take effect and the point at which a certain level is reached (75 % of asymptotic pressure in the wheel-brake cylinder as per EU Directive 71/320/ EEC [3], Annex III/2.4).

Initial response and pressure build-up time: The sum of the initial response and pressure build-up times is used to assess how the brake system behaves over time until the moment at which full braking effect is reached.

Active braking time $t_4 - t_1$: Elapsed time between the moment when the braking force starts to take effect and the moment when the braking force ceases. If the

vehicle stops before the braking force ceases, the time when motion ceases is the end of the active braking time.
Release time: Elapsed time between the moment when the control device starts to release and the moment when the braking force ceases.

Total braking time $t_4 - t_0$: Elapsed time between the moment when the control device on which the control force acts starts to move and the moment when the braking force ceases. If the vehicle stops before the braking force ceases, the time when motion ceases is the end of the active braking time.

Braking distance s
Distance traveled by the vehicle during the total braking time. If the time when motion ceases constitutes the end of the total braking time, this distance is called the "stopping distance".

Braking work W
Integral of the product of the instantaneous braking force F_f and the elementary movement ds over the braking distance s:

$$W = \int_0^s F_f \, ds \, .$$

Instantaneous braking power P
Product of the instantaneous total braking force F_f and the vehicle's road speed v:

$$P = F_f \, v \, .$$

Braking deceleration
Reduction of speed obtained by the brake system within the considered time t. A distinction is made between the following:

Instantaneous braking deceleration

$$a = \frac{dv}{dt} \, .$$

Mean braking deceleration over a period of time
The mean braking deceleration between two points in time t_B and t_E is

$$a_{mt} = \frac{1}{t_E - t_B} \int_{t_B}^{t_E} a(t) \, dt;$$

This means that:

$$a_{mt} = \frac{v_E - v_B}{t_E - t_B} \, ,$$

where v_B and v_E are the vehicle speeds at the times t_B and t_E.

Mean braking deceleration over a specific distance
The mean braking deceleration over the distance between two points s_B and s_E is:

$$a_{ms} = \frac{1}{s_E - s_B} \int_{s_B}^{s_E} a(s) \, ds \; ;$$

This means that:

$$a_{ms} = \frac{v_E^2 - v_B^2}{2 \, (s_E - s_B)}$$

where v_B and v_E are the vehicle speeds up to the points s_B and s_E.

Mean braking deceleration over the total braking distance
The mean braking deceleration is calculated according to the equation:

$$a_{ms0} = \frac{-v_0^2}{2 \, s_0} \, ,$$

where v_0 relates to the time t_0 (special instance of a_{ms} where $s_E = s_0$).

Mean fully developed deceleration d_m
Mean fully developed deceleration over the distance determined by the conditions $v_B = 0.8\, v_0$ and $v_E = 0.1\, v_0$ thus:

$$d_m = \frac{v_B^2 - v_E^2}{2 \, (s_E - s_B)}$$

The mean fully developed deceleration is used in ECE Regulation 13 [6] as a measure of the effectiveness of a brake system. Since positive values for d_m are used here, the mathematic sign has been reversed in this case. (In order to establish a relationship between braking distance and braking deceleration, braking deceleration must be expressed as a function of the distance traveled.)

Braking factor z
Ratio between the total braking force, F_f, and the permissible total static weight, G_s, exerted on the axle or axles of the vehicle:

$$z = \frac{F_f}{G_s} \, .$$

Legal regulations

General Certification for a vehicle with regard to its brake system may only be granted when the brake system complies with the following regulations:
– § 41 StVZO [4] (German Road Vehicle Registration Regulation) in conjunction with § 72 StVZO [5] and the associated directives.
– Council Directive of the European Community (RREG) 71/320/EEC [3], associated Amending Directives and Annexes.
– ECE Regulations R13 [6], R13H [7], R78 [8].

In § 41 StVZO, the requirements placed on the brake system differ depending on the type, gross weight rating, application, date of registration, and type-determined top speed. In the EC Directives, the requirements are allocated to individual vehicle categories. The vehicle categories are as follows:
– M1, M2, M3: Passenger cars with at least four wheels,
– N1, N2, N3: Commercial vehicles with at least four wheels,
– O1, O2, O3, O4: Trailers and semitrailers,
– L1, L2, L3, L4: Motorcycles, threewheelers.

The values stipulated in § 41 StVZO with regard to mean fully developed deceleration do not apply, for example, to the recurring inspections required in Germany for registered vehicles on the road (general inspection, safety inspection). In these inspections, the requirements of § 29 StVZO [9], s. 1, Annex VIII in conjunction with Annex VIIIa, Guideline for performing the general inspection and Guideline for performing the safety inspection, apply.

The requirements in § 41 StVZO and ECE-R13H with regard to brake equipment are essentially identical. However, ECE Regulations R13, R13H and R78 have been further updated and also contain, for example, regulations covering electronically controlled brake systems. The prescribed braking effects must be determined in accordance with Directive 71/320/EEC, s. 1.1.2, Annex II, amended by Directive 98/12/EC [10], or in accordance with § 41 StVZO, s. 12.

Requirements placed on brake systems
(as per § 41 StVZO, EC Directive 71/320/EEC, ECE-R13, as at 2009)
Category M and N vehicles must comply with the provisions which pertain to the service, secondary and parking brake systems. The brake systems may have common components. Such vehicles must have at least two mutually independent control devices for the brake systems, one of which must be lockable. The control devices must be fitted with separate transmission devices, each must be able to continue operating when the other fails. The distribution of braking force between the individual axles is prescribed and must be sensible. If a malfunction occurs, it must be possible to achieve the prescribed secondary braking effect with the remaining operational part of the brake system or with the vehicle's other brake system without the vehicle departing from its lane.

Vehicles in categories M2 and N2 and above must be fitted with automatic antilock braking facilities. Regulation EC 661/2009 [11] stipulates that from 1 November 2011 all new vehicle models and from 2014 all new category M1 and N1 vehicles to be brought onto the road must be equipped with an electronic driving-dynamics control system (Electronic Stability Program). This regulation also applies, with the exception of off-road vehicles as per Directive 2007/46/EC [12], Annex II, Part A, to vehicles in the following categories:
– M2 and M3, except vehicles with more than three axles, articulated buses and buses of category 1 or A,
– N2 and N3, except vehicles with more than three axles, tractor units with a total weight of between 3.5 and 7.5 t and special-purpose vehicles as per Directive 2007/46/EC, Annex II, Part A,
– O3 and O4, with pneumatic suspension, except vehicles with more than three axles, trailers for heavy transports and trailers with areas for standing passengers.

The implementation of this regulation for the vehicle categories, except categories M1 and N1, is defined in Regulation EC 661/2009 [11], Annex V.

Continuous-operation brake systems
Continuous-operation brake systems are additionally used to relieve the strain on the service brake on long downhill gradients. Category M3 vehicles for local and long-distance duty (buses weighing more than 5.5 t (except city buses)) and other category N2 and N3 vehicles with a gross weight rating of more than 9 t (Directive 71/320/EEC, §41 StVZO, s. 15) must be equipped with a retarder. Exhaust brakes or similar facilities are classed as retarders. The retarder must be designed to hold the vehicle when fully laden when driving on a downhill gradient of 7% and a distance of 6 km at a speed of 30 km/h.

Category O trailers
Category O1 trailers are not required to have their own brake system; a securing connection to the tractor vehicle is sufficient. Category O2 trailers and above must be fitted with service and parking brake systems, which may have common components. The distribution of braking force between the individual axles is prescribed in Directive 71/320/EEC. It must be sensibly distributed between the axles.

Category O3 trailers and above (ECE), as well as trailers and semitrailers with a gross weight rating of more than 3.5 t and a type-determined top speed of more than 60 km/h (§41b StVZO, s. 2), must be equipped with an antilock braking facility. Semitrailers only need to be equipped with ABS if the gross weight rating reduced by the fifth-wheel load exceeds 3.5 t.

Category O3 trailers (existing types) which are registered for use on public roads after 11.07.2014 or 01.11.2014 must be equipped with an electronic driving-dynamics control system (Electronic Stability Program). For new types, this regulation will already apply from 01.11.2011 or 11.07.2012 (Regulation EC 661/2009 [11], Annex V).

Category O2 trailers and below must be equipped with inertia brake systems. The trailer must brake automatically if it becomes decoupled from the tractor vehicle while moving, or (for trailers weighing less than 1.5 t) it must be equipped with a securing connection to the tractor vehicle.

Category L vehicles
Motorized two- and three-wheeled vehicles must be equipped with 2 mutually independent brake systems. In the case of duty category L5 three-wheel vehicles, the two brake systems must both act on all the wheels. A parking brake system must be fitted.

Tractor vehicles and trailers with compressed-air brake systems
The compressed-air connections between the individual vehicles must be of the dual- or multi-line design. This ensures that the compressed-air brake system in the trailer can also be refilled during the braking operation. When the service brake system on the tractor unit is operated, the service brake system on the trailer must also be operated with a variable degree of force. If a fault occurs in the service brake system of the tractor unit, that part of the system not affected by the fault must be capable of braking (controlling) the trailer with a variable degree of force. If one of the connecting lines between tractor unit and trailer is interrupted or develops a leak, it must still be possible to brake the trailer, or it must brake automatically.

The energy accumulators of the service brake systems must be designed such that, after eight full operations of the service brake, at least the requested secondary braking effect is furnished on the ninth braking. The energy accumulators must not be replenished during this test. The braking effect of the individual vehicles is prescribed as a function of the pressure at the “Brake” coupling head in Directive 71/320/EEC.

Vehicles with antilock braking facilities
Antilock braking facilities must comply with Directives 71/320/EEC, Annex X and ECE-R13, Annex 13. An antilock braking facility is part of a service brake system which automatically controls the slip in the direction of wheel rotation at one or more

of the vehicle's wheels during the braking operation. The requirements placed on the antilock braking facility differ, depending on the category, for vehicles ABS categories 1, 2 and 3, for trailers ABS categories A and B.

Essential requirements placed on the antilock braking facility (Category 1) are:

- Locking of the directly controlled wheels under braking must be prevented at speeds of over 15 km/h on all road surfaces.
- Directional stability and maneuverability must be maintained. Under a μ-split condition (extremely different coefficients of friction between the left and right wheels), steering corrections of 120° during the first two seconds and 240° in total are permissible.
- There must be a special visual warning system (yellow warning signal) to indicate electrical faults.
- Motor vehicles (except Categories M1 and N1) with ABS which are equipped to tow a trailer with ABS must be fitted with a separate visual warning system (yellow warning signal) for the trailer. Transfer must be effected via pin 5 of the electrical plug-in connection as per ISO 7638 [13].
- The energy accumulators of the service brake system in vehicles with ABS must be designed such that the prescribed secondary braking effect is still achieved even after a controlled braking operation of longer duration ($t = v_{max}/7$, at least 15 seconds) and then four uncontrolled full-braking operations without energy replenishment.

Requirements and test conditions

The required values and test conditions must be applied during the test in accordance with § 19 [14] and § 20 StVZO [15]. Departures from the test method described in Directive 71/320/EEC, Annex II, s. 1.1.2, last amended by Directive 98/12/EC and the test method specified in § 41 StVZO, s. 12, are permitted – especially during verification checks as per § 29 StVZO – if the condition and the effect can be ascertained by other means (§ 41 StVZO, s. 12). When vehicles to be newly registered are tested, a higher braking deceleration corresponding to the usual easing of the braking effect must be achieved; furthermore, sufficient state-of-the-art continuous brake duty must be guaranteed for longer stretches of downhill driving.

Minimum retardation and max. permissible control forces during the general inspection as per § 29 StVZO

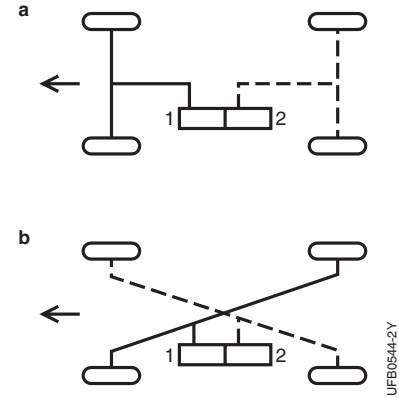
The required retardation values are determined on test benches and only in exceptional cases in road tests. The required values are maximum values, because the time response which is needed to determine the mean fully developed deceleration is not measured in these recurring inspections.

Structure and organization of brake systems

Essential requirements
The brake systems in motor vehicles must comply with the requirements of Directive 71/320/EEC, ECE-R13 Part 1, ECE-R13 Part 2 and ECE-R13 H, and other country-specific regulations. Motor vehicles must be equipped with two separate brake systems, one of which must be lockable. The brake systems must have separate control devices. In the event of a fault in the service brake system, it must still be possible for at least two wheels (not on the same side) to be braked.

Types of brake system
The brake systems comprise the service brake and parking brake systems and (in commercial vehicles and motor buses) the continuous-operation (retarder) brake system. The requested secondary brake system normally comes into play when a fault occurs in the service brake system. Special-purpose vehicles with special requirements may also have special braking functions such as a hill-climbing brake or an anti-jackknifing brake.

Type of force generation
When it comes to how the force is generated, there are three different types of system: muscular-energy, energy-assisted, and non-muscular-energy brake systems. In muscular-energy systems, the muscular force of the driver alone is effective, in energy-assisted systems this is boosted by booster systems (brake booster), and in non-muscular-energy systems, the driver's control force acts only as a control variable. The maximum required control forces are prescribed for each type of vehicle.



Transmission device
Force is transmitted from the control device to the wheel brakes by mechanical, hydraulic, pneumatic or electric means. Mechanical force transmission is only customary and prescribed for parking brake systems (§41 StVZO, s. 5).

Force transmission for the service brake system is performed via two separate brake circuits by hydraulic or pneumatic means so that at least one brake circuit remains in operation in the event of a fault.

Electrical brake operation has up to now only been used in electrically acting parking brake systems (see Electromechanical parking brake systems).

Brake-circuit configuration
Configuration of the brake circuits is governed by DIN 74000 [16]. In category M1 vehicles (passenger cars), the brake-circuit configuration is often diagonal (Figure 2b). But this is only possible in conjunction with suitable front-axle geometry (steering offset negative or neutral). In all other vehicle categories, the II configuration is used (Figure 2a). Here the front axle forms one of the brake circuits and the rear axle forms the other. All other brake-circuit configurations as per DIN 74000 are rarely used today and are therefore no longer described in these pages. The direct demand for a dual-circuit design of the transmission device is prescribed in §41 StVZO, s. 16 only for motor buses.

Figure 2: Variants of brake-circuit configuration
a) II configuration,
b) X configuration.
1 Brake circuit 1,
2 Brake circuit 2.
← Direction of travel.

Braking-force distribution
Directives 71/320/EEC, ECE-R13 and ECE-R13H also place requirements on braking-force distribution between the individual axles. This must be sensibly distributed in all load states between the axles. Braking-force distribution can be effected on the one hand through an assembly-related configuration of the wheel brakes and on the other hand through a vehicle-related configuration. Among other things, the center-of-gravity height, the wheelbase and the empty-empty ratio of the vehicle are taken into consideration.

In commercial vehicles, according to the diagrams in Directive 71/320/EEC, braking-force distribution is also dependent on the pressure at the "Brake" coupling head. Vehicle-related configuration of braking-force distribution is effected by the integration of a braking-force limiter or an automatically acting braking-force metering device (automatic load-sensitive braking-force metering).

In modern vehicles braking-force distribution is integrated as an additional function into the electronic wheel-slip control system (antilock braking facility, driving-dynamics control).

Assemblies
Brake systems in motor vehicles consist of the following assemblies, which differ in design depending on whether the system is hydraulic or pneumatic: energy supply, control devices, transmission devices, control facilities, wheel brakes, and auxiliary devices.

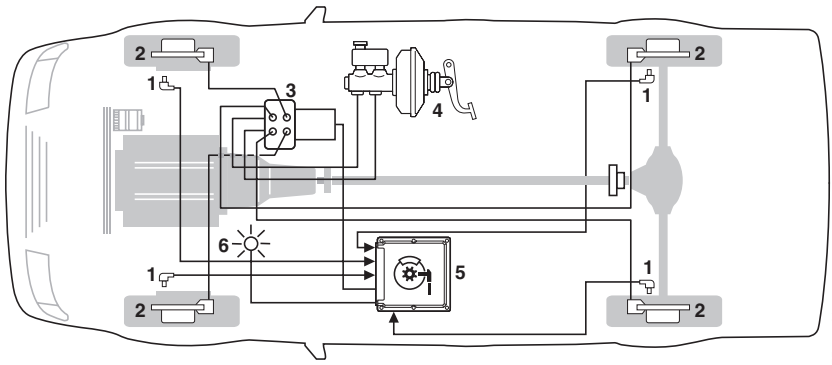
Brake systems for passenger cars and light commercial vehicles

Subdivision of passenger-car brake systems

Brake systems for passenger cars and light utility vehicles must comply with the requirements of various directives and statutory provisions, e.g., 71/320/EEC [1], ECE R13 [2], ECE R13-H [3] and in Germany §41 StVZO [4]. The requirements with regard to functioning, effect and test methods are set out in these regulations.

The entire system is subdivided into the service-brake system, the parking-brake system and the secondary-brake system.



Service-brake system
The service-brake system allows the driver to reduce with graduable effect the speed of a vehicle during normal driving or to bring the vehicle to a halt. In passenger cars and light utility vehicles it is normally designed as an energy-assisted brake system.

The driver meters the braking effect steplessly by pressing on the brake pedal. Force is transmitted to the wheel brakes via the tandem brake master cylinder to two mutually independent hydraulic transmission devices (Figure 1). The service-brake system acts on all four wheels.

Parking-brake system
The parking-brake system ("handbrake") is an independent brake system which holds the vehicle stationary, even on a gradient and especially when the driver is not in the vehicle. The holding-stationary mechanism is integrated in the wheel brake. Legal requirements stipulate that the parking brake must have a consistently mechanical connection between the control device and the wheel brake, e.g., by means of a linkage or a control cable.

The parking brake is usually actuated by a handbrake lever next to the driver's seat, and in some cases also by a pedal. In the case of electrically actuated parking-brake systems, the parking brake is locked or released by means of an electrical operating device (switch). The

5 ECU (can be directly mounted on the hydraulic modulator),
6 Warning lamp for antilock braking system and driving-dynamics control.

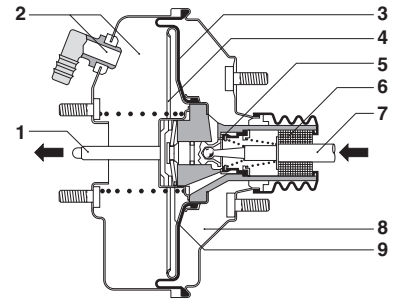
service- and parking-brake systems are thus equipped with separate, individual control and transmission devices. The parking-brake system may be graduable in design, acting on the wheels of only one axle.

The holding-stationary effect is calculated according to ECE R13-H on a downhill gradient with fully laden vehicles. The downhill gradient for single vehicles is 20 %. If the vehicle is equipped to tow a trailer, the holding-stationary effect must also be achieved with an unbraked trailer on a downhill gradient of 12 %.

Secondary-brake system
In the event of a fault, e.g., leak or fractured pipe, it must still be possible with the operational part of the brake system to achieve at least the secondary braking effect – with the identical control force at the control device. It must be possible to meter the secondary braking effect, which in turn must be at least 50 % (ECE R13-H) or 44 % (§41 s. 4a). The vehicle must not leave its lane when the secondary brake is applied.

The secondary-brake system does not need to be an independent third brake system (in addition to the service- and parking-brake systems) with a special control device. Either the intact brake circuit of a dual-circuit service-brake system or a graduable parking-brake system can be used as the secondary-brake system.

Components of the passenger-car brake system



Control device
The control device comprises those parts of the brake system which initiate the effect of this brake system. When the service brake is applied, the force of the driver's foot acts on the brake pedal. The lever-transmitted pedal force is boosted in the brake booster, depending on its design, by a factor of 4 to 10 and acts on the piston in the brake master cylinder (Figure 1). The control force is converted into hydraulic pressure. Under full braking, this pressure ranges between 100 and 160 bar, depending on the system configuration.

Vacuum brake booster
Function
The brake booster reduces the applied control force required for the braking operation, but must not impair the sensitive graduation of the braking force and the feeling of the measure of braking.

Design
Brake boosters function as vacuum-operated boosters or also hydraulically. Hydraulic brake boosters are supplied by the power steering or by a separate hydraulic pump and pressure-accumulator devices.

Passenger-car brake systems are usually equipped with vacuum brake boosters. These vacuum boosters utilize the negative pressure generated in the intake manifold during the induction stroke on gasoline engines or the vacuum (0.5 – 0.9 bar) produced by a vacuum pump on

Figure 2: Vacuum brake booster

diesel engines and on electric vehicles or hybrid vehicles to amplify the force applied by the driver's foot. A diaphragm separates the vacuum chamber with vacuum connection from the working chamber (Figure 2). The piston rod transmits the applied foot pressure to the working piston and the amplified force is passed to the brake master cylinder via the push rod.

Operating principle
If the brake is not operated, the vacuum chamber and working chamber are connected via the valve unit. Given that the vacuum connection is connected to a vacuum source, this means that there is a vacuum in both chambers.

As soon as a braking operation is initiated, the piston rod moves forwards in the direction of the arrow. After a short stroke the connection between the working chamber and the vacuum chamber is blocked. As the piston rod continues to move, the inlet valve in the valve unit is opened and atmospheric air flows into the working chamber. The pressure in the working chamber is then greater than in the vacuum chamber. The atmospheric pressure acts via the diaphragm on the diaphragm disk with which it is in contact. Because the diaphragm disk is attached to the valve unit, the latter moves when the disk moves, thereby assisting the foot pressure transmitted by the connecting rod. Maximum boost is dependent on the effective diaphragm or piston area, on the atmospheric pressure and on the effective vacuum.

When the braking operation has ended, the inlet valve is closed and the vacuum and working chambers are connected via the valve unit. In this way, the pressure (vacuum) is identical in both chambers.

Vacuum non-return valve
In all brake systems which have a vacuum brake booster a non-return valve is incorporated in the vacuum line between vacuum source and brake booster. While there is a vacuum present, the non-return valve remains open. It closes when the vacuum source ceases to produce a vacuum (engine is switched off) so that the vacuum inside the brake booster is retained. Thus, brake boost is effective even when the engine is switched off for several brake actuations.

Electromechanical brake booster
The electromechanical brake booster referred to as iBooster by Bosch satisfies, thanks to its electronic control, new demands imposed on brake systems. These demands include for example lower or no availability of vacuum in the vehicle, reduced CO_2 emissions, and redundancy for highly automated driving. The iBooster can be used with all drive concepts, including hybrid and electric vehicles. Like the vacuum brake booster, the iBooster supports the driver with an assisting force (electric motor via transmission).

Operating principle
The iBooster (Figure 3) detects the driver's brake request via an integrated differential-travel sensor and sends this information to the ECU. The ECU calculates the activation of the electric motor, which converts its torque via a gear unit into the requested assisting force. Here the electric motor is activated in such a way that the differential travel between the input rod connected to the brake pedal and the transmission element connected to the electric motor is compensated to zero. The sum total of the force supplied by the booster and the driver is converted into hydraulic pressure in a standard brake master cylinder. The iBooster's resulting pedal characteristic is dependent on the design of the components (e.g., on the maximum motor force). Certain parameters can, in contrast to the vacuum brake booster, be additionally influenced by the software logic.

Special features
The iBooster enables the pedal characteristic to be adapted whereby the assisting force is adapted by means of a change to the target-value calculation of the control facility. It is thus possible to adapt the so-called jump-in and the boost factor (Figure 4) within certain limits to the requirements specified by the vehicle manufacturer. Jump-in is the point at which the driver force proportionally influences the brake-booster braking force. Below the

jump-in the braking force comes solely from the booster itself. The driver must first overcome spring forces before his/her initiated force influences the braking force.

In vehicles with an electric or hybrid drive the iBooster, in combination with a special type of driving-dynamics control (Electronic Stability Control ESC), enables brake energy to be recuperated to a vehicle deceleration of 0.3 g without affecting the braking feel. Here during braking the decelerations caused by wheel brake and electric machine are variably matched to each other without additional components. In hybrid vehicles this regenerative braking reduces fuel consumption and CO_2 emissions – especially in the event of frequent braking and accelerating in urban traffic.

The iBooster can build up brake pressure automatically (without actuating the brake pedal) with the aid of the engine/transmission unit. Compared with typical driving-dynamics control systems, the required brake pressure is built up faster and adjusted with greater accuracy. This is beneficial for example for automatic emergency-braking systems and ACC functions.

In combination with driving-dynamics control the iBooster offers the brake-system redundancy required for automated driving. Both systems are, independently of one another, able to generate brake pressure and decelerate the vehicle.

Brake master cylinder

The brake master cylinder converts the foot force applied by the driver and boosted by the brake booster into hydraulic brake pressure.

Brake master cylinder with central valve

Design

In order to comply with statutory safety requirements, service-brake systems are

equipped with two separate service-brake circuits. If a leak occurs (circuit failure), the other circuit remains intact (secondary braking effect). This can be achieved by a tandem brake master cylinder (Figure 5). The compression spring of the intermediate-piston circuit in the rest state holds the intermediate piston and the push-rod piston against the rear stop. The compensating port and the central valve are opened. Both hydraulic service-brake circuits are depressurized (drive position).

Operating principle
The force applied at the brake pedal and boosted by the brake booster acts directly on the push-rod piston and pushes it to the left. After short piston travel the compensating port is sealed and a pressure build-up can take place in the push-rod circuit. This also causes the intermediate piston to be pushed to the left.

Brake master cylinder with captive piston spring
Design
The "captive" piston spring – a compression spring – in the rest state holds the push-rod piston and the intermediate piston always at the same distance (Figure 6). This prevents the piston spring in the rest state from pushing the inter-

mediate piston and the latter from overrunning the compensating port with the primary cup seal. In this situation pressure compensation via the compensating port would no longer be possible in the secondary circuit, and in the event of a residual pressure the brake shoes would not lift off the brake drums when the brake releases.

Operating principle
When the brake is actuated, the push-rod piston and the intermediate piston move in the direction of the arrow to the left, overrun the compensating ports and force brake fluid through the pressure ports into the brake circuits. As pressure increases the intermediate piston is no longer moved by the captive piston spring, but instead by the pressure of the brake fluid.

Expansion reservoir
The expansion reservoir, also called the brake-fluid reservoir, is mounted directly on the brake master cylinder and connected to it via two ports. It is both the reservoir for the brake fluid and the expansion reservoir. It compensates volume fluctuations in the brake circuits which occur after the brake is released, in response to wear of the brake linings and to temperature differences in the brake system, and during intervention by the antilock braking system (ABS) or the driving-dynamics control (Electronic Stability Control).

Transmission device
The hydraulic pressure is transmitted by the brake fluid via brake pipes as per DIN 74234 [5] and brake hoses as per SAE J 1401 [6] to the wheel-brake cylinders. Brake fluids must comply with the requirements laid down in SAE J 1703 [7] or FMVSS 116 [8] (see Brake fluids).

Wheel brakes
Floating-caliper disk brakes are usually used on the front wheels, but fixed-caliper disk brakes may also be used. Both floating-caliper disk brakes with integrated locking mechanism and Simplex drum brakes are used on the rear wheels (see Wheel brakes). Combinations of disk brakes and drum brakes (drum-in-head systems) can also be used on the rear wheels. In this case, the drum brake accommodated in the brake-disk chamber is used exclusively for the parking-brake system.

The parking-brake control device can be mechanically designed as a handbrake lever or a footbrake pedal with locking mechanism. Force is generally transmitted via cables or linkage to the wheel brakes on the rear axle. In the case of electromechanical parking brakes, the brake is actuated by means of electric motors and gearings (see Electromechanical parking-brake system).

Hydraulic modulator
Arranged between the brake master cylinder and the wheel brakes is the hydraulic modulator of the antilock braking system or the driving-dynamics control system and, depending on the scope of functions, a braking-force regulator or a braking-force limiter. These components, by limiting and adapting the brake pressure mostly on the rear axle, ensure a sensible distribution of braking force between the front and rear axles. This function can, especially in vehicles with markedly different load states, be executed on a load-sensitive basis (automatic load-sensitive braking-force metering).

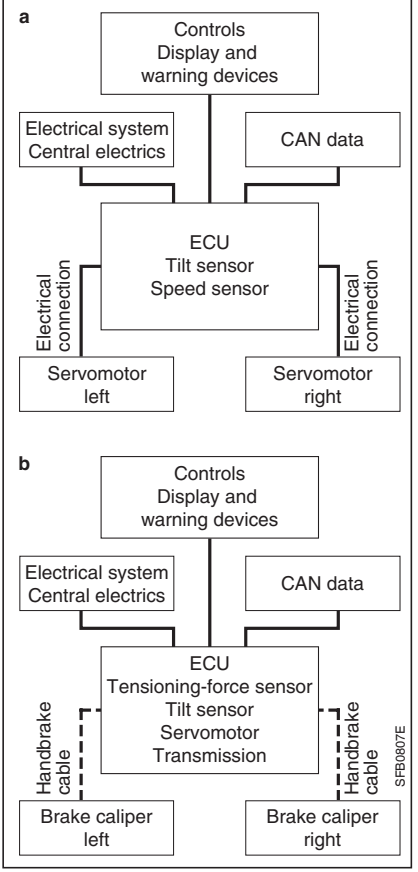
The hydraulic modulator modifies the brake pressure during the braking process in such a way that the wheels are prevented from locking. Depending on the control variation, this job is performed by several solenoid valves and an electrically driven supply pump. In passenger-car brake systems, the front axle is individually controlled, i.e., each wheel is braked according to the respective grip. The rear wheels are controlled according to the select-low principle so that both rear wheels are braked together according to the wheel which has the lower grip (see also Antilock braking system and Driving-dynamics control).

Electromechanical parking brake

System overview

Conventional parking-brake systems are muscular-energy brake systems and are operated by purely mechanical means via lockable hand levers or foot pedals or via a crankgear. In electromechanical parking-brake systems, also referred to simply as electromechanical parking brakes or automatic parking brakes, the control (operating) force is generated by an electric drive.

Operation and control are effected electrically via a switch or via logic control commands by other ECUs, which enable automatic closing or opening of the parking brake. The electromechanical parking brake can only be operated when the vehicle is stationary or at low speeds (usually 3 to 15 km/h). This must also be possible when the ignition and starting switch is turned off. If electric parking-brake systems are operated at higher speeds, an emergency-braking operation is first executed by the driving-dynamics control system. The parking brake is closed when the stationary vehicle status is attained within this braking operation.



The application force in the parking mechanism (see Parking brake) depends on the slope of the gradient on which the vehicle was parked. For this purpose, depending on the system, a tilt sensor is installed in the ECU of the electromechanical parking brake or corresponding sensor signals from other ECUs are used (e.g., airbag or chassis control). The retensioning of the brake necessitated by the cooling of the mechanical brake components is performed preventatively or according to a calculated temperature model and after vehicle movement has been detected.

A safety concept must ensure that unintentional activation in both the release and the closing directions due to electrical faults is ruled out. Furthermore, intentional activation of the electromechanical parking brake (emergency braking, only necessary if the control device of the service-brake system is broken) must not give rise to critical driving situations. If the operating unit of the electromechanical parking brake is deliberately actuated on a permanent basis, the driving-dynamics control system takes over the task of braking the vehicle at a speed in excess of 10 km/h. This ensures an optimally safe braking operation even in critical road situations. The electromechanical parking brake is locked only after the vehicle speed has dropped below a specific threshold. The systems communicate with each other through an adequate data link (usually CAN or FlexRay).

Electric parking-brake systems may feature additional functions such as automatic release when starting.

Electric parking-brake systems are energy-assisted systems and are equipped

Figure 7: Electric parking-brake system
a) System with servomotor on brake caliper,
b) System with cables.

with an emergency release device. It must also be possible for the system to be activated even when the ignition and starting switch is turned off, and the system may only be released when the ignition and starting switch is turned on and the brake pedal is simultaneously being pressed (or in the event of automatic release when the brake pedal is pressed).

The driver is always alerted to a locked parking brake system by a red warning lamp. Self-diagnosis detects malfunctions and faults, and indicates them via a warning lamp. A text message can also appear in a driver information display. The fault memory can be read out with a diagnostic tester and cleared after the fault has been corrected.

Diagnosis testers and relevant software may be required for servicing work, e.g., when replacing the brake pads.

Electromechanical parking brake with servomotor on the brake caliper

The electromechanical parking brake with servomotor comprises the following components (Figure 7a): operating unit, ECU, display and warning devices, tilt sensor (can be installed in the driving-dynamics control system), floating caliper with electric motor and multiple-stage gearing. A system distribution as described in VDA Recommendation 305-100 [9] is becoming increasingly common. This entails integrating the functionality of the parking brake in the driving-dynamics control system, thereby affording freedom in the choice of different manufacturers of these systems and the parking brake.

In the case of a brake caliper with an electric servomotor, force is transmitted for the parking-brake effect via a multiple-stage gearing and a threaded spindle. It is activated by way of an electrical switch (operating unit), which forwards the control commands to the ECU redundantly and in accordance with the safety concept. The ECU, taking into account further boundary conditions (e.g., road gradient), activates the electric servomotors via separate driver stages and electrical connecting leads.

A very high gear ratio means that very high application forces can be generated. These are in the region of 15 to 25 kN. As dictated by the concept, the electromechanical and hydraulic forces can be superimposed (superposition at the brake piston).

Electromechanical parking brake with cables

In the case of an electromechanical parking brake with cables, the following components are combined in a centrally arranged assembly – above the rear axle, in the passenger compartment or in the fender (Figure 7b): electric drive motor with gearing, required sensors (depending on the scope of functions, e.g., force, tilt, temperature and position sensors), ECU, and cable mechanism (if necessary with emergency release device).

This system too is activated by way of an electrical switch, which forwards the control commands to an ECU. The ECU activates the electric servomotor(s) via a driver stage. The application force can vary, depending on the road gradient. The system is automatically retensioned when the vehicle is stopped either after a cooling phase corresponding to a temperature model or after vehicle movement has been detected.

Electrohydraulic brake

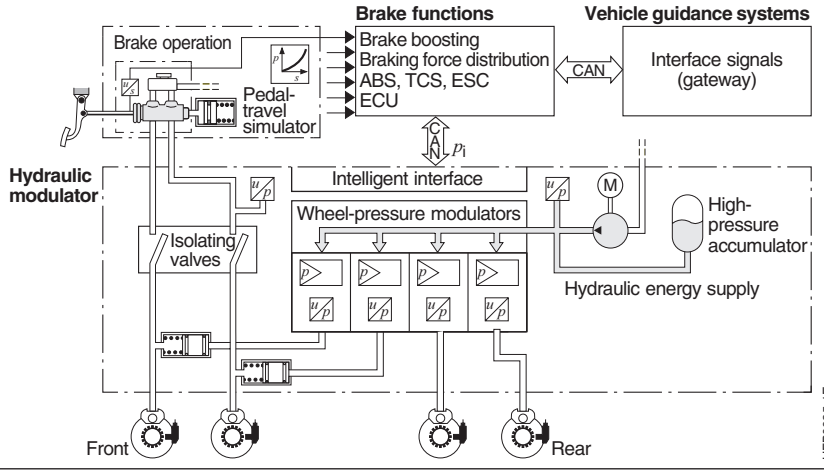
Function

The electrohydraulic brake (EHB, "Sensotronic Brake Control", SBC) is an electronic brake-control system with hydraulic actuator engineering. Like a conventional hydraulic brake, its function is to reduce vehicle speed, bring the vehicle to a halt, or keep the vehicle stationary. As an active braking system, it takes control of brake operation, braking-force boosting and braking-force control. Hydraulic standard wheel brakes are used as brakes.

Actuation unit

Mechanical operation of the brake pedal is detected by the actuation unit by means of electronic sensors with redundant backup (Figure 8). The pedal-travel sensor consists of two separate angle-position sensors. Together with the brake-pressure sensor for the pressure applied by the driver, this produces a threefold system for detecting driver input. The system can continue to function normally, even if one of the sensors fails.

The pedal-travel simulator produces an appropriate force/travel curve and calculates the amount of brake-pedal damping. The driver experiences the same "brake feel" with electrohydraulic brakes as with a very well designed conventional braking system.



A conventional brake booster is not required here. Only the driver's brake request is determined in the actuation unit during normal operation; the brake pressure is generated in the hydraulic modulator. The brake master cylinder performs its function in the event of a system failure. The expansion reservoir supplies the hydraulic modulator with brake fluid.

Electronic control

The brake request is determined in the remote-mounted ECU from the sensor signals of the actuation unit. Braking characteristics can be adapted to the driving conditions (e.g., sharper response with more dynamic driving styles). A "duller" pedal characteristic can be used to alert the driver to a reduction in braking effect, when the brakes reach the limits of their effectiveness before overheating induces brake fading.

Further, the functions for the antilock braking system, the traction control system, and the driving-dynamics control are integrated in the ECU. In addition, comfort and convenience functions such as for example hill hold control, automatic brake-system prefilling when the foot is quickly removed from the accelerator pedal, the chauf-

Figure 8: Interaction of electrohydraulic-brake function modules

feur brake (soft stop, jolt-free stopping by means of automated brake-pressure reduction shortly before standstill), and the brake-disk wiper are provided.

Thanks to complete electronic pressure control, the electrohydraulic brake can be easily networked with vehicle guidance systems (e.g., Adaptive Cruise Control, ACC).

Hydraulic modulator

Operating principle in normal operation

Figure 8 shows the electrohydraulic-brake components as a block diagram. An electric motor drives a hydraulic pump. This charges a high-pressure accumulator to a pressure of between approximately 90 and 130 bar, monitored by an accumulator pressure sensor. The four separate wheel-pressure modulators are supplied by the accumulator and set the required pressure at the wheel-brake cylinders separately for each wheel. The pressure modulators themselves each consist of two valves with proportional-control characteristics and a pressure sensor. Brake-pressure modulation and active braking are silent and generate no brake-pedal feedback.

In normal mode, the isolating valves isolate the brakes from the actuation unit. The system is in “brake-by-wire” mode. It electronically detects the driver’s braking request and transmits it “by wire” to the wheel pressure modulators. The interaction of electric motor, valves, and pressure sensors is regulated by the ECU. This has two microcontrollers which monitor each another. The essential feature of these electronics is their extensive self-diagnosis, which monitors the plausibility of every system state at all times. It means that any faults can be displayed to the driver before a critical condition arises. If components fail, the system automatically provides the optimal remaining partial function to the driver.

An intelligent interface with the CAN bus provides the link between the remote-mounted ECU and the add-on of the hydraulic modulator.

Braking in the event of system failure

The electrohydraulic brake is designed so that in the event of serious faults (e.g., power-supply failure), it switches to a state in which the driver can brake the vehicle without using the active brake-booster function. When de-energized, the isolating valves establish a direct connection to the actuation unit and allow a direct hydraulic connection from the actuation unit to the wheel-brake cylinders (hydraulic fallback level).

Integrated power brake

Design

In response to the increasing electrification of the drivetrain and as a result the lack of vacuum supply for the brake booster, new types of braking systems have been developed in recent years. The integrated power brake (IPB, Figures 9 and 10) is vacuum-independent and combines the following components of a conventional braking system in a single unit [11]:

– connection to the brake pedal,
– brake master cylinder,
– brake-light switch,
– brake booster,
– ESC hydraulic unit (Electronic Stability Control, electronic stability program).

Further classic brake-system components such as vacuum source or vacuum pump, long hydraulic lines from the brake master cylinder to the hydraulic unit of the brake-control system, and electrical connections are rendered superfluous. The installation requirement in the vehicle is reduced as a result.

Scope of functions

The integrated power brake (IPB) contains the following functions accordingly:

– brake boosting,
– wheel-individual brake-pressure modulation for the antilock braking system (ABS), the traction control system (TCS), and driving-dynamics control (ESC, Electronic Stability Control, electronic stability program),
– external deceleration requests, e.g., from Adaptive Cruise Control (ACC),
– highly dynamic brake-pressure build-up,
– monitoring of the hydraulic brake circuits (air and leakage monitoring),
– hydraulic fallback level for fault scenarios in accordance with functional safety (ISO 26262 [12]).

Thanks to its independence from the vacuum supply, its high energy efficiency owing to the direct use of electrical energy for brake-pressure build-up (without a hydraulic high-pressure accumulator), and its capacity to recover kinetic energy as electrical energy, the integrated power brake (IPB) is suitable for use in both vehicles with electric drives (hybrid and electric vehicles) and vehicles with internal-combustion engines. It can be used with both diagonal (X-split) and front/rear brake-circuit configurations (II-split).

Figure 9: Integrated power brake (IPB)
1 Brake pedal,
2 Adapter plate on the firewall,
3 Integrated power brake (IPB),
4 Battery, 5 Wheel brakes.

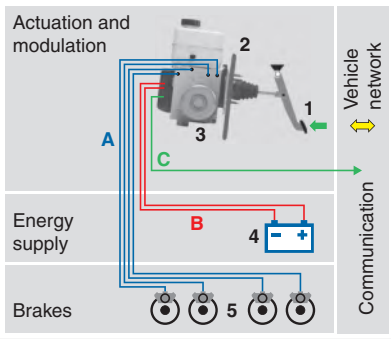
C Communication line.



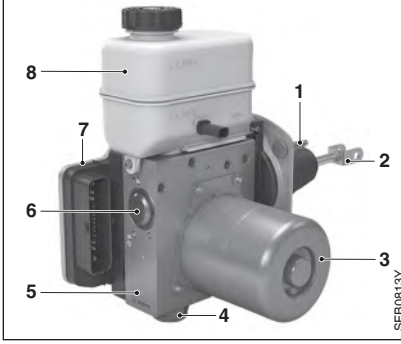


Figure 10: Components of integrated power brake (IPB)
1 Adapter for mounting on the firewall,
2 Connection to brake pedal,
3 Hydraulic module, 4 Pedal-feel simulator,
5 Valve housing, 6 Brake master cylinder,
7 Electronic control unit (ECU),
8 Brake-fluid reservoir.

The integrated power brake (IPB) is able to build up the necessary brake pressure for driver-assistance functions on the one hand very quietly and comfortably and on the other hand with high dynamic response.

The smaller number of brake-system components simplifies the production of vehicles for the vehicle manufacturer and also reduces the complexity of the value-added chain.

Functional description

Determination of the driver's braking request

The integrated power brake (IPB) is installed like a conventional brake booster on the firewall and connected with the brake pedal. The primary piston of the brake master cylinder is displaced when the brake pedal is pressed (Figure 12). The driver's braking request is determined by an integrated pedal-travel sensor.

By-wire mode

The “by-wire mode” is activated as soon as the unit detects that the driver wishes to brake (Figure 11a). The brake master cylinder is decoupled by valves from the wheel-brake cylinders and connected with a pedal-feel simulator. Because the brake pedal is decoupled from the wheel brakes the pedal feel is independent of the brake pressures at the wheels, which is beneficial to recuperation and to the configuration of the mechanical fallback level.

At the same time a plunger-cylinder system (hydraulic module) is connected via valves with the wheel brakes. The plunger of the hydraulic module is activated by an electric motor (Figure 12) precisely and in accordance with the driver's braking request. It forces brake fluid from the hydraulic module's working chamber into the wheel brakes and as a result the brake pressure requested by the driver is generated at the wheels.

Brake boosting
Brake boosting is simultaneously achieved by the pressure regulation of the hydraulic module. Because of the decoupling of the brake pedal and wheel brake pressure the brake pressure and the generator torque are masked in hybrid and electric vehicles. In other words, the braking effect of the wheel brakes can be reduced by the braking effect of the electric machine achieved by recuperation. The masking occurs continuously during recuperation and without any noticeable effects on the brake pedal.

In the case of brake-pressure requests not initiated by the driver, such as for example coming from an ACC system, pressure is generated at the wheels in the same way by means of the hydraulic module.

Wheel-individual brake interventions
For wheel-individual pressure generation or pressure modulation – similarly to an ESC system (see ESC hydraulic unit) – inlet and outlet valves (brake-pressure modulation valves, Figure 11) are integrated in the integrated power brake (IPB). A build-up of pressure at a wheel is effected via the hydraulic module when the inlet valve assigned to this wheel is opened. A reduction of pressure is effected by the opening of the outlet valve assigned to this wheel whereby the brake fluid flows directly back into the brake-fluid reservoir. The wheel-individual functions such as antilock braking system (ABS), traction control system (TCS), and lateral-dynamic stabilization by driving-dynamics control (electronic stability program).

Because the brake-fluid volume in the hydraulic module is limited by the design, the hydraulic module is recharged with brake fluid within a matter of a few milliseconds during a long ABS control operation. The brake pressure in the individual wheels is maintained during recharging and consequently there is no impact on the vehicle's braking effect.

Functional safety
In the case of safety-related vehicle components such as the braking system, safe operation and system behavior are of central importance. The electromechanical braking system (IPB) was therefore developed in accordance with the current functional-safety standards (ISO 26262).

Redundancy
Sensing of the driver's braking requests is redundantly designed in the interests of reliability. For the brake-master-cylinder piston travel the mechanism is simple and the sensor system and electronics are present in redundant form. The piston travel is also checked for plausibility against the measure brake-master-cylinder pressure.

Fallback level
To ensure that the driver is able to slow down the vehicle reliably in the event of a fault, the integrated power brake (IPB) has a direct, mechanical-hydraulic feedthrough from the brake pedal to the wheels as a fallback level (Figure 11b).

The process of decoupling the brake master cylinder from the wheel brakes (in by-wire mode) – in contrast to conventional braking systems – reduces the diameter of the brake master cylinder. In the mechanical fallback level a higher brake pressure and with it a greater deceleration of the vehicle are thus made possible with the same pedal force.

Monitoring for hydraulic changes
But, as a result of the smaller brake-master-cylinder diameter, the brake-fluid volume in the brake master cylinder is also reduced compared with a conventional braking system. The state of the braking system is therefore continuously monitored for hydraulic changes (e.g., leaks, ingress of air into the brake fluid due to leakage or faulty filling). The driver is warned before a critical system state can ensue in the event of a fault.

Reliability of the electrical power supply
The availability of brake boosting is directly allied with the supply of the integrated power brake (IPB) with electrical power. It is therefore essential to ensure that the vehicle electrical system is sufficiently reliable.

Redundancy for automated driving

Second pressure-build-up unit

For automated-driving vehicles where the driver is no longer responsible for control of the vehicle, the integrated power brake (IPB) can be enhanced by a second, independent pressure-build-up unit (RBU, redundant brake unit) to generate brake pressure. If the integrated power brake (IPB) fails, this independent unit ensures that the vehicle can be slowed down and brought to a stop.

Integrated redundancy

Integrated redundancy in the IPB may also be considered as an alternative to a second, independent pressure-build-up unit. Full redundancy is however not possible for all the system components. Seals or transmission elements for converting the rotary motion of the engine into a translatory motion of the piston cannot be redundantly designed automatically.

Market development

An integrated power brake (IPB) with integrated redundancy would result in a more complex design with increased dimensions. Automated driving is therefore only implemented with two independent pressure-build-up units, the integrated power brake (IPB) and the redundant brake unit (RBU).

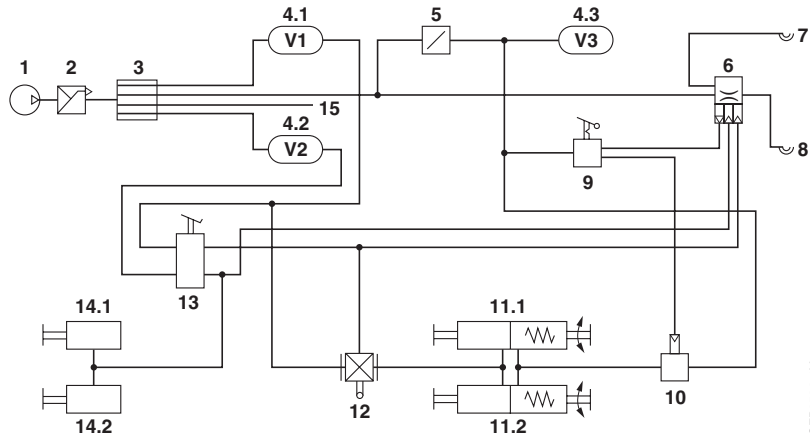
Brake systems for commercial vehicles

System overview

Brake systems for commercial vehicles and trailers must satisfy the requirements of various regulations such as, for example, RREG 71/320 EEC and ECE R13 [2]. Essential functions, effects and test methods are set out in these regulations. The entire system is subdivided into the service-brake, parking-brake, secondary-brake systems, and continuous-action brake systems.

Service-brake system

Service-brake system, tractor vehicle



The service-brake system, designed as an energy-assisted brake system in commercial vehicles (Figures 1 and 2), can operate with compressed air or also with a combination of compressed air and hydraulics.

In the event of a fault, e.g. brake-circuit failure, it must still be possible with the operational part of the system to achieve at least the secondary braking effect – with the identical control force at the normal control device. It must be possible to meter the effect, and the trailer must not be affected by this malfunction, i.e. the trailer control (trailer control valve) must have a dual-circuit design. The secondary braking effect must achieve at least 50 % of the braking effect of the service-brake system. It is therefore customary to split the system into two brake circuits already separate on the supply side, even though this configuration is only legally required in motor buses.

The energy supply to the trailer must be guaranteed even during the braking operation. The dual-line system became mandatory when RREG 71/320 came into force, but had already been available prior to this and was known by the name “Nato” brake.

7 “Supply” coupling head (red), 8 “Brake” coupling head (yellow),
9 Parking-brake valve with test position, 10 Relay valve,
11.1 Combination brake cylinder, rear right, 11.2 Combination brake cylinder, rear left,
12 Load-dependent braking-force regulator (ALB), 13 Service-brake valve,
14.1 Brake cylinder, front right, 14.2 Brake cylinder, front left,
15 Secondary loads/ancillaries (e.g. pneumatic suspension, door-closing system).

The trailer is continually supplied with a defined pressure via the supply line. This pressure must be between 6.5 and 8.0 bar on an intact tractor vehicle, irrespective of the tractor vehicle's operating pressure established by the manufacturer. The trailer must be exchangeable. The trailer's service-brake system is controlled by a second line, the brake line. This line is also governed by the regulations pertaining to trailer exchangeability. Thus the pressure in the brake line must be 0 bar in driving mode, and 6.0 to 7.5 bar in fully-braked mode.

Service-brake system, trailer

The trailer has an independent service-brake system, which is only partly subject to the demand for a secondary braking effect. According to the requirements in RREG 71/320, the braking effects of the service-brake systems in the tractor vehicle and in the trailer must be within closely set tolerances as a function of the control pressure in the brake line to the trailer, i.e. they must be approximately the same (design tolerance band RREG 71/320 and ECE R13).

If the supply line or the brake line is fractured, the trailer must be able to be fully or partly braked or it must initiate an automatic braking. Commercial vehicles with electronically controlled brake systems have – in addition to the pneumatic brake line – an electrical signal-transmission feature for electrically controlling the service-brake system in the trailer. This is

Figure 3: Compatibility diagram

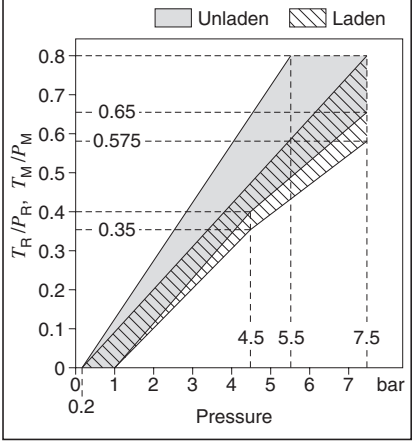
P_m Pressure at "Brake" coupling head.



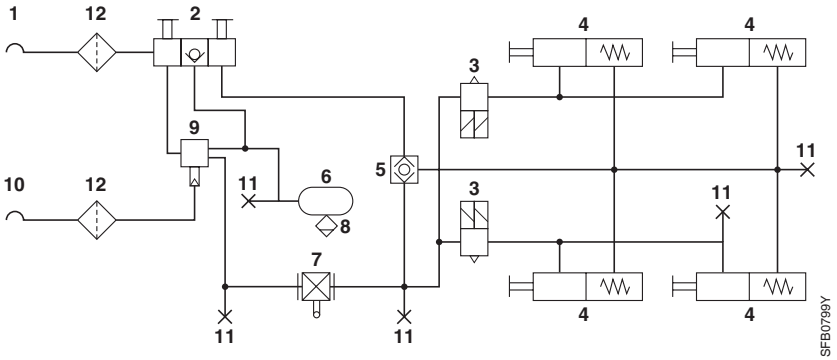


Figure 2: Compressed-air brake system of a 2-axle semitrailer with ABS (simplified representation)

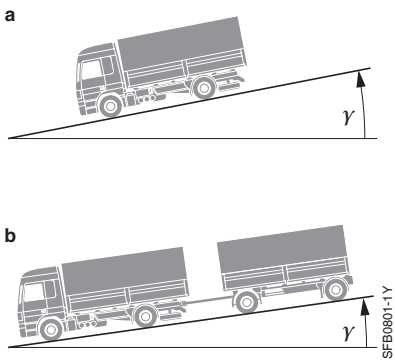
1 "Supply" coupling head (red), 2 Double release valve, 3 1-channel ABS pressure-control valve, 4 Combination brake cylinder, 5 Shuttle valve, 6 Air reservoir, 7 Load-sensitive braking-force regulator, 8 Drain valve, 9 Trailer brake valve, 10 "Brake" coupling head (yellow), 11 Test connection, 12 Line filter.

performed by a standardized electrical plug-in connection in accordance with ISO 7638 [3]; this plug-in connection may have 5 or 7 pins.



Tractor vehicles and trailers must be freely exchangeable. Compatibility conditions have therefore been defined in Annex 2 RREG 71/320 and ECE R13. Accordingly, the ratio between retardation and pressure at the "Brake" coupling head in the range depicted in Figure 3 must be in the range of 0.2 to 7.5 bar at the "Brake" coupling head. The diagram only applies to tractor vehicle and trailer. All other vehicles and vehicle combinations are covered by other diagrams.

Parking-brake system

The parking-brake system is an independent brake system which must hold the vehicle stationary after it has been brought to a stop, even when the driver is not in the vehicle. The holding-stationary effect is calculated on a downhill gradient with fully laden vehicles. The downhill gradient for Category M, N, O single vehicles (except O1) is 18%. If the vehicles are equipped to tow a trailer, the holding-stationary effect must also be achieved with an unbraked trailer. The downhill gradient is then only 12% (Figure 4).

Figure 4: Test condition for parking-brake system

a) Single vehicle, 18% downhill gradient.
b) Tractor vehicle and trailer, 12% downhill gradient; only the tractor vehicle is braked.
γ Gradient angle.

The parking-brake system in commercial vehicles and motor buses is usually designed as a spring-loaded brake system. The springs in the spring-type brake cylinders, when the wheel brakes are adjusted in accordance with the regulations, generate the same force as the pneumatic brake cylinders in the service-brake system when the nominal pressure (brake-system calculated pressure) acts on their nominal effective area. If certain malfunctions occur, e.g. brake-circuit failure or energy-source failure, the spring-loaded brakes may not brake automatically and must therefore be protected and designed accordingly.

Energy-assisted parking-brake systems (spring-loaded brake systems) must be equipped with at least one emergency release device. This may be a mechanical, pneumatic or hydraulic device. The parking-brake system must then only be designed for graduated (metered) operation if it has to be engaged to achieve the prescribed secondary braking effect.

In the trailer, the parking-brake system frequently operates as a muscular-energy brake system. If the trailer control system in the tractor vehicle is configured in such a way that the service brake in the trailer also responds when the parking brake is operated in the tractor vehicle (trailer control valve with port 4.3), the parking-brake valve must be provided with a test setting. This makes it possible to release the service brake in the trailer when the parking brake in the tractor vehicle is operated. This in turn makes it possible to check whether only the tractor vehicle braked with the parking-brake system can hold the entire vehicle combination.

Secondary-brake system

There is no independent secondary-brake system. It comes into effect if a malfunction, e.g. brake-circuit failure or energy-source failure, occurs in the service-brake system. In this event, it must still be possible for at least two wheels (not on the same side) to be braked.

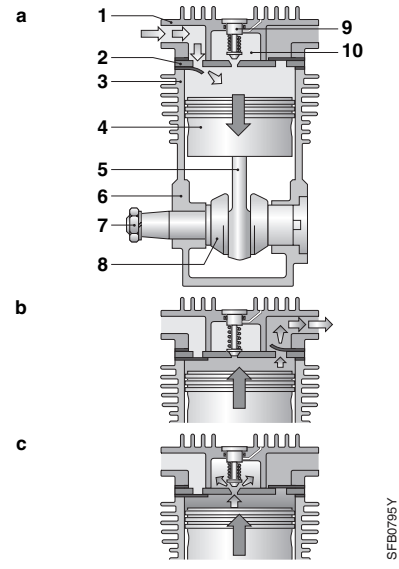
The brake system in the trailer too must not be affected by this malfunction. For this reason, the brake systems and activation of the trailer have dual-circuit designs.

The supply volume must be designed such that, in the event of an energy-source failure, after eight full operations of the service brake there is still enough pressure available to achieve the secondary braking effect on the ninth full operation. In the event of a failure of a brake circuit on the supply side, it is essential to ensure that, when the energy source is intact, the pressure in the intact brake circuits does not drop permanently below the nominal pressure. This is achieved by using special protective devices, e.g. a four-circuit protection valve or an electronic unit.

Continuous-operation brake system
The wheel brakes used are not designed for continuous operation. Prolonged braking (e.g. on hill descents) can result in the brakes being thermally overloaded. This causes a reduction in braking effect ("fading") or, in extreme cases, in complete brake-system failure.

A wear-free brake system is referred to as a continuous-operation (retarder) brake system. In Germany, they are required in accordance with StVZO §41 s. 15 [4] for motor buses with a gross weight rating of more than 5.5 t and for other motor vehicles with a gross weight rating of more than 9 t. A retarder must hold a fully laden vehicle over a distance of 6 km and a downhill gradient of 7% at a speed of 30 km/h.

The service brake must be designed accordingly for trailers. Operation of the retarder in the tractor vehicle must not cause the service brake in the trailer to be operated (see also StVZO §72 [5]).



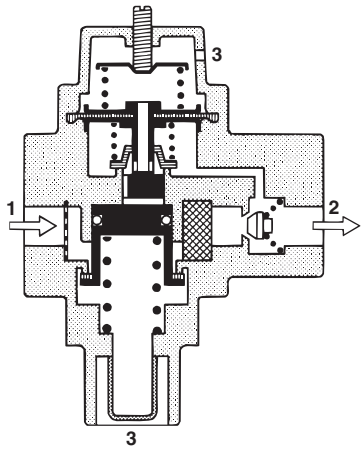
Components of commercial-vehicle brake systems

Air supply and air processing
Air supply and processing comprises the energy source, pressure control, air processing, and compressed-air distribution.

Compressor
A compressor is the source of energy. It takes in air and compresses it to compressed air, the working medium for the brake systems and the ancillaries (e.g. pneumatic suspension, door-closing system).

The compressor is a plunger pump where the crankshaft is driven directly by the vehicle engine (Figure 5). It is fitted to

Figure 5: Compressor
a) Induction,
b) Compression and discharge,
c) Compression into the additional clearance.
1 Cylinder head, 2 Intermediate plate (with inlet and outlet valves), 3 Cylinder, 4 Piston, 5 Connecting rod, 6 Crankcase, 7 Drive 8 Crankshaft, 9 ESS valve (Energy-Saving System), 10 Additional clearance.



the vehicle engine by means of a flange. Its component parts are:
– The crankcase, which forms a monobloc unit with the cylinder. It contains the crankshaft with connecting rod and piston.
– The cylinder head with intake and pressure connections, as well as connections for water cooling.
– The intermediate plate with inlet and outlet valves.

To reduce losses in the idle mode (opening and flow resistances in valves and lines), an energy-saving system (ESS) is used; this activates a clearance and thus reduces compression work. This reduces fuel consumption.

During its return stroke, the piston draws in air after the inlet valve opens automatically due to vacuum. The inlet valve closes at the start of the piston's return stroke. In the fore stroke, the piston compresses the air. When a certain pressure is reached, the outlet valve opens and compressed air is supplied to the brake system.

Nowadays, compressors achieve a stroke displacement of up to 720 cm^3, a pressure level of up to 12.5 bar, and a maximum speed of 3,000 rpm. Their features include high efficiency, low oil consumption, and a long service life.

Figure 6: Pressure regulator
1 From compressor,
2 To the compressed-air reservoirs,
3 Venting.

Pressure regulator
The pressure regulator controls the compressed air supplied by the compressor in such a way that the operating pressure lies within the activation and cutoff pressure (Figure 6).

As long as the pressure in the compressed-air reservoirs lies below the cutoff pressure, connections 1 and 2 are connected and compressed air passes the pressure regulator. Once the cutoff pressure is reached, the pressure regulator switches to idle mode. Here, the venting piston is activated and connection 1 is connected to the atmosphere (venting).

Air drier
The air drier cleans the compressed air and dries it to prevent corrosion and freezing in the brake system during winter operation.

Basically, an air drier consists of a desiccant box and a housing. The housing incorporates the air passage, a bleeder valve, and a control element for granulate regeneration (Figure 7). The granulate is regenerated by activating a regeneration-air tank.

When the bleeder valve is closed, compressed air from the compressor flows through the desiccant box and from there to the supply-air reservoirs. At the same time, a regeneration-air tank is filled with dry compressed air. As compressed air flows through the desiccant box, water is removed by means of condensation and adsorption.

The granulate in the desiccant box has a limited water absorption capacity and must therefore be regenerated at regular intervals. In the reverse process, dry compressed air from the regeneration-air reservoir is reduced to atmospheric pressure via the regeneration throttle upstream of the air drier, flows back through the moist granulate from which it draws off the moisture, and flows as moist air via the open bleeder valve to the atmosphere.

The pressure regulator and air drier can be combined into one unit.

Four-circuit protection valve

The four-circuit protection valve distributes the compressed air to the various brake and ancillary circuits, isolates the circuits from one another, and ensures the water supply for the remaining circuits in the event of failure of a circuit (Figure 8).

The function of the four-circuit protection valve is provided by overflow valves specially developed for this application. In contrast to a normal overflow valve, the design of this type of overflow valve features two different effective areas on the intake-flow side. The incoming pressure from the pressure regulator acts on one effective area, while the pressure available in the pneumatic circuit acts on the other. The opening pressure of the overflow valves is thus dependent on the (residual) pressure of the assigned pneumatic circuit.

The overflow valves can be arranged differently. Often service-brake circuits 1 and 2 and ancillary circuits 3 and 4 are connected in pairs in succession. This ensures that at least one of the two service-brake circuits is filled as a matter of priority.

4 Valve seat,
5 Non-return valve,
6 Fixed throttle.

I – IV overflow valves

Ports:
1 Energy input,
21 – 24 Energy output to circuits 1 – 4.

The ancillary circuits for this type of valve are additionally protected by two non-return valves. These non-return valves can be omitted from four-circuit protection valves with central intake flow. These overflow valves may also be provided with variable flow restrictors. These enable an empty system to be filled with small quantities of air.

If a malfunction occurs for example in circuit 1 (circuit failure due to a leak), the pressure drops initially only in circuit 1 to 0 bar and in circuit 2 to the closing pressure. The pressure in circuits 3 and 4 is initially maintained by the effect of the non-return valves, but will also drop through consumption to the closing pressure. The intact circuits continue to be supplied under subsequent delivery by the compressor, because the residual pressure in circuits 2, 3 and 4 acts on the secondary effective area of the corresponding overflow valves. The intact circuits are filled again until the opening pressure of the defective circuit (circuit 1) acts on the primary effective area of the corresponding overflow valve, opening this valve. A further pressure increase is not possible, because from this moment the delivered compressed air is lost through the defective circuit. The opening pressure via the primary effective area is adjusted in such a way that it is equal to or above at least the nominal pressure (calculated pressure) of the brake system. This ensures both a sufficient supply of compressed air for the intact service-brake circuit and the secondary braking effect. The supply to the ancillaries such as, for example, trailer, parking-brake system and pneumatic suspension is also maintained.

Electronic air-processing unit

Nowadays, the pressure control, air processing, and compressed-air distribution are combined in one electronic unit, the air-processing unit. The electronic air-processing unit (EAC, Electronic Air Control) is a functional agglomeration of the pressure regulator, air drier and multiple-circuit protection valve into one mechatronic device. In addition, the control system of the parking brake is integrated in part. In all, integrating many functions in a mechatronic unit offers significant benefits with regard to system expenditure, functionality, and energy saving.

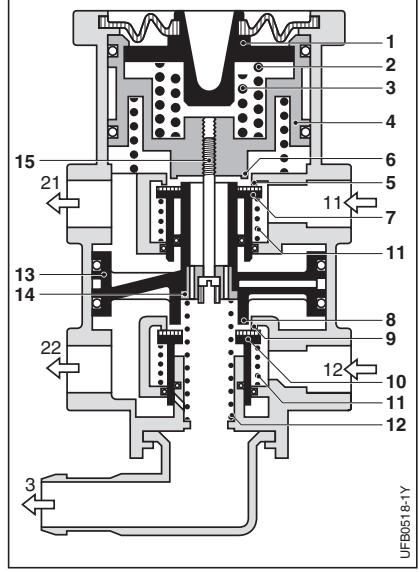
Energy storage

The energy required for the braking operation and for the function of the ancillaries is provided and stored in sufficient quantities in compressed-air reservoirs approved for use in road vehicles. The volume must be designed such that, without subsequent delivery, after eight full brakings the secondary braking effect prescribed for this vehicle is still achieved at least by the ninth full braking.

Despite the use of an air drier, the compressed-air reservoirs are equipped with manual or automatically acting drain devices. Compressed-air reservoirs are subject to the requirements of § 41a s. 8 [4] in conjunction with § 72 StVZO [5], and must be approved for use and permanently identified.

The supply systems for the brake systems must be fitted with warning devices. The following requirements apply:
– Red warning light,
– visible to the driver at all times
– comes on no later than on brake application or if the pressure in the supply system for the service brake has dropped to 65 % nominal pressure. 80 % nominal pressure applies to the supply system for the parking-brake system (spring-loaded brake).

Service-brake valve



Service-brake valves (Figure 9) have a dual-circuit design and control the service-brake circuits according to the control force (force-controlled valves).

Circuit 1 is actuated by the control device, the push rod and the compression springs (travel-compensating springs). The reaction piston is forced downwards, first closing the outlet valve and then opening the inlet valve. Compressed air is admitted into brake circuit 1 and the pressure increases. The brake pressure acts in the upward direction against the reaction piston, forcing it against the compression springs as long as the partial braking range is not exceeded. The brake end position is reached, with an equilibrium of forces existing at the reaction piston.

Circuit 2 is controlled by the brake pressure in circuit 1. This acts, instead of the control device from above, on the reaction piston of circuit 2. At approximately the same time, the brake end position is reached in circuit 2 as well. In the full-braking position or in the event of a failure of circuit 1, both reaction pistons are mechanically moved to their full extent by means of the control device. The outlet valves are closed, and the inlet valves remain open. Circuits 1 and 2 are pneumatically fully and safely isolated from each other.

Special designs facilitate different controlled brake pressures for circuits 1 and 2. These are required if a dual-circuit booster cylinder is actuated by the service-brake valve, or if circuit 2 is subject to load-sensitive control. This is made possible by installing an appropriate spring assembly or a reaction piston with several effective areas.

22 Brake pressure, circuit 2.

Parking-brake valve

Parking-brake valves (Figure 10) control the pressure in the spring-type brake cylinders as a function of the lever travel (travel-controlled valves). The lever must be permanently and securely lockable in the brake-applied position. Parking-brake valves must only operate under graduated (metered) application when the effect of the parking brake is required to achieve the secondary braking effect. Parking-brake valves must be provided with a test setting when the service-brake system is activated in the trailer on actuation of the parking brake.

Different variants of parking-brake valve exist, depending on their application: non-graduated, graduated or graduated with steep-droop characteristic curve. The latter variant provides for a highly sensitive graduable effect, because the operating range of spring-type brake cylinders, considered over the lever angle of the parking-brake valve of approximately 80°, is optimally used. The operating range of spring-type brake cylinders is between approximately 5 bar (start of braking) and approximately 2 bar (end of braking, see diagrams in Figure 11).

In pneumatic high-pressure brake systems (operating pressure greater than 10 bar), the parking-brake valve can be fitted with a pressure limiter so that standard spring-type brake cylinders can be used. The facility in parking-brake valves for attaining the capability of metering the controlled pressure is similar to the facility in service-brake valves, but operates in the opposite direction, because the spring-type brake cylinders are ventilated

Figure 10: Parking-brake valve (driving mode)

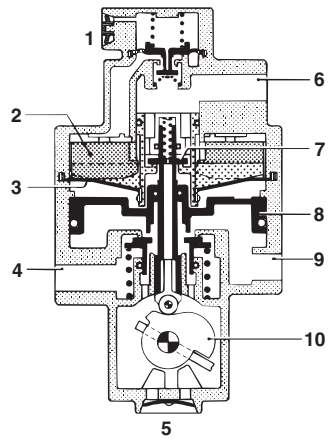
in driving mode and the brake-applied mode is achieved by bleeding.



Parking-brake valves can have a dual-circuit design. The system is supplied in this case from circuit 3 and – the pneumatic auxiliary release device of the spring-type actuators – from circuit 4. An additionally required rotary-knob, shuttle or check valve can be omitted.

In the version with steep-droop characteristic curve (Figure 11), the start of braking is attained earlier and the actuation range is significantly greater. This is particularly advantageous when the parking brake is used as a secondary brake.

As an alternative to the pneumatic parking-brake valve, there are electronically controlled parking-brake systems (Electronic Parking Brake, EPB). These consist of an EPB module (which can optionally also be integrated in the air-processing unit) and an operating unit. The EPB module contains a bistable valve that can be controlled via integrated solenoid valves and further solenoid valves for executing the trailer test function.

Figure 12: Braking-force regulator with relay valve

1 Vent, 2 Rake, 3 Transfer diaphragm, 4 Energy input from air reservoir, 5 Vent, 6 Uncontrolled pressure from service-brake valve, 7 Control valve, 8 Relay piston, 9 Controlled brake pressure to brake cylinders, 10 Rotary cam.

The parking brake can be applied and released using the operating unit, whereby the last active state is retained even after the supply voltage is shut off. Since the operating unit must have a graduable design, the parking brake can also be operated in stages and consequently function as a secondary brake.

As well as manual activation by operating unit, the EPB also provides for a series of comfort and convenience functions, e.g., automatic application when the vehicle is at a standstill (Autopark) and automatic release when starting (Autorelease).

Automatic load-sensitive braking-force regulator

A facility frequently used in the service-brake system of commercial vehicles with pneumatically controlled service-brake systems is automatic load-sensitive braking-force control (ALB). Valves that handle the braking-force distribution enable adjustment of the braking forces to the low axle loads in the partially laden and unladen state and thus a correction of the braking-force distribution on the axles of an individual vehicle or a certain braking level in road trains or semitrailers.

The braking-force regulator (Figure 12) is connected between service-brake valve and brake cylinder. Depending on vehicle payload, it regulates the applied braking pressure. The device has a transfer diaphragm with variable effective area. The diaphragm is held in two radially arranged, interlocking rakes. Depending on the vertical position of the control-valve seat, there is a large reaction area (valve position at bottom) or a small reaction area (valve position at top). Consequently, the brake cylinders are supplied via an integrated relay valve with a reduced pressure which is lower than (unladen), or which is the same as (fully laden) the pressure coming from the service-brake valve. The control-valve can be moved into the load-sensitive position by means of an eccentric element that is connected via linkage to the vehicle axle or by means of a wedge (in the case of vehicles with pneumatic suspension).

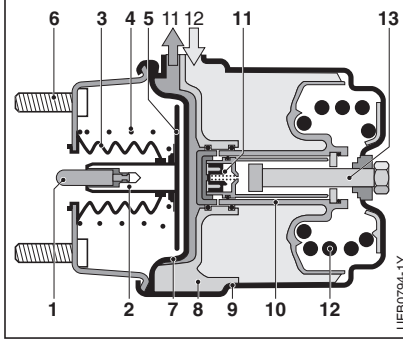
The pressure limiter which is integrated into the device at the top allows a small

partial pressure (approx. 0.5 bar) to flow in to the top of the diaphragm. Thus, up to this pressure there is no reduction in brake-cylinder pressure. This results in the synchronous application of the brakes on all vehicle axles.

As an alternative to the pneumatic ALB valve, pneumatically controlled brake systems are increasingly making use of the EBD function (Electronic Brakeforce Distribution) of ABS, with which braking-force distribution is optimized as a function of the wheel slip (see Wheel-slip control systems).

The electronically controlled brake (EBS) has become the predominant system used in heavy European commercial vehicles. This system performs braking-force distribution electronically as a function of the laden state and other parameters (see Electronically controlled brake system)

Combination brake cylinder



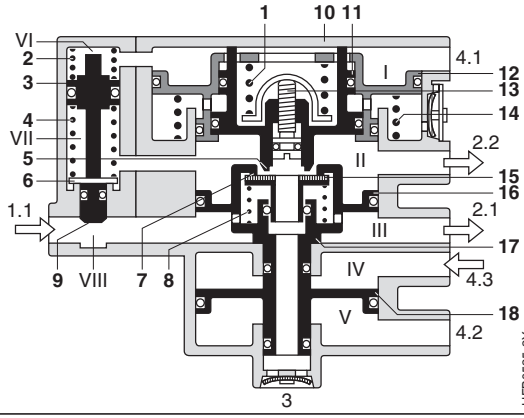
The combined cylinder in the commercial vehicle consists of a diaphragm cylinder part for the service brake and a spring-type actuator part for the parking brake (Figure 13). They are arranged one behind the other and exert force on a joint push rod. A distinction can be made between combined cylinders for S-cam brakes, wedge-actuated brakes, and disk brakes based on the type of wheel brake.

The two cylinders can be actuated independently of one another. Simultaneous actuation results in the addition of their forces. This can be prevented by installing a special relay valve in order to automatically prevent mechanical overloading of other downstream components (e.g. brake drums).

A central release screw allows for a tensioning of the spring of the spring-type brake cylinder without compressed air having to be applied (mechanical emergency release device). This is necessary to assist fitting or, in the event of failure of the compressed air, to be able to maneuver the vehicle.

Figure 13: Combination brake cylinder for disk brake (driving mode)

1 Pressure pin, 2 Piston rod,
3 Bellows with seal to disk brake,
4 Compression spring (diaphragm cylinder),
5 Piston (diaphragm cylinder),
6 Housing with fastening bolts,
7 Diaphragm, 8 Intermediate flange,
9 Cylinder housing (spring-type brake actuator),
10 Piston (spring-type brake actuator),
11 Bleeder valve (spring-type brake actuator chamber),
12 Compression spring (spring-type brake actuator),
13 Release device (spring-type brake cylinder).
Air ports: 11 Service brake, 12 Parking brake.



When the service brakes are operated, compressed air flows into the diaphragm cylinder and presses the plunger disk and the push rod against the lever in the disk brake. A drop in air pressure releases the brake.

When compressed air flows into the spring-type actuator part, the piston presses the springs together and the brake is released. If the chamber is vented, the spring-type brake cylinder exerts a force via the piston rod on the diaphragm part and presses the push rod into the mechanism of the disk brake via the piston disk.

3 Central vent.

Trailer control valve

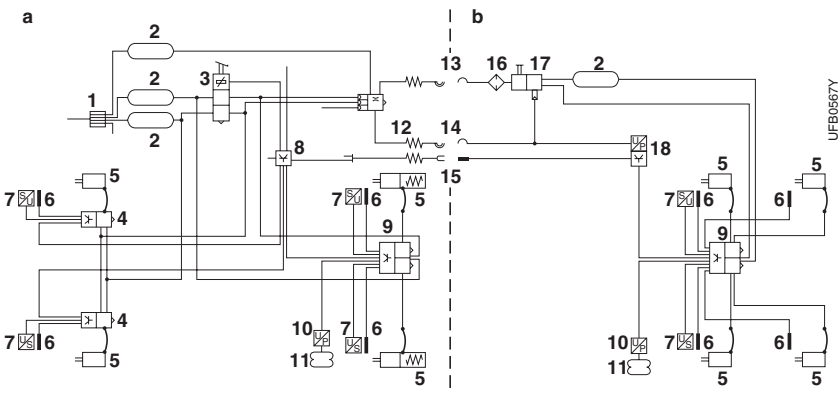
The trailer control valve installed in the tractor controls the trailer's service brake. This multi-circuit relay valve is triggered by both service-brake circuits and by the parking brake (Figure 14). In the driving mode, supply chamber III and chamber IV of the parking-brake circuit are under the same pressure. The brake line to the trailer is connected to the atmosphere via the central venting. A pressure increase in chamber I of brake circuit 1 and in chamber V of brake circuit 2 leads to the corresponding pressure increase in chamber II for the brake line to the trailer. A pressure drop in both brake circuits also leads to the same pressure drop in the brake line. Operation of the parking-brake system leads to venting of the parking-brake circuit (chamber IV). This increases the pressure in chamber II for the brake line to the trailer. When air enters chamber IV, the brake line is vented again.

If the brake line to the trailer is pulled off, it is prescribed that the pressure in the supply line to the trailer must have fallen to a pressure of 1.5 bar in less than two seconds (RREG 71/320). To achieve this, the compressed-air supply to the supply line is throttled by means of an integrated valve.

Electronically controlled brake system

Requirements and functions

With the further development of the dual-line compressed-air brake system, an electronic (or electronically controlled) brake system (EBS) was created in the mid-1990s. On account of the modular design, it is possible to cover different vehicle types with just a few components. Vehicle-specific differences and factors can be covered to a large extent by programming the central ECU accordingly. The control arrangement is determined by the number of axles and their arrangement and the required scope of functions, and ranges from 4S/4M to 8S/6M (S wheel-speed sensor, M pressure-control module).



Design and operating principle

The electronic brake system (Figure 15), like a conventional compressed-air brake with antilock braking system (ABS), comprises a compressed-air supply system, but the pressure-regulator, air-drier and multiple-circuit protection-valve functions can be combined in an electronic unit (EAC, Electronic Air Control). It is thus possible to adapt certain functions – such as e.g. fill sequences or regeneration – better to the required conditions and to guarantee even greater functional reliability.

In the electronic brake system too, energy is stored in compressed-air reservoirs and from there made available to the pressure-control modules and to the service-brake valve. The service-brake valve consists of an electric pedal-travel sensor and a pneumatic section which is functionally identical to the previous design. The pedal-travel sensor consists of a redundant travel sensor (e.g. two redundantly arranged electrical potentiometers or a redundant inductive travel sensor) which is deflected via the control device and delivers the redundant output signal to the central ECU. From this the ECU cal-

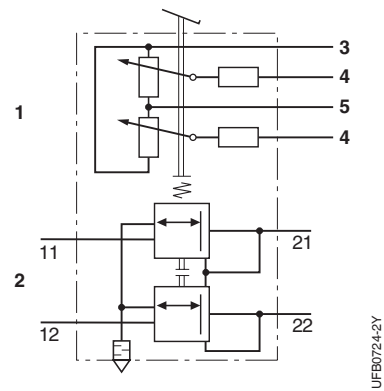
culates for each wheel an individual brake pressure and in turn activates the pressure-control modules on the individual axles so that the required brake pressure is applied to the brake cylinders downstream of the pressure-control modules. The applied brake pressure is regulated with the aid of integrated pressure sensors in the pressure-control modules. A pneumatic brake-pressure generation is performed in parallel in the pneumatic part of the service-brake valve which on the one hand determines the brake feel and on the other hand acts as a fallback level in the event of an electrical fault.

The brake-pressure modules are available as one-channel or two-channel designs. If the vehicle is set up to tow a trailer, a trailer control module is also provided as a substitute for the trailer control valve. This trailer control module is likewise activated in the braking operation by the central ECU and makes an adapted control pressure available at the “Brake” coupling head (yellow). This makes it possible to carry a conventionally braked trailer. If a trailer is carried with an independent electronic brake system, this is controlled by an electrical connection via the plug-in connection as per ISO 7638 (ABS connector). The trailer must nevertheless also be pneumatically coupled, because this is the only way that the trailer can be supplied with pressure and in the event of a system failure pneumatically controlled. By controlling the electronic brake system in the trailer, it is possible to provide optimum matching with regard to braking performance between the tractor vehicle and the trailer. Simultaneous and matched braking performance facilitate optimized coupling-forcing matching.



Further functions, such as antilock braking system (ABS), traction control system (TCS) and driving-dynamics control system (Electronic Stability Program), are integrated into the electronic brake system’s scope of functions. The turning behavior of the wheels is monitored by the wheel-speed sensors and the antilock braking system. Depending on the design, the information is made available to the central ECU or to the pressure-control module, where it is processed. In the event of incipient wheel locking, depending on the system arrangement and design, a control intervention is effected via the pressure-control modules or by downstream pressure-control valves in accordance with the control variants known to the ABS system (individual control, modified individual control, or select-low control). Intervention by the traction control system when the wheels spin takes the form of an engine and brake intervention. Further sensors are needed for the functions of the driving-dynamics control system. The steering-wheel angle is recorded by a steering-angle sensor. A yaw-velocity sensor, also known simply as a yaw sensor, records the rotational speed about the vehicle vertical axis. A lateral-acceleration sensor also records the lateral acceleration. When the data have been evaluated, swerving or jackknifing is detected and stabilized by the specific introduction of brake pressure into the relevant brake cylinders and intervention in other systems (see Driving-dynamics control for commercial vehicles).

If an electrical fault occurs, the vehicle can be braked by means of one or two redundant pneumatic circuits with at least the demanded secondary braking effect, and the trailer brake system controlled.

Optimum cooperation between all the systems can be achieved through data communication with other systems in the vehicle and the trailer. Optimized deceleration and acceleration processes and additional functions can be realized in this way.

Advantages of electronic brake systems in a commercial vehicle are:
– Fast and simultaneous brake-pressure buildup in all the brake cylinders,
– good metering capability, thus optimum braking comfort,
– optimum matching between tractor and trailer through control of coupling forces,
– exact braking-force distribution,
– uniform brake-lining wear,
– ABS, TCS and ESC functions are integrated (brake and engine interventions), traction control for offroad applications can be easily realized,
– driving-dynamics control via engine and brake interventions when oversteering or understeering is detected, in response to the risk of swerving (articulated road train, articulated bus), and intervention in response to the risk of overturning,
– ease of servicing thanks to extensive diagnosis functions.

Figure 16: Service-brake valve with two pneumatic control circuits

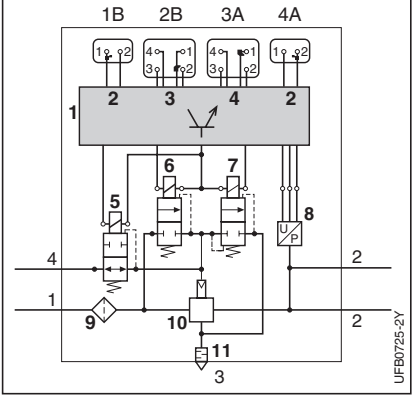
Components of the electronic brake system

Electronic control unit (ECU)
The control point of an electronic brake system consists of a central ECU in which all the system functions run. Aside from the cab-mounted variants, frame-mounted ECUs are increasingly gaining acceptance. The benefit of the latter is that the sensors for yaw rate and lateral acceleration can be integrated and consequently there is no need for a separate sensor to be fitted.



Service-brake valve
A service-brake valve for the electronic brake system is similar in design to conventional, purely pneumatic service-brake valves. However, in the service-brake valve the electronic setpoint values for brake-pressure control are also recorded (Figure 16). It thus fulfills two functions: A redundant sensor detects the driver's brake request by measuring the operating travel of the valve tappet. The measured value is transmitted to the central ECU and converted there into a braking request. In the same way as a conventional service-brake valve, the pneumatic control pressure is applied according to the actuation travel. These control pressures are required for "backup" control in the event of a fault.

Pressure-control modules
The pressure-control modules (Electro-Pneumatic Modulator, EPM, Figure 17) are the interface between the electronic brake system and the pneumatically actuated wheel brakes. They convert the required braking pressures transmitted via the CAN bus into pneumatic pressures. This conversion operation is usually performed with an inlet and outlet solenoid combination. A pressure sensor measures the controlled brake pressure and thus facilitates brake-pressure control in the closed control loop. The electrically activated "backup" valve shuts off the pneumatic control pressures of the service-brake valve in order to permit interference-free electrical pressure control.

Figure 17: Single-channel pressure-control module
1 ECU, 2 Speed sensor,
3 Brake-lining sensor,
4 CAN, 5 "Backup" valve,
6 Inlet valve, 7 Outlet valve,
8 Pressure sensor, 9 Filter,
10 Relay valve, 11 Muffler.

Connectors:
1B Connector, speed sensor 1,
2B Connector, brake-lining sensor,
3A Connector, supply and CAN bus,
4A Connector, speed sensor 2.

Ports:
1 Energy input,
2 Brake pressure to brake cylinder,
3 Vent,
4 Back-up control input.

Mounting the pressure-control modules close to the wheels means that the electrical wires for connecting the wheel-speed sensors and the brake-lining wear sensors can be kept short. The information is prepared in the pressure-control module and transmitted via the CAN bus to the central ECU. This reduces the outlay on cabling in the vehicle.

Trailer control module
The electronic trailer control module (Trailer Control Module, TCM) enables modulation of the trailer control pressure according to the functional requirements of the electronic brake system. The limits of the electrical control ranges are defined by legal requirements. The electronically specified setpoint value is converted into a physical braking pressure by means of a solenoid arrangement similar to that in the pressure-control module. The "backup" pressure is shut off either by a "backup" solenoid or by pneumatic retention, depending on the type of design adopted.

Under all normal conditions, the trailer control module must be activated by two independent control signals. This may be two pneumatic signals from two control circuits, or one pneumatic and one electrical control signal.

Continuous-operation brake systems

Commercial vehicles essentially use two types of continuous-operation brake systems, deployed separately or in combination: the exhaust-brake system and the retarder.

Exhaust-brake systems
The resistance which an engine brings to the speed imposed from the outside without a fuel supply is termed the engine or exhaust brake, or drag power. The drag power of standard engines is 5 to 7 kW per liter displacement. With a pure exhaust brake the regulation according to §41 or the road traffic licensing regulations in Germany (StVZO), s.. 15 cannot be observed. Further measures can be used to increase the effect of the exhaust brake.

Exhaust-brake system with exhaust flap
In the exhaust brake with exhaust flap, a valve with a flap closes the exhaust train. The fuel supply is interrupted at the same time. As a result, back pressure is generated in the exhaust-gas system and must be overcome by each piston during its exhaust stroke (Figure 18). The braking power can be regulated by means of a pressure-control valve in the exhaust train. Additionally, this valve ensures that at high revs an excessively high pressure does not result in valve or valve-gear damage.

The exhaust brake is the most common variant used in trucks and buses, delivering a braking power of 14 to 20 kW per liter displacement.

Exhaust-brake system with constant throttle
The exhaust brake with constant throttle is also known as a decompression brake. In this system, the work performed by the engine in the compression phase is not utilized. The exhaust valves or an additional valve (constant throttle, Figure 19) is/are specifically opened at the end of the compression cycle, thereby relieving the pressure built up in the compression phase. Thus, no further work can be delivered to the crankshaft in the expansion phase.

Engine brake system with exhaust flap and constant throttle
Braking power can be further improved by a combination of exhaust flap and constant throttle (Figure 19). This combination can deliver braking power of 30 to 40 kW per liter displacement.

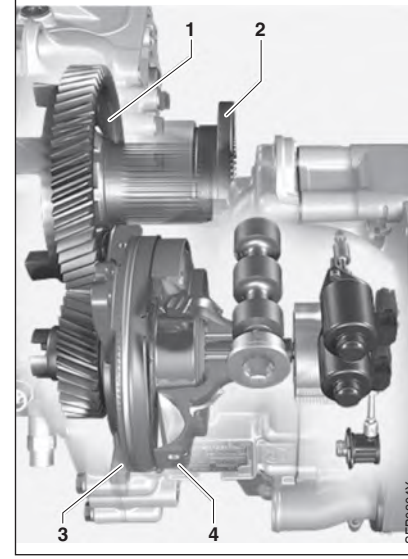
Retarder
Retarders are wear-free continuous-operation brakes. There are two types that differ in how they operate: hydrodynamic and electrodynamic retarders. Both systems, and the exhaust-brake systems, relieve the load on the service brake system and thereby increase the economic efficiency of the vehicle. The use of a hydrodynamic retarder can increase the service life of the service brake by a factor of 4 to 5.

In modern vehicles, retarders are incorporated into the brake-management system. The exhaust brake and the retarder are often combined as a continuous-operation brake in a vehicle. The brakes must then be activated by means of the electronic brake-management system.

Hydrodynamic retarder
Hydrodynamic retarders, also known simply as hydraulic retarders, can be subdivided into the categories of primary retarders and secondary retarders.

The primary retarder is located between the engine and the transmission, the secondary retarder between the transmission and the powered axle. Both primary and secondary retarders operate in the same way. When the retarder is activated, oil is pumped into the working area. The driven rotor accelerates this oil and transfers it at the outside diameter to the stator (Figure 20). There the oil strikes the static stator blades and is decelerated. The oil flows at the inside diameter to the rotor. The rotor's rotary motion is inhibited, and the vehicle is decelerated.



The kinetic energy is primarily converted into heat. For this reason, some of the oil must be permanently cooled by a heat exchanger.

The braking torque can be input using a hand lever or the brake pedal (in the case of a retarder integrated into the EBS electronically controlled brake system). A retarder's braking torque is dependent on the degree of fill in the working area between the rotor and the stator. The degree of fill is regulated by an ECU via a control pressure which is adjusted by proportioning valves.

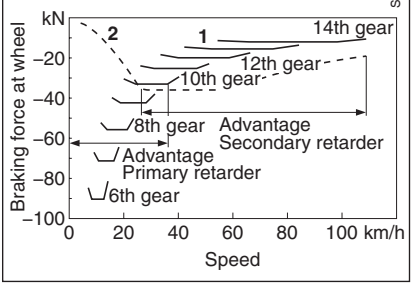
A retarder can be activated hydraulically or pneumatically, whereby the braking torque can be achieved in discrete braking stages and also steplessly. Oil is primarily used as the working medium in a retarder. Current hydraulic retarders can deliver braking power up to 600 kW for brief periods. However, the continuous braking power of a retarder is dependent on the cooling capacity of the vehicle's cooling system. Modern vehicles can dissipate a continuous braking power from a retarder of 300 to 350 kW via the cooling system. Sensors are used to record overheating of the retarder or the cooling system, and if necessary the braking power is reduced under controlled conditions until the braking power equals the dissipatable quantity of heat.

Primary retarder
In the case of a primary retarder located in the drivetrain between the engine and transmission after the converter, force is

Figure 20: Functioning principle of a retarder as illustrated by a ZF intarder by way of example
1 High-speed stage,
2 Output flange,
3 Stator, 4 Rotor.

transmitted through the powered axles and the transmission in such a way that the total overrun torque is directed through the transmission. The braking effect of the primary retarder is dependent on the engine speed and the selected gear, but is not dependent on the vehicle's output speed and driving speed. This lack of dependence on the output speed is one of the major advantages of primary retarders. These are highly effective at speeds below 25 to 30 km/h (Figure 21). This is the reason why primary retarders are primarily used in vehicles which are driven at lower average speeds such as city buses and municipal vehicles. Their compact design is another advantage. A disadvantage of primary retarders is that the braking force is interrupted during a gear change. The braking force must be reduced during gear changing.

Figure 21: Operating ranges of primary and secondary retarders
1 Primary retarder, 2 Secondary retarder.



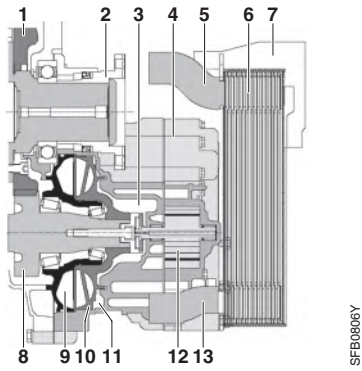


Figure 22: Hydrodynamic secondary retarder up to 600 kW braking power (ZF)

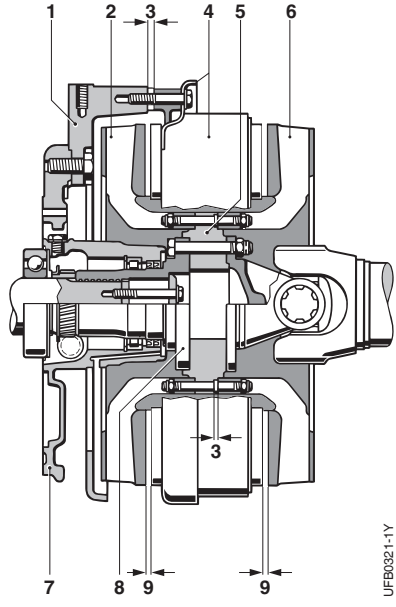
5 Coolant inlet, 6 Heat exchanger,
7 Electronics, 8 Pinion shaft, 9 Stator,
10 Rotor, 11 Discharge passage,
12 Pump, 13 Coolant outlet.

Secondary retarder

In the case of a secondary retarder (Figure 22), which is located after the engine, clutch and transmission, force is transmitted directly via the output shaft. Unlike a primary retarder, there is no interruption of the braking force during a gear change with a secondary retarder. The braking effect is dependent on the ratio of the output shaft and on the driving speed. It is not dependent on the selected gear. The braking torque of a secondary retarder is very much dependent on the rotor speed. For this reason, the rotor speed is often increased by means of a high-speed stage.

The secondary retarder demonstrates great efficiency at speeds over 40 km/h (Figure 21); at speeds below 30 km/h the braking torque falls off dramatically. Because of its design, the secondary retarder can also be subsequently adapted to a transmission. The extra weight of a secondary retarder with accompanying heat exchanger and oil fill is often cited as a disadvantage, since the additional mass reduces the vehicle payload.

Secondary retarders are primarily used in long-distance vehicles which are driven at high average speeds, such as trucks and tour buses.



Electrodynamic retarder (eddy-current brake)

The electrodynamic retarder (Figure 23) contains two non-magnetizable steel disks (rotors) which are connected with torsional strength to the input and output shafts (here: propshaft), and a stator which is equipped with 8 or 16 coils and fastened by means of a star-shaped bracket to the vehicle frame. As soon as electric current (from the alternator or battery) flows through the coils, magnetic fields are generated which are closed by the rotors. These magnetic fields induce eddy currents in the rotors as they turn. These eddy currents in turn generate magnetic fields in the rotors which counteract the exciting

magnetic fields and thus build up a braking effect. The braking torque is determined by the strength of the excitation field, the rotational speed, and the air gap between the stator and the rotors. The braking torque decreases as the air gap increases; this air gap can be adjusted by means of spacers. Shift stages with different braking torques (Figure 24) are obtained by interconnecting the field coils in different configurations. The heat generated is dissipated by convection and radiation to atmosphere via the internally ventilated rotor disks.

As the rotors are increasingly heated, the braking power of the electrodynamic retarder decreases significantly (Figure 25). The retarder's braking power is reduced by thermal protection in order to prevent the retarder from being destroyed by excessive temperature during braking operation.

Figure 23: Electrodynamic retarder

Like the primary retarder, the electrodynamic retarder is distinguished by high braking power at low engine speeds and relative design simplicity. On the downside, however, it can weigh up to 350 kg, depending on its size.

Wheel brakes

Wheel brakes are friction brakes that convert kinetic energy into heat energy during braking. Disk and drum brakes are used as wheel brakes. Hydraulic pressure (for passenger cars) and pneumatic pressure and spring force (spring-loaded brake, for heavy commercial vehicles) are converted into an application force to press the brake pads and linings against the brake disks and drums respectively.

In passenger-car applications the thermal demands placed on wheel brakes can, in view of ever-increasing vehicle weights and higher attainable driving speeds, only be satisfied by disk brakes. Drum brakes are now only used in subcompact-size cars on the rear axle.

In the commercial-vehicle sector disk brakes have gained acceptance for on-road applications in Europe and increasingly in North America as well. In markets with less well developed road infrastructures and in applications with greater off-road usage drum brakes still play a significant role since they react more robustly to dirt and are easier to handle (maintenance, repair, etc.).

Disk brakes for passenger cars

Functioning principle

Disk brakes generate the braking forces on the surface of a brake disk that rotates with the wheel (Figure 2). The U-shaped brake caliper with the brake pads is mounted to non-rotating vehicle compo-

nents (wheel carrier). The floating-caliper design with or without parking-brake mechanism has proven successful.

Principle of the fixed-caliper brake
In a fixed-caliper brake, both halves of the housing (flange and cover parts) are joined by the housing connecting bolts. Each half of the housing contains a piston to press the brake pad against the brake disk (Figure 2a). Ports in the housing halves connect the two pistons hydraulically.

Principle of the floating-caliper brake
In a floating-caliper brake, a piston presses the piston-side (inner) brake pad against the brake disk (Figure 2b). The generated reaction force moves the brake-caliper housing and thereby presses the outer brake pad indirectly against the brake disk. In this brake caliper the piston is therefore only seated on the inner side.

Floating-caliper brake for passenger cars
The brake caliper can be moved axially in the brake anchor plate and is guided by two sealed guide pins in the brake anchor plate (Figure 1).

Braking with the service brake
The hydraulic pressure generated by the brake master cylinder enters the cylinder chamber behind the piston via the hydraulic connection. The piston is shifted forwards and the brake pad on the piston side is applied to the brake disk. The reaction force that arises shifts the brake-caliper housing mounted in a bolt guide against the direction of piston movement. This also means that the outer brake pad is applied to the brake disk. The path of the brake pads and of the piston covered up to that point is referred to as clearance. Another increase in pressure increases the downforce of the brake pads.

Releasing the service brake
When the piston moves through the clearance, the sealing ring, which is rectangle in its initial position, is deformed. The deformed sealing ring pulls the piston back by the clearance when the hydraulic pressure drops (roll-back effect).

Braking with the integrated parking brake
When the integrated parking brake is operated, the force is transferred via the handbrake cable to the parking-brake lever. This is then twisted and the rotary motion is transferred via the shaft to the cam plate. As the balls run onto the cam plate, the piston is shifted via the pressure sleeve in the parking-brake mechanism; the threaded spindle bolted in this mechanism is shifted towards the brake pad. After crossing the clearance, first the brake pad on the piston side and then the outer brake pad are pressed against the brake disk.

Releasing the parking brake
After releasing the handbrake lever, the parking-brake lever, the shaft and the cam plate turn back to their initial positions. The pressure sleeve, the threaded spindle and the piston are pressed back into their initial position by the springs in the parking-brake mechanism. The final clearance is reached as the sealing ring reassumes its shape.

Automatic self-adjusting mechanism
Wear on the brake pads and brake disks increases the clearance and thus has to be balanced out. This automatic clearance compensation takes place during braking. The inside diameter of the rectangular piston sealing ring is slightly smaller than the piston diameter. The sealing ring thus surrounds the piston with a pre-tension. During braking the piston moves towards the brake disk and tensions the sealing ring, which as a result of its static friction can then slip on the piston only when the piston travel between brake pad and brake disk has in response to abrasion on the brake pads has become greater than the envisaged clearance. When the brake is released the piston is pulled back only by the envisaged clearance. In this way, stepless readjustment to a constant clearance is possible.

The clearance compensation of the parking-brake mechanism also takes place on application of the service brake.

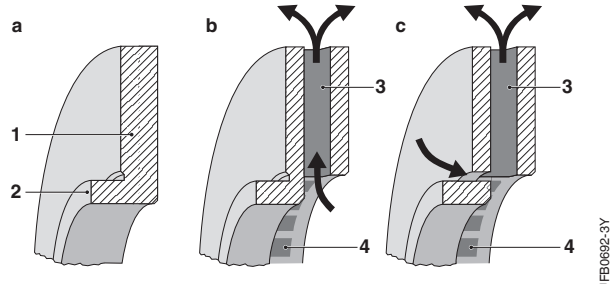
The clearance of a brake caliper is approx. 0.15 mm and is thus in the range of the maximum permissible static disk run-out (axial movement per brake-disk

rotation on account of manufacturing tolerances or bearing clearances).

Brake disks

The energy converted during braking into heat is mainly absorbed by the brake disk and then dissipated to the ambient air. A fundamental distinction is made between solid disks and ventilated brake disks (Figure 3).

There are two different types of ventilated brake disk: Internally and externally ventilated. On account of the higher thermal load ventilated brake disks are used on the front axle and in high-performance or heavy vehicles also on the rear axle. Perforated or grooved friction rings improve the cooling effect and also improve wet starting response. Ventilated brake disks with radial cooling slots are used to further improve heat dissipation (Figure 3).



Brake disks are usually manufactured from gray cast iron. A higher proportion of carbon improves the heat-absorption capability and noise-damping performance. Alloys containing chrome or molybdenum for example also increase wear resistance. More thermally resistant brake disks made of ceramic containing silicon carbide reinforced with carbon fiber are also used on sports cars and luxury-class cars.

High corrosion requirements are imposed on brake disks due to their installation position directly on the wheel and the high mileage. Brake disks are partially or completely coated to improve corrosion resistance. High-heat-resisting paints or for example coatings containing zinc are used.

The last few years have also seen the introduction of built-up brake disks. These brake disks have a separation between the friction ring and the chamber area. The chamber area is usually made of a different material (aluminum or sheet steel) in order to achieve weight savings. These brake disks furthermore offer benefits with regard to warping (friction-ring deformation under thermal influence). A distinction is made between screwed, cast, riveted, and combined positive and non-positive connections.

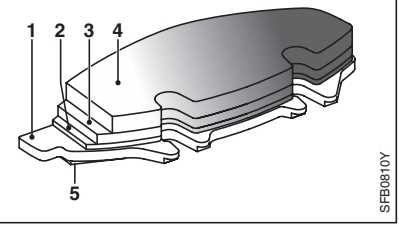
Brake pads for disk brakes
Function and requirements
The decelerating force during the braking operation is generated by sliding friction between the brake pad and the brake disk. The coefficient of friction denotes the ratio between the tensioning force generated by the brake caliper and the resulting decelerating frictional force between the pad and the disk. For passenger cars it ranges between 0.3 and 0.5 and is included in the chassis-system configuration.

As part of a safety system this function must be performed with absolute reliability and ensue in a predictable way as transparently as possible for the vehicle driver. This therefore requires that the coefficient of friction of the brake pad against the brake disk used always be identical wherever possible under all the varying – even extreme – operating conditions in wide ranges. Furthermore, the wear on the brake pads and the brake disk must be appropriately low. The dust emissions associated with wear should also be kept as low as possible and the composition of these emissions should pollute the environment as little as possible. Brake systems should also operate with as little noise as possible.

Optimum tuning of the brake system to the vehicle is quite significantly achieved via the properties of the brake pad, the design and manufacture of which, of all the components in the system, opens up the most wide-ranging possibilities.



Design
The brake pad (Figure 4) consists of a number of parts whose properties must all be meticulously matched to each other to meet the complex functional requirements. A back plate (carrier) usually made of steel serves to support the braking force exerted by the friction lining against the brake caliper and conversely to transfer the piston force as uniformly as possible to the lining friction surface. To this end, the back plate must adhere to exact dimensional tolerances so as to avoid braking noises or unreliable functioning. In addition, the material must exhibit sufficient strength so as not to permit any plastic deformation at the contact faces or hooks. In many a design the back plate still supports the strength of the brake caliper.

For the most part, anti-noise shims or films are glued, riveted or even attached with clips to the back of the brake pad painted for corrosion-protection purposes. They are for the most part essential for avoiding noise emissions. It is important here to ensure that the shims cannot be appreciably displaced over the period of operation. Otherwise, unwanted contact between the anti-noise shim and brake or wheel components may result under adverse circumstances. Clips for positioning and locating in the piston and caliper may still be required for fitting in the brake.

Manufacture
The most cost-effective solution is, after cleaning off oxide coatings and oil residues, to apply a coating of a highly thermally and chemically stable adhesive. Racing cars and a number of heavy, high-performance premium vehicles also use bonding variants which establish positive locking between the pad and the carrier, and thus are above all much more thermally resistant but at the same time significantly more expensive than an adhesive bonding.

Finally, the friction lining is applied. The friction lining is for the most part pressed from a molding powder or granulate in a heated press onto the back plate. At temperatures between 130 °C and around 170 °C the binder component of the friction-lining mixture combines permanently

Figure 4: Structure of a brake pad for disk brakes
1 Back plate,
2 Adhesive layer,
3 Intermediate layer,
4 Friction lining,
5 Anti-noise shim.

with the back-plate adhesive to form a component. In the process all the other ingredients are also integrated into the binder matrix usually consisting of highly chemically and thermally resistant phenolic resin. This so-called hot-pressing process with dry mixtures has become established in the mass market as the best combination of reliability, range of adjustments of physical properties, product variance, and costs.

Composition of brake pads

The recipe for the molding compound of a typical European brake pad consists of up to more than twenty different ingredients. These can be grouped into the categories of binders, metals, graphite and coke, fillers, organic fibers, abrasives, and lubricants. Table 1 shows by way of example some of the raw materials normally used in brake pads. Aside from their concentration in the recipe, their effect in the brake pad is also determined by their individual composition, microstructure, and particle size. Reliable braking performance with low wear is obtained only by choosing ideal ingredients and carefully optimizing the concentrations of the metal, abrasive, and lubricant proportions. Physical-mechanical properties for sufficient strength and particularly also for comfortable, noise-free braking are adjusted by means of tribologically neutral fillers in broad concentration ranges. Only with this complexity of recipes can the high, sometimes contradictory requirements regarding friction loss, reliability, wear, and braking comfort be optimally reconciled for the majority of drivers.

Between the friction lining and the adhesive a roughly 2…3 mm thick intermediate layer similar mechanically and chemically to the friction lining can be used for example to improve the pad connection or damp braking noises.

Finally, a brake pad must be clearly marked to denote its country of use in order for example to display the regulatory approval for use in public traffic. The markings are usually printed or stamped on the backs of the brake pads.

Special regional requirements

Unlike in Europe – and in particular unlike in Germany – in many regions around the world drivers cannot drive very fast by vehicle since speed limits are enforced even on expressways and freeways. Resulting lower friction-coefficient requirements, but higher requirements with regard to wear and dust formation led for example in Asia and the USA to the development of different friction materials from those in Europe. From Japan come the so-called NAO materials (Non Asbestos Organics), which are characterized by very low brake-disk corrosion and consequently also by low dust formation. However, at present these recipes cannot deliver friction coefficients that are as high as those produced by the recipes customary in Europe. In contrast to European recipes, they typically contain no steel wool or iron powder. They are therefore also referred to as non-steel pads or more promotionally effectively as ceramics. In contrast, the materials customary in Europe are called low-steel or low-met pads. The combination of the good friction loss of European recipes with the low dust generation of NAO rec-

Table 1: Raw-material groups with typical concentration ranges of brake-pad recipes for use in Europe

Raw-material group	Raw material	Volume %

ipes constitute a current conflict of goals for the development of friction materials.

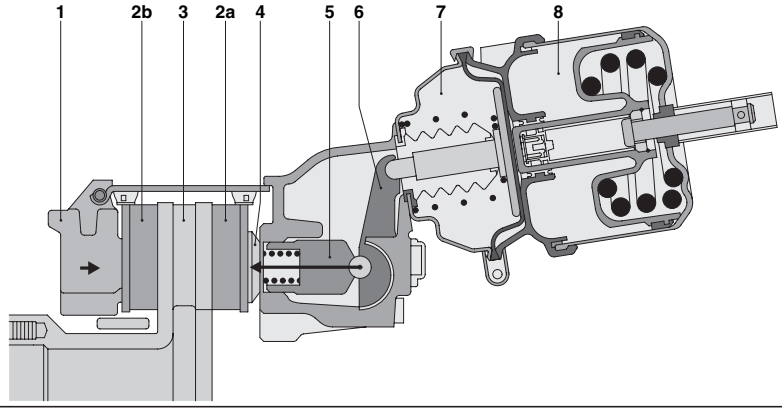
Up to half the weight of semi-met pads is made up of iron materials. They represent a good cost compromise with weaknesses in the high-load and high-temperature ranges.

Disk brakes for commercial vehicles

Special disk brakes have been developed for commercial vehicles. These disk brakes are actuated with compressed air. Because the pressure here is much smaller than that in a hydraulic brake, the brake cylinders cannot be integrated into the brake calipers. They must be flanged into position (Figure 5).

Functioning principle

Operating concept of the service brake



When air enters the service brake cylinder, the eccentrically mounted brake lever is actuated. The brake cylinder force is boosted by the lever ratio and transferred via the bridge and plungers to the inner brake pad. The reaction force that arises at the brake caliper is transferred by shifting the brake caliper to the outer brake pad.

Operating concept of the parking brake

When the spring-type brake cylinder is vented, the force of the pre-tensioning springs is released. Via the spring-type brake piston, this moves the piston and the push rod of the service brake cylinder to operate the brake. In the case of the parking brake, the pressure in the spring-type brake actuator is completely

Figure 5: Disk brake with combination brake cylinder

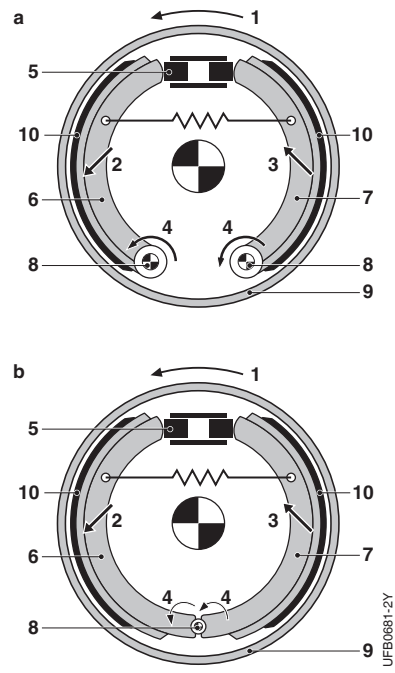
5 Bridge, 6 Eccentrically mounted brake lever, 7 Service-brake cylinder, 8 Spring-type actuator.

eliminated, thus releasing the force of the pre-tensioning springs to achieve maximum braking effect.

Automatic self-adjusting mechanism
Disk brakes pneumatically or mechanically actuated by the spring-type actuator are fitted with automatic clearance compensation.

Wear monitoring
Continuous wear monitoring may also be provided. This is required in the case of electronic brake systems for wear adaptation and for service information systems.

Brake disks
Solid brake disks are used less frequently on commercial vehicles because they can only dissipate the heat slowly. Internally ventilated brake disks have a larger surface through which heat exchange can take place. In this design two friction rings are connected via bridges. The rotation of the brake disk creates on the inside a radial ventilation effect in the outward direction.



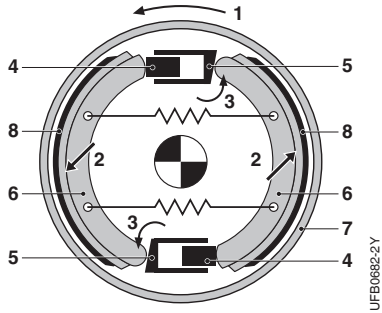
Brake disks for commercial vehicles are usually manufactured from gray cast iron. The carbon content increased up to the saturation limit provides good thermal conductivity.

Drum brakes

Drum brakes are radial brakes with two brake shoes. They generate their braking force on the inner friction surface of a brake drum.

Drum-brake designs
There are two different designs of drum brake, based on how the brake shoes are guided:
– brake shoes with fixed pivot (Figures 6a and 6b),
– brake shoes as sliding shoes (Figure 7).

Figure 6: Principle of simplex brake
a) Brake shoe with two single pivots,
b) Brake shoe with one double pivot.
1 Direction of rotation of brake drum with vehicle moving forwards,
2 Self-augmentation, 3 Self-inhibition,
4 Torque,
5 Double-acting wheel-brake cylinder,
6 Leading brake shoe (primary shoe),
7 Trailing brake shoe (secondary shoe),
8 Fulcrum (pivot),
9 Brake drum, 10 Brake lining.



At the brake shoe that rotates in the direction of the brake drum (primary shoe, leading brake shoe, Figure 6), the friction force during the braking operation creates a turning force around the brake-shoe fulcrum which in addition to the application force presses the shoe against the drum. This generates a self-augmenting effect. In a simplex brake a turning force is created around the fulcrum of the trailing brake shoe (secondary shoe) which diminishes the applied application force. This therefore creates a self-inhibiting effect.

Sliding-shoe guides are used in simplex, duplex, duo-duplex, servo and duo-servo brakes. Brake shoes with a fixed pivot are subject to unequal levels of wear in that they cannot center themselves like sliding shoes.

Principle of the simplex brake
A double-acting wheel-brake cylinder actuates the brake shoes (Figures 6a and 6b). The fulcrums of the brake shoes are pivots (two single pivots or one double pivot). When the vehicle is moving forwards, self-augmentation affects the leading brake shoe and self-inhibition affects the trailing brake shoe; the pattern is the same when the vehicle is backing up.

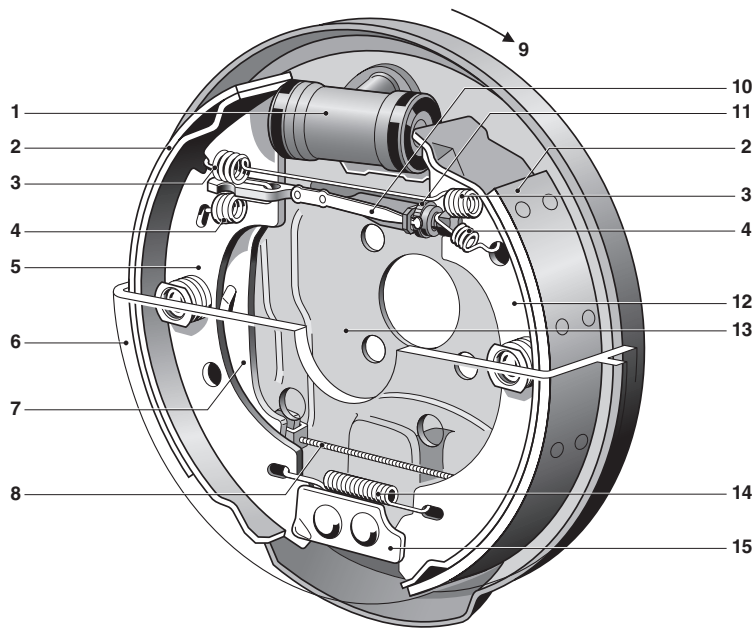
Figure 7: Principle of duplex brake
1 Direction of rotation of brake drum with vehicle moving forwards,
2 Self-augmentation, 3 Torque,
4 Wheel-brake cylinder, 5 Fulcrums,
6 Brake shoes, 7 Brake drum,
8 Brake lining.

Principle of the duplex brake
Each brake shoe is actuated by a single-acting wheel-brake cylinder (Figure 7). The brake shoes designed as sliding shoes are supported on the back of the opposing wheel-brake cylinder. The duplex brake is single-acting, i.e., it has two leading self-augmenting brake shoes when the vehicle is moving forwards. There is no self-augmentation when the vehicle is backing up.

Simplex drum brake
Functioning principle of passenger-car brake
The principle of a drum brake is explained using a hydraulically operated simplex drum brake with integrated parking brake and automatic self-adjusting mechanism as an example (Figure 8). Other drum brake designs (e.g., duplex brake, duo-duplex brake) are rarely used today.

When driving extension springs pull the two brake shoes away from the brake drum so that a clearance is created between the drum friction surface and the brake linings. In the case of simplex brakes, a two-sided hydraulic wheel-brake cylinder generates the application force for the brake shoes during braking by converting the hydraulic pressure into mechanical force. Here, the leading and the trailing brake shoes with the brake pads press against the brake drums. The other ends of the brake shoes on the opposite side to the wheel-brake cylinder are braced by a support bearing that is attached to the brake anchor plate.

The leading brake shoe (primary shoe) generates a higher proportion of braking torque than the trailing brake shoe (secondary shoe). Wear is therefore greater on the primary lining. This lining is thicker or longer in design to compensate.



Functioning principle of simplex brake with S-cam for commercial vehicles
In commercial vehicles with compressed-air brake systems, the application force is frequently generated by a rotatable S-cam. S-cam rotation is effected by the brake cylinder, the brake lever (slack adjuster), and the brake-cam shaft (Figure 9).

Functioning principle of wedge-actuated brake
Wedge-actuated brakes are also used in commercial vehicles. Here, the application force for the brake shoes is generated by a wedge actuated by the brake cylinder (Figure 10).

During braking the diaphragm brake cylinder is exposed to compressed air. This displaces the wedge to the right. The wedge slides between the pressure rollers. These roll on the wedge and the thrust members. The generated application force is transferred via the thrust members to the brake shoes. The excessive clearance created by brake-lining wear is compensated for by the adjusting mechanism.

Automatic adjusters
Wheel brakes must be fitted with adjusters to compensate for the increased clearance caused by lining wear. The brakes must be easily adjustable or have an au-

Figure 8: Simplex drum brake with integrated parking brake

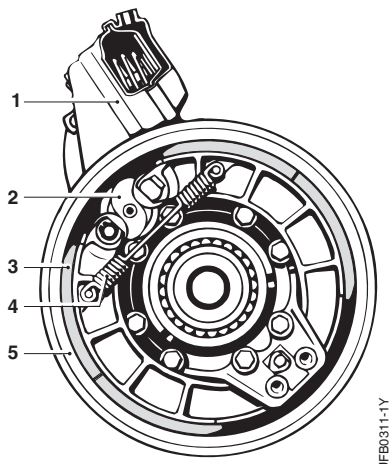
13 Brake anchor plate, 14 Extension spring (for brake shoes),
15 Brake-shoe pin bushing.



tomatic adjuster (§ 41 s. 1 StVZO [1], ECE R13-H [2]).

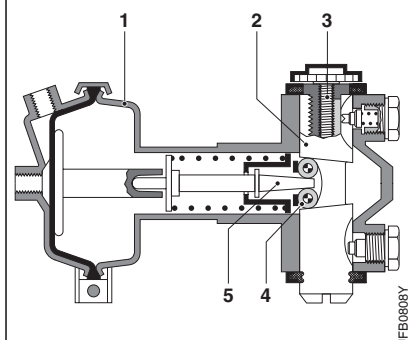
On simplex drum brakes for passenger cars, the adjuster is part of the push rod or pressure sleeve situated under initial spring tension between the brake shoes. When the permissible clearance is exceeded, the adjuster automatically lengthens the push rod or pressure sleeve (to different extents depending on the adjuster design) and thereby adjusts the clearance between brake shoe and brake drum. Automatic adjusters mostly operate in conjunction with a thermocouple on a temperature-sensitive basis in order to prevent adjustment when the brake drum is hot (expanded).

In commercial vehicles with S-cams, the adjuster is part of the brake lever. For this purpose it has manual adjustment or is designed as an automatic linkage adjuster.

In wedge-actuated brakes, an automatically acting adjuster is integrated into the wedge mechanism.

Figure 9: Simplex drum brake with S-cam
1 Diaphragm-type cylinder,
2 S-cam,
3 Brake shoes,
4 Return spring,
5 Brake drum.

Parking brake



A parking brake is integrated in the drum brake. The brake cable is actuated either via the handbrake lever inside the vehicle or via an electric motor with spindle. The handbrake lever is mounted at the top of the trailing brake shoe. When the parking brake is operated, the brake cable pulls the handbrake lever downwards to the right, causing the handbrake lever to press the brake shoes via the push rod against the brake drum.

In a commercial vehicle the drum brake is actuated as a parking brake by venting the spring-type brake cylinder.

Wheel-slip control systems

Function and requirements

Slip

When starting off, accelerating and braking, the efficiency required to transfer forces to the road depends on the traction available between the tires and the road surface. Slip occurs when the speed v_R at which the wheel center moves in the longitudinal direction (vehicle speed) differs from the speed v_U at which circumference rolls.Brake slip λ_B and drive slip λ_A are calculated as follows:

$$\lambda_B = \frac{v_U - v_R}{v_R}\,,\ \lambda_A = \frac{v_U - v_R}{v_U}\,.$$

When a wheel is locked, according to this definition brake slip $\lambda_B = -1$; when the vehicle is stationary with spinning wheels drive slip $\lambda_A = 1$ (see Slip, Fundamentals of automotive engineering).

Adhesion/slip curves

The tire must roll with slip so that it can transmit force to the road. A tire without slip would not deform on the wheel contact area and therefore could not transmit either a longitudinal force or a lateral force. The transmittable forces are dependent on the slip. The adhesion/slip curves (Figure 2) illustrate this dependence. They progress identically for braking and propulsion/traction.

Wheel-slip control systems ensure the optimum transmission of forces between tires and road to keep the vehicle directionally stable and more easily controllable for the driver. For this purpose the longitudinal slip of the individual wheels – i.e.,

Figure 2: Adhesion/slip curve

6 Hydraulic unit with add-on ECU.

the wheel speed referred to the velocity of the wheel center in the longitudinal direction – is regulated by modulating the braking or drive torque. There is a fundamental distinction between the antilock braking function (ABS, antilock braking system) and the traction control system (TCS).

The vast majority of acceleration and braking operations involve only limited amounts of slip, allowing response to remain within the stable range in the adhesion/slip curves. Any rise in slip (brake slip when braking and drive slip when accelerating) is accompanied initially by a corresponding increase in adhesion. Beyond this point, any further increases in slip take the curves through the maxima and into the unstable range (Figure 2) where any further increase in slip generally results in a reduction in adhesion. When braking, this results in wheel lock within a few tenths of a second. When accelerating, one or both of the driven wheels start to spin more and more as the drive torque exceeds the adhesion by an ever increasing amount.

Effect of ABS and TCS

As brake slip increases the ABS function becomes active and prevents the wheels from locking; as drive slip increases TCS prevents the wheels from spinning. Thanks to ABS the vehicle retains its directional stability and steerability even under emergency braking on a slippery road surface. The dangerous phenomenon of jackknifing is also prevented in commercial-vehicle combinations. The TCS function optimizes the transmission of forces of the drive wheels when accelerating and thereby improves both traction and stability.

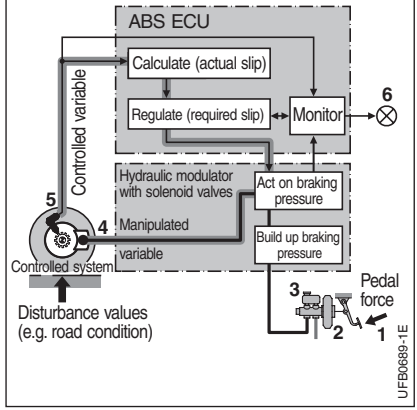
Figure 1 shows an ABS system with its components for a passenger car with a hydraulic brake system. In contrast to passenger cars, commercial vehicles have pneumatic power-brake systems (air brakes). Nevertheless, the functional description of an ABS or TCS control process for passenger cars also applies in principle to commercial vehicles.

The functions of ABS and TCS have in the meantime been integrated into the driving-dynamics control.

Control systems

ABS control

Basic closed-loop control process



The wheel-speed sensor senses the state of motion of the wheel (Figure 3). If one of the wheels shows signs of incipient lock, there is a sharp rise in peripheral wheel deceleration and in wheel slip. If these exceed defined critical levels, the ABS controller sends commands to the solenoid-valve unit (hydraulic unit) to stop increasing or to reduce wheel brake pressure until the danger of wheel lock is averted. The braking pressure must then rise again to ensure that the wheel is not underbraked. During automatic brake control, the stability or instability of wheel motion must be detected constantly, and kept within the slip range at maximum braking force by a sequence of pressure-rise, pressure-retention and pressure-drop phases.

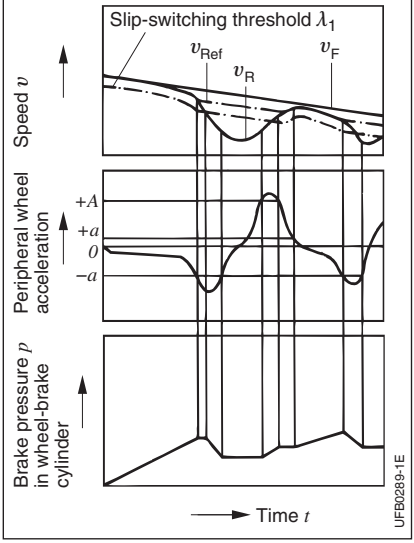
Typical control cycle

The control cycle depicted in Figure 4 shows automatic brake control in the case of a high friction coefficient. The change in wheel speed (braking deceleration) is calculated in the ECU. After the value

Figure 3: ABS control loop of a passenger-car system

1 Brake pedal, 2 Brake booster,
3 Brake master cylinder with fluid reservoir,
4 Wheel-brake cylinder,
5 Wheel-speed sensor,
6 Indicator lamp.

falls below the (–a) threshold, the hydraulic-unit valve unit is switched to pressure-holding mode. If the wheel speed then also drops below the slip-switching threshold λ_1, the valve unit is switched to pressure drop; this continues as long as the (–a) signal is applied. During the following pressure-holding phase, peripheral wheel acceleration increases until the (+a) threshold is exceeded; the braking pressure is then kept at a constant level.



After the relatively high (+A) threshold has been exceeded, the braking pressure is increased, so that the wheel is not accelerating excessively as it enters the stable range of the adhesion/slip curve. After the (+a) signal has dropped off, the braking pressure is slowly raised until, when the wheel acceleration again falls below the (–a) threshold, the second control cycle is initiated, this time with an immediate pressure drop.

In the first control cycle, a short pressure-holding phase was initially necessary to filter out any faults. In the case of high wheel moments of inertia, low friction coefficient and slow pressure rise in the wheel-brake cylinder (cautious initial braking, e.g., on black ice), the wheel might lock without any response from the deceleration switching threshold. In this case, therefore, the wheel slip is also included as a parameter in the brake-control system.

Under certain road-surface conditions, passenger cars with all-wheel drive and with differential locks engaged pose problems when the ABS system is in operation; this calls for special measures to take into account the reference speed during the control process, lower the wheel-deceleration thresholds, and reduce the engine-drag torque.

Figure 4: ABS control cycle for high friction coefficients

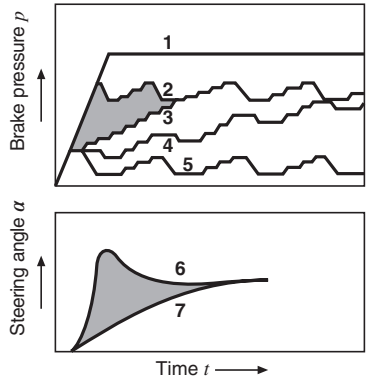
Control cycle with yaw-moment build-up delay

When the brakes are applied on a road surface with uneven grip (μ split: left-hand wheels on dry asphalt, right-hand wheels on ice), vastly different braking forces at the front wheels result and induce a turning force (yaw moment) about the vehicle's vertical axis (Figure 5).

On smaller cars, ABS must be supplemented by an additional yaw-moment build-up delay device to ensure that control is maintained during panic braking on asymmetrical road surfaces. Yaw-moment build-up delay holds back the pressure rise in the wheel-brake cylinder on the

Figure 5: Yaw-moment build-up induced by large differences in friction coefficients

M_{yaw} Yaw moment, F_B Braking force,
μ_{HF} Coefficient of friction.
1 "High wheel", 2 "Low wheel".



front wheel with the higher coefficient of friction at the road surface ("high wheel").

The yaw-moment build-up delay concept is demonstrated in Figure 6: Curve 1 represents the brake-master-cylinder pressure p_{MC}. Without yaw-moment build-up delay, the braking pressure at the wheel running on asphalt quickly reaches p_{high} (Curve 2), while the braking pressure at the wheel running on ice rises only to p_{low} (Curve 5); each wheel brakes with the maximum transferable braking force (see Individual control).

The yaw-moment build-up delay 1 system (Curve 3) is designed for use on vehicles with less critical handling characteristics, while yaw-moment build-up delay 2 is designed for cars which display an especially marked tendency toward yaw-induced instability (Curve 4). In all cases in which yaw-moment build-up delay comes into effect, the high wheel is under-braked at first. This means that the yaw-moment build-up delay must always be very carefully adapted to the vehicle in question in order to limit increases in stopping distances.

4 Brake pressure p_{high} w/ YMBD 2,
5 Brake pressure p_{low} at "low wheel",
6 Req. steering angle α w/o YMBD,
7 Req. steering angle α w/ YMBD.

Curve 6 in Figure 6 shows that for an ABS system without yaw-moment build-up delay a significantly higher steering angle is required when countersteering.

ABS control methods

The axle-based ABS control methods differ essentially in the number of control channels and the behavior when braking at μ split.

Individual control

Individual control, whereby each wheel is individually slip-controlled, produces the shortest braking distances. The drawback, however, is the yaw moment occurring under μ-split conditions, which must be compensated for by appropriate countersteering. This method is used exclusively on the rear axle since the steering and yaw moments occurring at the front axle would not be controllable for the driver when braking at μ split.

Select-low control

Select-low control (SL) is used to avoid yaw and steering moments entirely. Here, single-channel wheel-slip control is effected at the wheel with the lowest friction coefficient (select low), as a result of which both wheels on one axle receive the same brake pressure. Therefore only one single pressure-control channel per axle is required. Under μ-split conditions this produces optimum steerability and directional stability at the expense of braking distance. In the case of homogenous friction coefficients, braking distance, steerability, and directional stability are similar to those of the other methods.

Individual control, modified

"Individual control, modified" (IRM) has proven to be a good compromise between steerability, stability, and braking distance. This two-channel control method necessitates a pressure-control channel at each wheel on the axle. By appropriately limiting the brake-pressure difference between the right and left sides, the yaw and steering moments are restricted to a controllable extent. This results in a braking distance which is only a little longer than that for individual control, but it does ensure that vehicles with critical handling characteristics remain controllable.

TCS control
The traction control system has two fundamental tasks:
– optimizing traction by utilizing the available friction coefficient in the best possible way,
– ensuring vehicle stability (directional stability) by preventing the drive wheels from spinning.

To optimize traction all the driven wheels must utilize their individual friction coefficients to the maximum to the best possible extent. To this end, the wheel speeds are synchronized by active braking of the spinning wheels (brake controller or electronic differential-lock function). In this way, the braking torque exerted on the spinning wheel is available through transmission by the differential to the non-spinning wheel as drive torque.

To ensure directional stability, the wheel slip is controlled with the aid of the drive torque by the engine controller in such a way as to achieve the best possible compromise between traction and lateral stability.

Using the brake-control function described above, the driving wheels can also be synchronized so that a mechanical differential lock, if fitted, can be activated automatically, e.g., with the aid of a pneumatic cylinder. The ABS/TCS ECU calculates the correct point and conditions for releasing the differential lock.

In contrast to mechanical differential locks, the tires do not scrub on tight corners. A fundamental observation about this type of system (when it assumes an electronic brake-control function) is that it is not intended for continuous use on difficult offroad terrain. Since the brake-control function is achieved by braking the relevant wheel, brake heating is an inevitable consequence.

For multi-axle vehicles with complex drive configurations and a number of differentials (e.g., 6×4 or 8×6 with three or five differentials) the TCS function can control up to six wheels individually.

Engine drag-torque control
Particularly at low load with a low friction coefficient or very powerful engines the wheels on the powered axle can lock due to high engine-drag torques (e.g., when downshifting), which results in unstable handling. In this case, engine drag-torque control increases the wheel speeds by increasing the drive torque and thereby prevents the impending instability. The actively exerted drive torque is limited for safety reasons.

Electronic load-dependent braking-force regulation
Load differences and the dynamic axle-load shift that occurs during sharp braking call for an adaptation of the braking forces. This was originally performed by ALB valves (automatic load-dependent braking-force regulator), which reduce the brake pressure usually on the rear axle depending on the axle load. In current ABS systems this function is assumed by electronic load-dependent braking-force regulation. Here, under minimal deceleration conditions, the differential slip between the front and rear axles is minimized, whereby the brake pressure on the rear axle is electronically reduced. This results, assuming the same friction conditions on both axles, in identical braking and consequently optimum braking under driving-dynamics considerations. This function dispenses with the need for the additional ALB valve.

ABS/TCS systems for passenger cars

The requirements imposed on an ABS system are described in the regulations ECE-R13 [1]. This regulation defines ABS as a component of a service-brake system (Figure 1) which automatically controls wheel slip in the direction of wheel rotation on one or more wheels when braked.

ECE-R13 Annex 13 defines three categories. The present generation of ABS meets the highest level of requirements (Category 1).

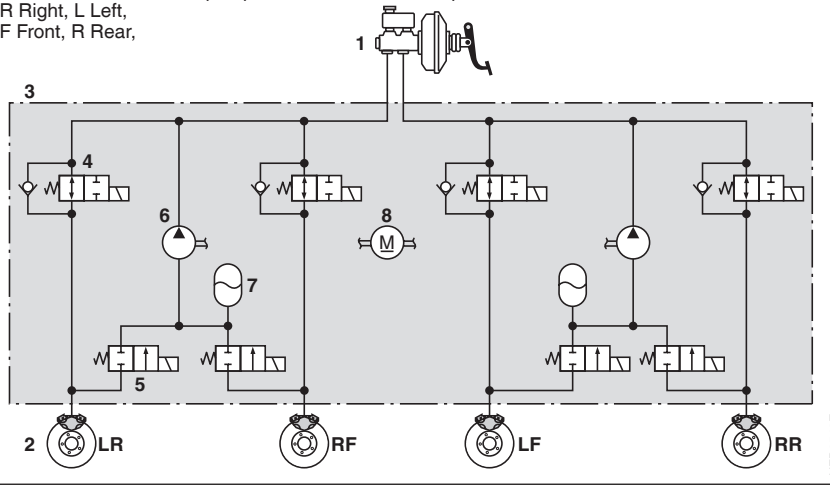
Components

An ABS or ABS/TCS system consists of the following components: wheel-speed sensors, electronic control unit (ECU), and hydraulic unit (for passenger cars) or pressure-control valves (for commercial vehicles).

Wheel-speed sensors

The most important input variables for controlling wheel slip are the wheel speeds, which are recorded by wheel-speed sensors. These sensors scan a rotating sensor ring and generate an electrical signal with a frequency proportional to the rotational speed (see rpm sensors).

There are basically two different types of rpm sensor: active and passive. The active rpm sensors used predominantly in passenger cars operate according to the Hall principle and can record, aside from the road-speed signal, further information such as the temperature and transmit it to the ECU.



Hydraulic unit of an ABS system

The main hydraulic components of the hydraulic unit – also called the hydraulic modulator – are the following (Figure 7):

- one return pump per brake circuit,
- accumulator chamber,
- damping functions, previously performed by an accumulator chamber and a flow restrictor, are now performed both hydraulically and by control systems, i.e., software,
- 2/2-way solenoid valves with two hydraulic positions and two hydraulic connections.

There is one pair of solenoid valves for each wheel (except in the case of 3-channel configurations with front/rear brake-circuit split, see ABS system variants) – one of which is open when de-energized for pressure rise (inlet valve, IV) and one which is closed when de-en-

Figure 7: Hydraulic system of an antilock braking system.

R Right, L Left,
F Front, R Rear,

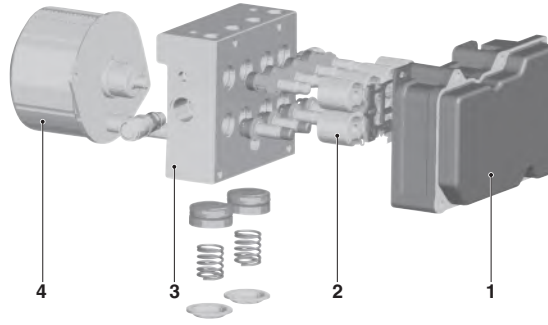
ergized for pressure drop (outlet valve, OV). In order to achieve rapid pressure relief of the wheel brakes when the pedal is released, the inlet valves each have a non-return valve which is integrated into the valve body (e.g., non-return valve sleeves or unsprung non-return valves).

The assignment of pressure-rise and pressure-drop functions to separate solenoid valves with only one active (energized) setting has resulted in compact valve designs, i.e., smaller size and weight, as well as lower magnetic forces compared to the previous 3/3-way solenoid valves. This allows optimized electrical control with low electrical power loss in the solenoid coils and the control unit. In addition, the valve block (Figure 8) can be made smaller. This results in quite significant savings in weight and size.

The 2/2-way solenoid valves are available in a variety of designs and specifications, and, because of their compact dimensions and excellent dynamics, they allow fast electrical switching times sufficient for pulse-width-modulated cyclic operation. In other words, they have “proportional-valve characteristics”.

ABS 8 from Bosch (Figure 8) benefits from current-signal-modulated valve control which substantially improves function (e.g., adaptation to changes in coefficient of friction) and ease of control (e.g., smaller deceleration fluctuations with the aid of pressure stages and analog pressure control). This mechatronic optimization has positive effects not only on function but also on user-friendliness, i.e., noise and pedal feedback.

ABS 8 is capable of specific adaptation to individual vehicle-class requirements by varying the components (e.g., using motors of different power ratings, varying accumulator chamber size, etc.). The power of the return motor can vary within a range of approx. 90 to 200 watts. The accumulator-chamber size is also variable.



Hydraulic unit of an ABS/TCS system

On passenger cars with hydraulic brake systems, an expanded ABS hydraulic unit is required for TCS brake intervention. Depending on the variant, the expansion can comprise an intake valve and a changeover valve (Figure 9). An additional hydraulic presupply pump and a pressure accumulator may be required. During a necessary brake intervention, the intake and changeover valves assigned to the spinning wheel and the ABS return pump are electrically actuated. The return pump can draw brake fluid from the brake master cylinder through the intake valve. The changeover valve blocks the return flow to the brake master cylinder. The pressure generated by the return pump passes through the inlet valve to the wheel-brake cylinder of the spinning wheel, as a result of which the wheel is braked and prevented from spinning. Braking pressure is built up, as dictated by the situation and adapted by continuous monitoring of the control process, by alternating and electrically clocked actuation of the inlet and outlet valves in the hydraulic unit.

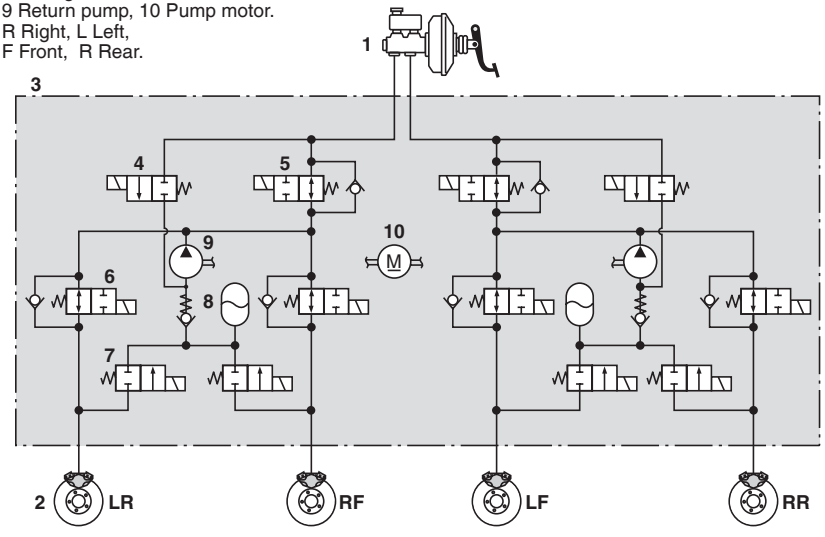
On completion of the control phase, electrical actuation is terminated and the braking pressure applied for TCS control,

Figure 8: Design of ABS 8 hydraulic unit from Bosch

1 ECU,
2 Coil group,
3 Hydraulic unit,
4 Pump motor.

as following a normal braking operation, is reduced via the intake and changeover valves and the brake master cylinder.

Electronic control unit (ECU)
The ECU processes the signals supplied by the wheel-speed sensors. After these signals have been conditioned and filtered, a vehicle reference speed is calculated and this forms the basis for the wheel-slip calculation. To form the reference speed the individual rotational-speed signals are, depending on the respective driving situation and other criteria, corrected if necessary with different weighting.



The associated solenoid valves are activated depending on the individual wheel-slip values and the target values.

Because of the safety relevance of the slip-control functions, the ECUs contain comprehensive safety and diagnostic functions to monitor the complete system on a permanent basis. Detected faults lead to partial or full shutdown of the system and are stored in a fault memory. This can be interrogated in the garage-workshop with a diagnosis tester and deleted after the faults have been cleared.

ABS system variants
A variety of versions are available depending on the brake-circuit configuration, the vehicle's drivetrain configuration, functional requirements and cost considerations. The most common brake-circuit configuration is the diagonal split (X brake-circuit configuration), followed by the front-rear split (II brake-circuit configuration) (see Brake-circuit configuration). The HI and HH brake-circuit configurations (e.g., in the DaimlerChrysler Maybach) are specialized applications and are rarely used in combination with ABS. The ABS system variants are distinguished according to the number of control channels and wheel-speed sensors.

4-channel system with four sensors
These systems (Figure 10) allow individual control of the wheel brake pressure at each wheel by the four hydraulic channels, with the brake circuits split front/rear (for type-II brake-circuit configuration) or diagonally (for type-X brake-circuit configuration). Each wheel has its own wheel-speed sensor to monitor wheel speed.

Figure 9: Schematic diagram of an ABS/TCS hydraulic circuit for passenger cars with X brake-circuit configuration

R Right, L Left,
F Front, R Rear.

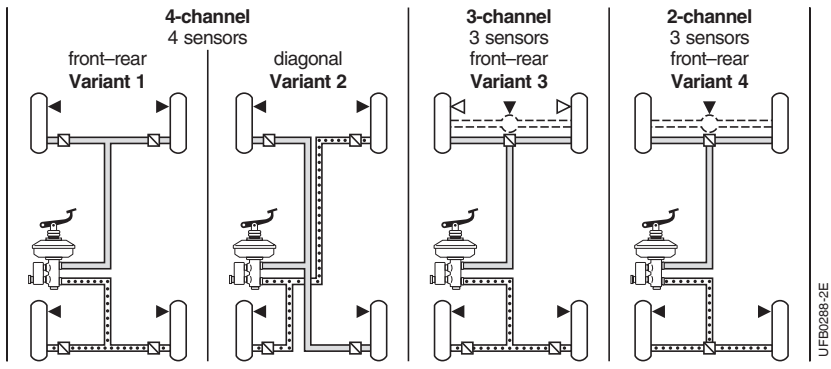
3-channel system with three sensors
Instead of the familiar arrangement with a separate speed sensor on each wheel, the rear wheels with this variant share a single sensor which is fitted in the differential. Due to the characteristics of the differential, it allows the measurement of wheel-speed differences with certain restrictions. Due to the select-low control characteristic for the rear wheels, i.e., parallel connection of the two rear-wheel brakes, a single hydraulic channel is sufficient for (parallel) control of the rear braking pressures.

Hydraulic 3-channel systems require a type-II brake-circuit configuration (front and rear split).

3-sensor systems can only be used on vehicles with rear-wheel drive, i.e., primarily small commercial vehicles and light trucks. The number of vehicles fitted with such systems is generally dropping off.

2-channel system with one or two sensors
Two-channel systems were produced because of the smaller number of components required and the resulting potential for cost savings. Their popularity was limited as their functionality does not match that of "full-fledged" systems. These systems are now hardly ever used in cars.

TCS engine-control intervention in passenger cars
On passenger cars with diesel engines, engine-control intervention is performed, depending on the variant, by means of electronic diesel control or the ETC (electronic throttle control) system (by reduced delivery).



On passenger cars with gasoline engines, torque reduction is usually performed by means of a combination of several functions. In this way, it is possible to reduce the engine torque according to the requirements by specifically suppressing injection pulses, retarding the ignition timing or closing the throttle device (ETC).

The engine-management systems receive the TCS request via signal or CAN data lines from the TCS control system.

Use of ABS on motorcycles
It has been possible to reduce the size and weight of car ABS systems substantially in recent years. As a result, volume-production ABS systems are now a very attractive option for motorcycles. Consequently, this class of vehicle will also be able to benefit from the advantages of ABS as a safety system.

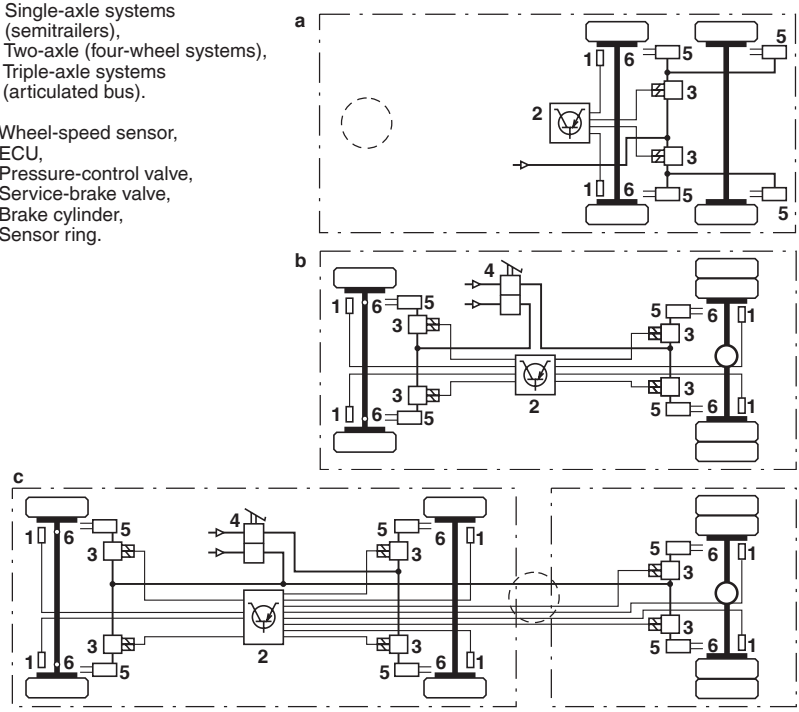
The car system is modified for use on motorcycles. Instead of the usual eight 2/2-way valves in the hydraulic unit for cars (with X-configuration brake circuits), motorcycles normally only require four valves. The control algorithm also differs fundamentally from that of a car ABS system.

Figure 10: ABS system variants
◹ Control channel, ◀ Sensor, ◁ Sensor (alternative to differential sensor).

Other system variants have arisen from the demand for combined brake systems (CBS), i.e., systems in which both the front and rear brakes can be operated either by a foot pedal or a hand-operated lever, possibly in combination with a separate means of actuating the front brakes. This type of special case requires a 3-channel hydraulic unit. However, the CBS variant is very model-specific in design.

ABS/TCS systems for commercial vehicles

In an ABS or ABS/TCS system for commercial vehicles, depending on the vehicle configuration and the number of axles, four or six wheel-speed sensors, up to three to six pressure-control valves, and – in the case of a TCS system – one TCS valve are used (Figure 11 and Figure 12).



During a learning operation on initial commissioning, the control unit adjusts to the corresponding vehicle depending on the connected components. This involves detecting the number of axles, the ABS control method, and any additional functions that may be required, such as TCS.

If one axle is a lifting axle, it is automatically excluded from the ABS control process when lifted. When two axles are close together, often only one of them is fitted with wheel-speed sensors. The brake pressure of two wheels arranged

Figure 11: Examples of ABS systems for commercial vehicles

6 Sensor ring.

one after the other is then controlled jointly by a single pressure-control valve. In multi-axle vehicles where the axles are further apart, such as articulated buses for example, three-axle control is used out of preference.

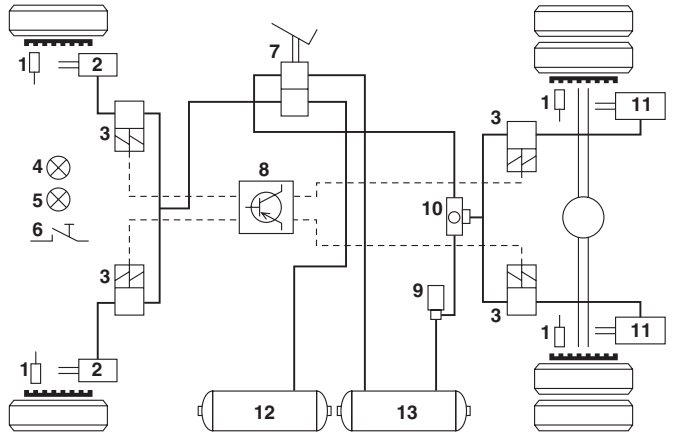
In light commercial vehicles with pneumatic-hydraulic converters, ABS intervenes in the pneumatic brake circuit via pressure-control valves and defines the hydraulic braking pressure.

When the vehicle is running on a low-friction-coefficient road surface, the operation of an additional retarding brake (exhaust brake or retarder) can lead to excessive slip at the driven wheels. This would impair vehicle stability. ABS therefore also monitors brake slip here and controls it to permissible levels by switching the retarder on and off.

In addition, there is an ABS system independent of the tractor vehicle in the trailer, which in turn consists of two or four wheel-speed sensors and an mechatronic pressure-control module with integrated electronics.

Components

Wheel-speed sensors



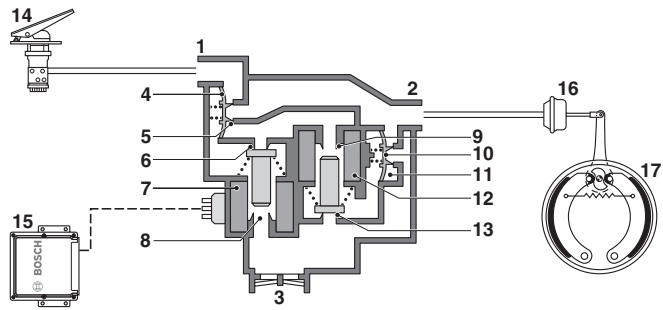
Virtually exclusively passive speed sensors in accordance with the inductive measuring principle have hitherto been used in the commercial-vehicle sector. Owing to the principles involved, these sensors can only sense speeds greater than 0 km/h, which means that – unlike active sensors, which can also detect a stationary sensor wheel – stationary detection is not possible.

Pressure-control valve

The pressure-control valves are located between the service-brake valve and the brake cylinders, and control the brake pressure of one or more wheels (Figure 13). As pilot-controlled valves, they consist of a combination of two solenoid valves and in each case a downstream pneumatic diaphragm valve, which are designed as outlet and holding valves (single-channel pressure-control valve). The electronics control the solenoid valves in the appropriate combination so that the required function is performed ("pressure holding" and "pressure drop"). If no pilot-valve actuation takes place, "pressure rise" is the result.

Figure 12: Traction control system for commercial vehicles

1 Wheel-speed sensor with sensor ring, 2 Brake cylinder, 3 ABS pressure-control valve, 4 ABS warning lamp, 5 TCS lamp, 6 TCS switch, 7 Service-brake valve, 8 ABS/TCS ECU, 9 TCS valve, 10 Shuttle valve, 11 Spring-type brake cylinder, 12 Compressed-air reservoir, circuit 1, 13 Compressed-air reservoir, circuit 2.



When braking normally (i.e., without ABS response = no incipient wheel locking), air flows through the pressure-control valves unhindered in both directions when pressure is applied to or vented from the brake cylinders. This ensures fault-free functioning of the service-brake system.

TCS valve
Usually a directly controlled TCS solenoid valve designed as a 2/2-way directional-control valve in combination with a pneumatic shuttle valve is provided for the driver-independent pressure rise for the TCS brake controller (Figure 12). In the event of a brake intervention the supply pressure is applied via the electrically actuated TCS solenoid valve and the shuttle valve to the ABS pressure-control valves, whereby the shuttle valve blocks the connection to the service-brake valve according to select-high. At the same time, on the non-active side, the holding magnet of the ABS pressure-control valve is actuated to prevent the pressure rise in the associated wheel-brake cylinder. The brake pressure can now be controlled according to the desired wheel speed with the ABS pressure-control valve on the active side.

TCS engine-control intervention in commercial vehicles
Engine-control intervention is performed – similarly to passenger cars with diesel engines – via electronic diesel control (e.g., by reduced delivery). The engine-management system receives the corresponding signal via a CAN data bus from the ABS/TCS ECU.

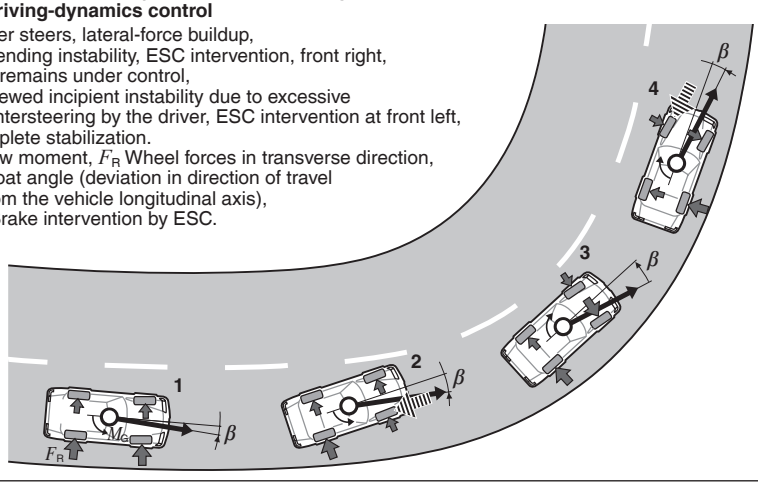
Driving-dynamics control system

Function

Human error is the cause of a large portion of road accidents. Even under normal driving conditions, a driver and his vehicle can reach their physical operating limits on account of, for example, an unexpected bend in the road, a suddenly appearing obstacle or an unanticipated change in the condition of the road surface. Increased speed can also result in the driver not being able to control his vehicle safely, since the lateral-acceleration forces acting on the vehicle in such a situation reach levels which make excessive demands on him.



If the tires' coefficients of friction are exceeded, the vehicle will suddenly behave differently from what the driver with his driving experience expects. In such situations of operating limits, the driver is often no longer able to stabilize the vehicle himself; as a rule, he will intensify the instability through reactions arising from fear and panic. As a result, a significant discrepancy is built up between the longitudinal motion of the vehicle and the longitudinal axis of the vehicle (float angle β). Even by steering in the opposite direction, a normal driver will barely be able to restabilize his vehicle on his own at float angles in excess of 8°.

Driving-dynamics control is known by different names – the Electronic Stability Program (ESP®, brand name of Daimler AG) or the neutral designation Electronic Stability Control (ESC). The system makes a substantial contribution to neutralizing such limit situations by helping the driver to keep his/her vehicle under control within the framework of the physical limits. Sensors constantly record the behavior of both the driver and the vehicle. By comparing the actual state with a target state appropriate for the relevant situation, the system, in the event of significant discrepancies, makes interventions in the braking system and in the drivetrain to stabilize the motion of the vehicle (Figure 1).

The integrated functionality of the antilock braking system (ABS) prevents the wheels from locking when the brakes are applied, while the similarly integrated traction control system (TCS) inhibits excessive wheel spin during acceleration. ESC as an overall system, however, embraces capabilities extending far beyond those of either ABS or ABS and TCS combined. The system ensures that the vehi-

cle does not swerve outwards with its rear end (oversteering) or does not push excessively outwards with its front end (understeering), but instead follows the driver's steering input as far as is physically possible.

ESC is based on ABS and TCS components. In this way, the individual wheels can be actively braked with high dynamic response. The engine torque and thus the traction-slip values at the wheels can be influenced by means of the engine-management system. The systems communicate via, for example, the CAN bus.

Table 1: Terms and quantities

a_y	Measured vehicle lateral acceleration
F_x	Tire force in longitudinal direction
F_y	Tire force in lateral direction (lateral force)
F_N	Tire force in normal direction (normal force)
L	Distance between front and rear axles
M_{BrNom}	Nominal braking torque
M_{DifNom}	Nominal differential torque
M_{EngNom}	Nominal engine torque
$M_{MWhlNom}$	Nominal sum torque
ΔM_{RedNom}	Setpoint change of engine-torque reduction
ΔM_Z	Stabilizing yaw moment
p_{Whl}	Wheel-cylinder pressure
p_{Adm}	Admission pressure
r	Radius of bend
v_{ch}	Characteristic vehicle speed
v_{Dif}	Wheel-speed differential of drive wheels (on one axle)
v_{DifNom}	Nominal wheel-speed differential of drive wheels (on one axle)
v_{MWhl}	Mean wheel speed of driven axle
$v_{MWhlNom}$	Setpoint value of mean wheel speed
v_{Whl}	Measured wheel speed
v_x	Vehicle linear velocity
v_y	Vehicle lateral velocity
α	Tire slip angle
β	Float angle
δ	Steering-wheel angle
λ	Tire slip

μ	Coefficient of friction
$\dot{\psi}$	Yaw velocity
$\dot{\psi}_{Nom}$	Nominal yaw velocity

Requirements

Driving-dynamics control contributes to increasing driving safety. It improves vehicle behavior up to the physical operating limits. The vehicle's reaction remains foreseeable to the driver and can thus be better controlled even in critical driving situations.

At the vehicle's physical driving limits, vehicle and directional stability are enhanced in all operating states, such as full braking, partial braking, coasting, accelerating, overrunning and load changes, and also for example in the case of extreme steering maneuvers (fear and panic reactions). The risk of skidding is drastically reduced.

In a variety of different situations, further improvements are obtained in the exploitation of traction potential when ABS and TCS come into action, and when engine drag-torque control is active (automatic increase in engine speed to inhibit excessive engine braking torque). This leads to shorter braking distances and greater traction with enhanced stability and higher levels of steering response.

Incorrect system interventions could have an impact on safety. A comprehensive safety concept ensures that all faults that are not essentially avoidable are detected in time and the ESC system is shut down fully or partially depending on the type of fault.

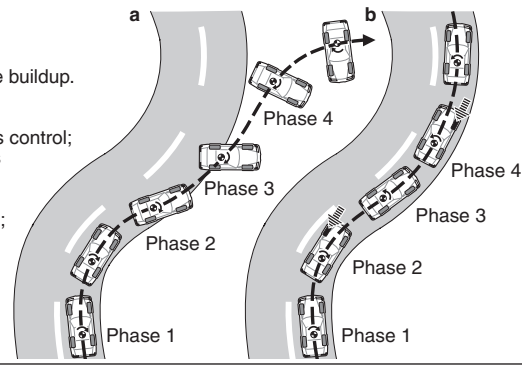
Numerous studies (e.g. [1] and [2]) have demonstrated that ESC drastically reduces the number of accidents caused by skidding and the number of associated fatalities. The upshot of this is that ESC will become mandatory in vehicles in North America by September 2011. In the European Union (EU), all new passenger cars and light commercial vehicles have had to be fitted with a driving-dynamics control system since November 2011 (integral part of ECE-R 13-H [12]). Other new cars were subject to a transition period which must be complied with by the end of 2014. Other regions such as Japan and Australia for example will also be introducing or have already introduced such a control system.

Operating principle

Driving-dynamics control (ESC) is a system which uses a vehicle's brake system and drivetrain to deliberately influence the vehicle's longitudinal and lateral motion in critical situations. When the stability-control function assumes operation, it shifts the priorities that govern the brake system. The basic function of the wheel brakes – to decelerate and/or stop the vehicle – assumes secondary importance as ESC intervenes to keep the vehicle stable and on course. ESC can also accelerate the drive wheels by means of engine interventions to contribute to the vehicle's stability.

Both mechanisms act on the vehicle's intrinsic motion. During steady-state circular-course driving, there is a defined connection between the driver's steering input and the resulting vehicle lateral acceleration and thus the tire forces in the lateral direction (self-steering effect). The forces acting on a tire in the longitudinal and lateral directions are dependent on the tire slip. It follows from this that the vehicle's intrinsic motion can be influenced by the tire slip. The specific braking of individual wheels, e.g. of the rear wheel on the inside of the bend in the case of understeering or of the front wheel on the outside of the bend in the case of oversteering, helps the vehicle to remain on the course determined by the steering angle as precisely as possible.

Typical driving maneuver



To compare how a vehicle handles at its operating limits with and without ESC, the following example is given. The driving maneuver reflects actual operating conditions, and is based on simulation programs designed using data from vehicle testing. The results have been confirmed in subsequent road tests.

Rapid steering and countersteering
Figure 2 demonstrates the handling response of a vehicle without ESC and of a vehicle with ESC negotiating a series of S-bends with rapid steering and countersteering inputs on a high-grip road surface (coefficient of friction $\mu = 1$), without the driver braking and at an initial speed of 144 km/h. Figure 3 shows the curves for dynamic-response parameters. Initially, as they approach the S-bend, the conditions for both vehicles, and their reactions, are identical. Then come the first steering inputs from the drivers (phase 1).

Vehicle without ESC
As can be seen, in the period following the initial, abrupt steering input the vehicle without ESC is already threatening to become unstable (Figure 2a, Phase 2). Whereas the steering input has quickly generated substantial lateral forces at the front wheels, there is a delay before the rear wheels start to generate similar forces. The vehicle reacts with a clockwise

Figure 2: Vehicle tracking during right-left cornering sequence

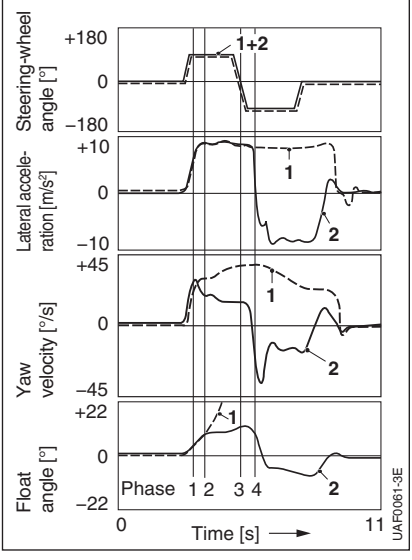
b) Vehicle with ESC.
Brake intervention by ESC.



Phase 1: Driver steers, lateral-force buildup.
Phase 2: Incipient instability.
Phase 3: Countersteering:

Phase 4: Vehicle without ESC is no longer under control;
Vehicle with ESC fully stabilized by ESC intervention at front right.

movement around its vertical axis (inward yaw). The vehicle barely responds to the driver's attempt to countersteer (second steering input, Phase 3), because it is no longer under control. The yaw velocity and the side-slip angle rise radically, and the vehicle breaks into a skid (phase 4).

Vehicle with ESC
The vehicle with ESC is stabilized after the initial steering input by active braking of the front left wheel to counter the threat of instability (Figure 2b, Phase 2): This occurs without any intervention on the driver's part. This action limits the inward yaw with the result that the yaw velocity is reduced and the float angle is not subject to an uncontrolled increase. Following the change of steering direction, first the yaw moment and then the yaw velocity reverse their directions (between Phases 3 and 4). In Phase 4, a second brief brake application – this time at the right front wheel – restores complete stability. The vehicle remains on the course defined by the steering-wheel angle.

Figure 3: Dynamic-response curves during a right-left cornering sequence
1 Vehicle without ESC, 2 Vehicle with ESC. Phases 1-4 see Figure 2.

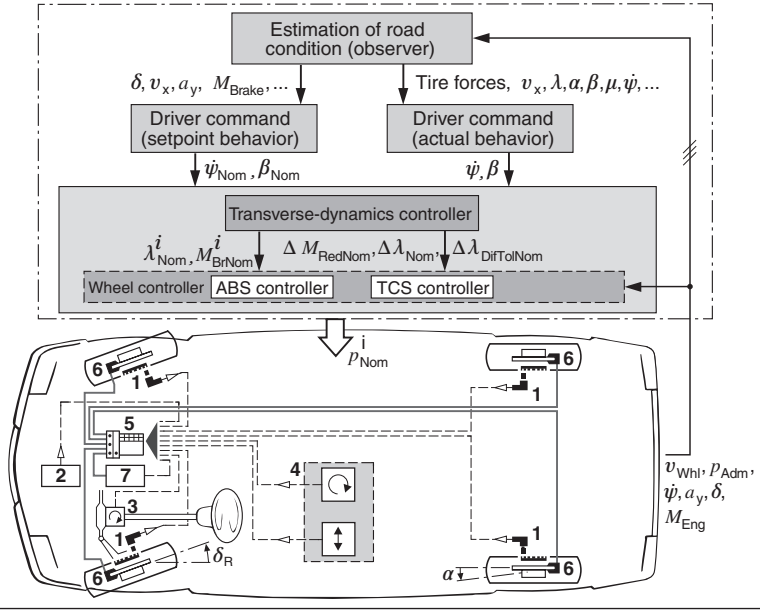
Structure of the overall system

Objective of driving-dynamics control
The control of the handling characteristics at the vehicle's physical driving limits is intended to keep the vehicle's three degrees of freedom in the plane of the road – linear velocity v_x, lateral velocity v_y and yaw velocity $\dot{\psi}$ about the vertical axis – within the controllable limits. Assuming appropriate operator inputs, driver demand is translated into dynamic vehicular response that is adapted to the characteristics of the road in an optimization process designed to ensure maximum safety.

System and control structure
The ESC system comprises the vehicle as a controlled system, the sensors for determining the controller input variables, the actuators for influencing the braking, motive and lateral forces, as well as the hierarchically structured controller, comprising a higher-level transverse-dynamics controller and lower-level wheel controllers (Figure 4). The higher-level controller determines the setpoint values for the lower-level controller in the form of moments or slip, or their changes. Internal system variables that are not directly measured, such as the float angle β for example, are determined in the driving-condition estimation ("observer").

In order to determine the nominal behavior, the signals defining driver command are evaluated. These comprise the signals from the steering-wheel-angle sensor (driver's steering input), the brake-pressure sensor (desired deceleration input, obtained from the brake pressure measured in the hydraulic unit) and the accelerator-pedal position (desired drive torque). The calculation of the nominal behavior also takes into account the utilized friction-coefficient potential and the vehicle speed. These are calculated in the observer from the signals sent by the wheel-speed sensors, the lateral-acceleration sensor, the yaw sensor, and the brake-pressure sensor. Depending on the control deviation, the yaw moment, which is necessary to make the actual-state variables approach the desired-state variables, is then calculated.

In order to generate the required yaw moment, it is necessary for the changes in desired braking torque and slip at the wheels to be determined by the transverse-dynamics controller. These are then set by means of the lower-level brake-slip and traction controllers together with the brake-hydraulics actuator and the engine-management actuator.



Driving-condition estimation

To determine the stabilization interventions, not only knowledge of the signals from the sensors for wheel speeds v_{Whl}, admission pressure p_{Adm}, yaw rate (yaw velocity) $\dot{\psi}$, lateral acceleration a_y, steering-wheel angle δ and engine torque is important, but also knowledge of a series of further internal system variables which can be measured indirectly with appropriate effort. These include, for example, the tire forces in the longitudinal, lateral and normal directions (F_x, F_y and F_N), the vehicle linear velocity v_x, the tire slip values λ_i, the slip angle α on one axle, the float angle β, the vehicle lateral velocity v_y, and the coefficient of friction μ. They are estimated on a model-supported basis from the sensor signals in the observer.

The vehicle linear velocity v_x is of crucial importance to all the wheel-slip-based controllers and must therefore be calculated with great accuracy. This is done on the basis of a vehicle model using the measured wheel speeds. Numerous influences must be taken into account here. The vehicle speed v_x differs for example already in normal driving situations on account of brake or drive slip from the wheel speeds v_{Whl}. For all-wheel-drive vehicles, special linking of the wheels must be taken into account in particular. During cornering, the

Figure 4: ESC overall control system

6 Wheel brakes, 7 Engine ECU.

wheels on the inside of the bend follow a different course from the wheels on the outside of the bend, and consequently rotate at a different speed.

Vehicle handling changes during normal use in response to varying load, altered tractive resistance (e.g. road gradient or surface, wind) or wear (e.g. of the brake pads).

Under all these boundary conditions, the vehicle linear velocity must be estimated with a deviation of a few % in order to ensure the enabling and intensity of stabilization interventions to the necessary extent.

Basic transverse-dynamics controller

The function of the transverse-dynamics controller is to calculate the actual behavior of the vehicle from, for example, the yaw-velocity signal and the float angle estimated in the observer, and to bring the driving behavior in the driving-dynamic limit range into line with behavior in the normal range as closely as possible (nominal or setpoint behavior).

The connection that exists during steady-state circular-course driving between the yaw velocity and the steering-wheel angle δ, the vehicle linear velocity v_x and characteristic vehicle variables are used to determine the nominal behavior. The single-track vehicle model (see e.g. [3]) is used to produce

$$\dot{\psi} = \frac{v_x}{l} \; \delta \; \frac{1}{1+\left(\frac{v_x}{v_{ch}}\right)^2}$$

as the basis for calculating the vehicle nominal motion. In this formula, l denotes the distance between the front and rear axles. Geometric and physical parameters of the vehicle model are summarized in the "characteristic vehicle speed" v_{ch}.

The variable $\dot{\psi}$ is then limited according to the current friction-coefficient conditions and to the special properties of the vehicle dynamics and the driving situation (e.g. braking or acceleration by the driver) and to the particular conditions such as a sloping road surface of different friction coefficients under the vehicle (μ split). The driver command is thus known as the nominal yaw velocity $\dot{\psi}_{Nom}$.

The transverse-dynamics controller compares the measured yaw velocity with the associated setpoint value and in the event of significant deviations calculates the yaw moment that is required to match the actual state variable to its setpoint state. At a higher level, the float angle β is monitored and, as the values rise, increasingly taken into consideration in the calculation of the stabilizing yaw moment ΔM_z. This controller output variable is applied by means of braking-torque and slip inputs to the individual wheels which must be adjusted by the lower-level wheel controllers.

Stabilization interventions are performed at the wheels, the braking of which generates a yaw moment in the required direction of rotation and at which the limit of the transmittable forces has not yet been reached. For an oversteering vehicle, the physical limit is first exceeded on the rear axle. Stabilization interventions are therefore performed via the front axle. For an understeering vehicle, the situation is reversed (see e.g. [6]).

The nominal slip values requested by the transverse-dynamics controller λ^i_{Nom} at individual wheels are set with the aid of lower-level wheel controllers (see Figure 4). A distinction is made between the following three application cases.

Wheel control in the coasting case

In order to exert as accurately as possible the yaw moments required to stabilize the vehicle, the wheel forces must be altered under defined conditions by controlling the wheel slip. The nominal slip requested by the transverse-dynamics controller at a wheel is adjusted in the unbraked case by the lower-level brake-slip controller by way of an active pressure build-up. The current slip at the wheel must be known as precisely as possible for this purpose. This is calculated from the measured wheel-speed signal and the vehicle linear velocity determined in the observer v_x. The nominal braking torque at the wheel is formed from the deviation of the actual wheel slip from its setpoint value using a PID control law.

It is not only in the event of an active pressure build-up by transverse-dynamics control that a wheel can be subject to

brake slip. Following downshifts and when the accelerator is suddenly released, inertia in the engine's moving parts exerts a degree of braking force at the drive wheels. Once this force and the corresponding reactive torque rise beyond a certain level, the tires will lose their ability to transfer the resulting loads to the road and will tend to lock (e.g. because the road is suddenly slippery). The brake slip for the driven wheels can be limited in the coasting case by engine drag-torque control. This acts like "gentle acceleration" by the driver.

Wheel control in the braked case
In the braked case, different actions overlap at individual wheels, depending on the driving situation:
– driver input via the brake pedal and the steering wheel,
– effect of the ABS controller, which prevents individual wheels from locking,
– interventions of the transverse-dynamics controller which ensures vehicle stability by specifically braking individual wheels if necessary.

These three requirements must be coordinated in such a way that the driver's deceleration and steering inputs are implemented as much as possible. If wheel control is performed primarily with the objective of maximum vehicle deceleration, it can be performed on the basis of wheel acceleration which can be robustly determined with minimal sensor information (instability control). In order to specifically adjust the longitudinal and lateral tire forces to stabilize the vehicle, the principle of slip control [4] must be applied because it also permits wheel control in the unstable range of the friction-coefficient/slip characteristic. From the available sensor information, however, it must be possible to determine the absolute wheel slip to a few %, depending on the vehicle speed.

The function of the ABS controller is to ensure vehicle stability and steerability in all road conditions and in so doing exploit as much as possible the friction between wheels and road. It does this also in its capacity as the lower-level controller to the transverse-dynamics controller by modulating the brake pressure at the wheel in such a way that the maximum possible longitudinal force can be exerted while maintaining sufficient lateral stability. However, more variables are measured in ESC than in a pure ABS configuration, which only contains the wheel-speed sensors. Thus, individual vehicle-motion information, such as for example yaw rate or lateral acceleration, is available through direct measurement of greater accuracy than is the case with model-supported estimation of the basis of few measured values.

In certain situations, it is possible to increase performance by adapting ABS control by means of inputs from the transverse-dynamics controller. When a vehicle decelerates on unequal road surfaces (μ split), very different braking forces occur at the wheels on the left and right sides of the vehicle. This generates a yaw moment about the vehicle vertical axis, to which the driver must react by countersteering in order to stabilize the vehicle. How quickly this yaw moment is built up – and how fast the driver must consequently react – depends on the vehicle's moment of inertia about the vertical axis. ABS features yaw-moment build-up delay to hold back the pressure rise at the front wheel with the higher coefficient of friction at the road surface ("High" wheel). This ABS facility can also use information from the higher-level transverse-dynamics controller (on the driver's reaction and the vehicle behavior) and thereby react even better to the actual vehicle motion.

If, when braking in a bend, the vehicle starts to turn under certain conditions, the oversteer tendency can be counteracted by means of electronic braking-force distribution through pressure reduction in individual wheels. If this is not sufficient on its own, the transverse-dynamics controller helps by actively building up pressure at the front wheel on the outside of the bend (reduction of lateral force). If, on the other hand, the vehicle understeers, the braking torque is increased at the rear on the inside (provided the wheel is not subject to ABS control) and decreased slightly at the front on the outside.

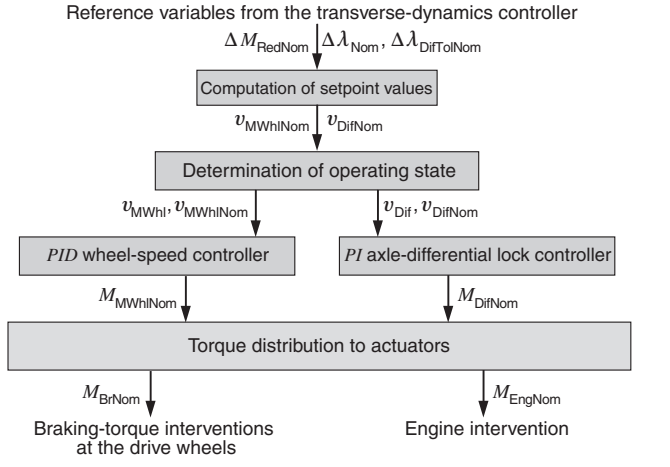
If the vehicle starts to oversteer during a fully or partially braked lane change, the pressure at the rear wheel on the inside of the bend is specifically decreased (increase in lateral force) and the pressure at the front wheel on the outside of the bend increased (decrease in lateral force). If the vehicle understeers while braking in the bend, the braking torque is increased at the rear on the inside (provided the wheel is not yet in the ABS control range) and decreased slightly at the front on the outside.

Wheel control in the drive case

The lower-level traction controller (TCS) is activated as soon as the drive wheels start to spin in the drive case. The measured wheel speed and the respective drive slip can be influenced by changing the torque balance at each drive wheel. The TCS controller limits the drive torque at each drive wheel to the drive torque that can be transferred there to the road. In this way, the driver command is implemented after acceleration as well as is physically possible and, at the same time, fundamental directional stability is ensured, since the lateral forces at the wheel are not too greatly reduced.

In a vehicle with a powered axle, the mean wheel speed of the driven axle

$$v_{\mathrm{MWhl}} = \frac{1}{2}\left(v^{\mathrm{L}}_{\mathrm{Whl}} + v^{\mathrm{R}}_{\mathrm{Whl}}\right)$$



and the wheel-speed differential

$$v_{\mathrm{Dif}} = v^{\mathrm{L}}_{\mathrm{Whl}} - v^{\mathrm{R}}_{\mathrm{Whl}}$$

between the measured wheel speed of the left wheel $v^{\mathrm{L}}_{\mathrm{Whl}}$ and the right wheel $v^{\mathrm{R}}_{\mathrm{Whl}}$ are used as controlled variables.

The structure of the entire TCS controller is depicted in Figure 5. The reference variables of the transverse-dynamics controller are included in the setpoint-value calculation for the mean wheel speed and the wheel-speed differential, as well as the setpoint slip values and the coasting wheel speeds. In the calculation of the setpoint values v_{DifNom} (setpoint wheel-speed differential of the drive wheels on one axle) and v_{MWhlNom} (setpoint value of the mean wheel speed), the inputs for changing the setpoint slip $\Delta\lambda_{\mathrm{Nom}}$ and the permissible slip differential $\Delta\lambda_{\mathrm{DifTolNom}}$ of the drive axle(s) act in the form of an offset on the basic values calculated in the TCS. In addition, an understeer or oversteer tendency identified by the transverse-dynamics controller directly influences, through the setpoint change of the en-

Figure 5: Structure of TCS controller
Quantities, see Table 1.

gine-torque reduction ΔM_{RedNom}, the determination of the maximum permissible drive torque.

The dynamic response of the drivetrain depends on the highly differing operating states. It is therefore necessary to determine the current operating status (e.g. selected gear, clutch actuation) in order to be able to adapt the controller parameters to the controlled system's dynamic response and to nonlinearities.

Because the mean wheel speed is affected by variable inertial forces originating from the drivetrain as a whole (engine, transmission, drive wheels, and the propshaft itself), a relatively large time constant is employed to describe its correspondingly leisurely rate of dynamic response. The mean wheel speed is controlled by means of a nonlinear PID controller, whereby in particular the gain of the I-component (dependent on the operating status) can vary over a wide range. In the stationary case, the I-component is a measure for the torque which can be transferred to the road surface. The output variables of this controller is the setpoint sum torque $M_{MWhlNom}$.

In contrast, the time constant for the wheel-speed differential is relatively small, reflecting the fact that the wheels' own inertial forces are virtually the sole determining factor for their dynamic response. Furthermore, in contrast to the mean wheel speed, it is influenced only indirectly by the engine. The wheel-speed differential v_{Dif} is controlled by a nonlinear PI controller. Because brake interventions at a drive wheel initially only become noticeable through the torque balance of this wheel, they change the distribution ratio of axle differential and thereby emulate a differential lock. The controller parameters of this axle-differential-lock controller are only dependent on the engaged gear and engine influences to a minimal extent. If the differential speed on the driven axle deviates more than currently permissible (dead zone) from its setpoint value v_{DifNom}, calculation of a setpoint differential torque M_{DifNom} starts. The dead zone is widened if TCS brake interventions are to be avoided, for example when cornering at the operating limits.

Setpoint sum and setpoint differential torques are the basis for distributing the positioning forces to the actuators. The setpoint differential torque M_{DifNom} is set by the braking-torque difference between the left and right drive wheels by means of corresponding valve actuation in the hydraulic unit (asymmetrical brake intervention). The setpoint sum torque $M_{MWhlNom}$ is adjusted by both the engine interventions and a symmetrical brake intervention.

With a gasoline engine, adjustments undertaken through the throttle valve are relatively slow to take effect (lag and the engine's transition response). Retarding the ignition timing and, as a further option, selective suppression of injection pulses are employed for rapid engine-based intervention. In diesel-engine vehicles, the electronic diesel control system (EDC) reduces the engine torque by modifying the quantity of fuel injected. Symmetrical brake intervention can be applied for brief transitional support of engine-torque reduction.

Traction plays a special role in off-road applications. Normally, in vehicles with off-road requirements, traction control is automatically adapted by way of special situation identification in order to achieve the best levels of performance and robustness possible. Other vehicle manufacturers give the driver the opportunity to choose different adjustments from deactivation of engine-torque limitation through to adaptations tailored to special road conditions (e.g. ice, snow, grass, sand, slush, and rocky ground).

Supplementary transverse-dynamics functions

The basic ESC functions described above can also feature supplementary driving-dynamics functions for special vehicle categories, such as sport utility vehicles (SUVs) and small vans for example, and for special vehicle-stabilization requirements.

Enhanced understeering control

It is possible even in normal driving conditions for the vehicle to fail to comply adequately with the driver's steering input

(it understeers) if, for example, the road surface in a bend is suddenly wet or contaminated. ESC can therefore increase the yaw rate by exerting an additional yaw moment. This enables the vehicle to negotiate a bend at the maximum speed physically possible. The expected frequency of interventions and the comfort requirements of the vehicle manufacturer differ from vehicle type to vehicle type, and there are accordingly different expansion stages for executing such brake interventions which influence the vehicle's understeering behavior.

If the driver requests a smaller radius of bend than is physically possible, then only the reduction of the vehicle speed remains. This can be read from the connection applicable during steady-state cornering between the radius of bend r, the vehicle linear velocity v_x and the yaw rate $\dot{\psi}$:

$$r = \frac{v_x}{\dot{\psi}} .$$

In order to ensure a desired track course, the vehicle is then – without a yaw moment being applied – braked as far as necessary by specific braking of all the wheels (Enhanced Understeering Control, EUC).

Rollover prevention

In particular, light commercial vehicles and other vehicles with a high center of gravity, such as sport utility vehicles (SUVs), can overturn when high lateral forces are generated by a spontaneous steering reaction by the driver in the course of an evasive maneuver on a dry road for example (highly dynamic driving situations) or when the lateral acceleration of a vehicle slowly increases into the critical range as it negotiates a freeway exit with a decreasing radius of bend at excessive speed (quasi-stationary driving situations).

There are special functions (Rollover Mitigation Functions, RMF) which identify these critical driving situations by using the normal ESC sensors and stabilize the vehicle by intervening in brake and engine control. In order to ensure intervention on time, in addition to the driver's steering input and the measured reaction of the vehicle (yaw rate and lateral acceleration), a predictive process is used to estimate the vehicle's behavior in the near future. The two wheels on the outside of the bend, in particular, are braked if an imminent danger of overturning is identified. This action reduces the lateral forces on the wheels and thereby reduces the critical lateral acceleration. Particularly in the event of highly dynamic evasive maneuvers, wheel control must be effected with such high levels of sensitivity that, in spite of the wildly fluctuating vertical forces F_N, vehicle steerability is not diminished by the tendency of individual wheels to lock. The reduction of wheel speed by individual wheel braking also ensures that the driver is able to keep the vehicle in lane. In quasi-stationary driving situations, punctual reduction of the engine torque also prevents the driver from provoking a critical situation.

The moment of intervention and the intensity of the stabilizing interventions must be adapted as accurately as possible to the current vehicle behavior. This behavior can change significantly with the load, for example in the case of vans or sport utility vehicles fitted with roof racks. Such vehicles therefore make use of additional estimation algorithms which calculate the vehicle mass and the change in the center of mass caused by load distribution, if this is required to adapt the ESC functions (Load Adaptive Control, LAC).

Trailer sway mitigation

Depending on the vehicle speed, combinations of towing vehicle and trailer are prone to swaying about their vertical axis. If the vehicle is traveling at a slower speed than the "critical speed" (normally between 90 km/h and 130 km/h), these swaying motions are adequately damped and are quick to die down. If, however, the combination is traveling at a higher speed, small steering movements, crosswinds or driving over a pothole can suddenly induce such swaying motions, which then quickly intensify and can ultimately cause an accident due to the combination jackknifing.

Clear periodic oversteering triggers normal ESC stabilization interventions, but these normally arrive too late and on their own are not sufficient to stabilize the combination. The Trailer Sway Mitigation (TSM) function identifies swaying motions in good time on the basis of the customary ESC sensors; it does this by model-based analysis of the towing vehicle's yaw rate while taking into account the driver's steering movements. When these swaying motions reach a critical level, the combination is automatically braked in order to reduce the speed to such an extent that not even the smallest subsequent excitation will cause an immediate critical oscillation again. In order to damp the oscillation as effectively as possible in a critical situation, in addition to symmetrical deceleration through all the towing vehicle's wheels, individual wheel interventions are performed which swiftly damp the swaying motion of the combination. Limitation of the engine torque prevents dangerous acceleration by the driver during the stabilization process.

Activation of further driving-dynamics actuators

In addition to utilization of the hydraulic wheel brakes, other actuators are provided by means of which the driving-dynamic properties of a vehicle can be specifically influenced. When active steering and chassis systems are linked with ESC to form the composite system known as Vehicle Dynamics Management (VDM), they can, in their entirety, support the driver even better and thereby improve safety and driving dynamics even further.

While the combination of the steering or roll-stabilization system with the brake system has been introduced in the last few years [5], systems for activating differential locks in the drivetrain have been established on the market for some time now. The large number of such systems means that linking with ESC is possible in many cases. The supplementary actuator can basically be activated either directly from the extended ESC function (cooperation approach) or via a separate ECU which exchanges information with the ESC ECU (coexistence approach).

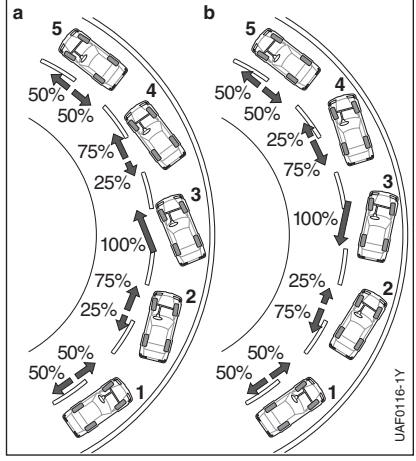
In all-wheel-drive vehicles, the drive torque is distributed via a central element to both powered axles (Figure 6). When the engine acts first and foremost on one axle and the second axle is linked via the central element, this is known as a hang-on system. If this central element is an open differential (without a locking action), drive torque is limited when one axle demonstrates increased slip. In the most unfavorable case, propulsion cannot be achieved if a wheel spins. In combination with ESC, symmetrical brake interventions by the all-wheel TCS controller can limit the differential speed between the axles and thereby achieve a longitudinal locking action.

The traction control of ESC can also be matched to the special operating concept of other types of central elements such as Torsen and viscous couplings. Basically, all the controllable drivetrain actuators must demonstrate a defined locking moment and dynamic response when opening and closing in order to specifically adapt the vehicle's self-steering properties with them.



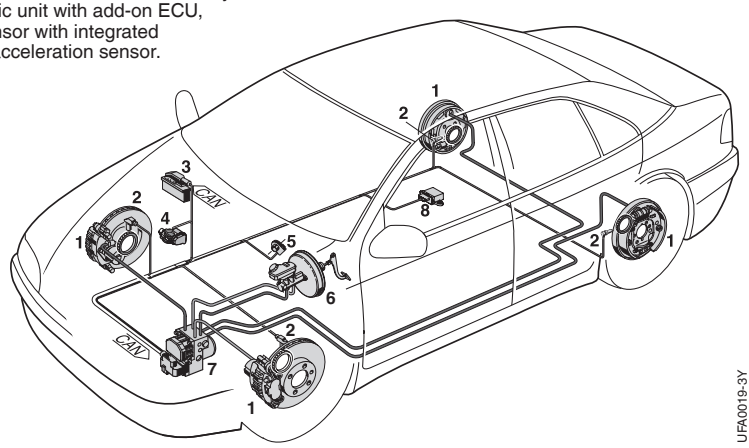
If the drivetrain of a vehicle can be manually switched over between different configurations, ESC can be automatically adjusted to the operating mode selected by the driver. Because ESC is based on individual wheel control, cooperation with mechanical differential locks for specific off-road conditions is only possible if the differential lock can be automatically opened during interventions by the transverse-dynamics controller. The system must otherwise be switched to an ABS fallback level when the lock is engaged, because driving-dynamics interventions at one wheel would also affect other wheels if the axles were rigidly linked.

In addition to simple links between the two axles, there are controllable central locks in which an electric or hydraulic actuator activates a coupling and thereby adapts the locking moment (Figure 6, A). In this way, it is possible with the ESC driving-dynamics information (e.g. wheel speeds, vehicle speed, yaw rate, lateral acceleration, and engine torque) and by also taking into account actuator-specific variables (such as e.g. the mechanical load on the component) to optimally adapt the linking of the two axles to the current driving situation (Dynamic Coupling Torque at Center, DCT-C).

The example in Figure 7 shows how variable drive-torque distribution influences the vehicle behavior. If, in the event of a risk of oversteering in a bend, provisionally more drive torque can be shifted to the front axle, it is necessary only much later to avoid instability, to lower the engine torque or even stabilize the vehicle with brake interventions (the maximum possible drive-torque shift is shown). If a vehicle tends to understeer, this tendency can be lessened by shifting drive torque to the rear axle. In both cases, vehicle behavior with improved response and better stability is achieved. The limits within which shifting the drive torque is actually possible are dependent on the concrete drivetrain configuration.

Figure 7: Influence of drive-torque distribution on vehicle behavior

a) Oversteer: Stability limit is first exceeded on the rear axle,
b) Understeer: Stability limit is first exceeded on the front axle.
1 Standard distribution during stable driving,
2 Incipient instability, drive torque is shifted to the axle which still has stability potential,
3 Maximum shift of drive torque,
4 Withdrawal of shift,
5 Standard distribution is re-established after instability has been reduced.



A controllable element on one axle can be activated by ESC along similar lines to the flexible linking of the two axles described. In terms of basic operation, the Dynamic Wheel Torque Distribution (DWT) function barely differs from the axle-differential lock effected by TCS via the hydraulic wheel brakes. However, such a supplementary actuator also actively distributes the drive torque between the wheels on one axle in normal situations. This is done with minimal losses and which much greater sensitivity and comfort than can be achieved by traction control in combination with braking-torque control and engine-torque reduction while taking into account the wear of the ESC hydraulic unit.

System components

The hydraulic unit, the ECU directly connected to it (add-on ECU) and the speed sensors are suitable for the rugged ambient conditions that are encountered in the engine compartment or the wheel arches. The yaw sensor and the lateral-acceleration sensor are either integrated into the ECU or like the steering-angle sensor installed in the passenger cell. Figure 8 shows by way of example the installation locations of the components in the vehicle with the electrical and mechanical connections.

Electronic control unit (ECU)
The ECU of printed-circuit board design comprises, as well as a dual-core computer, all the drivers and semiconductor relays for valve and pump activation, as well as interface circuits for sensor-signal conditioning and corresponding switch inputs for supplementary signals (e.g. brake-light switch). There are also interfaces (CAN, FlexRay) for communicating with other systems, such as engine and transmission management for example.

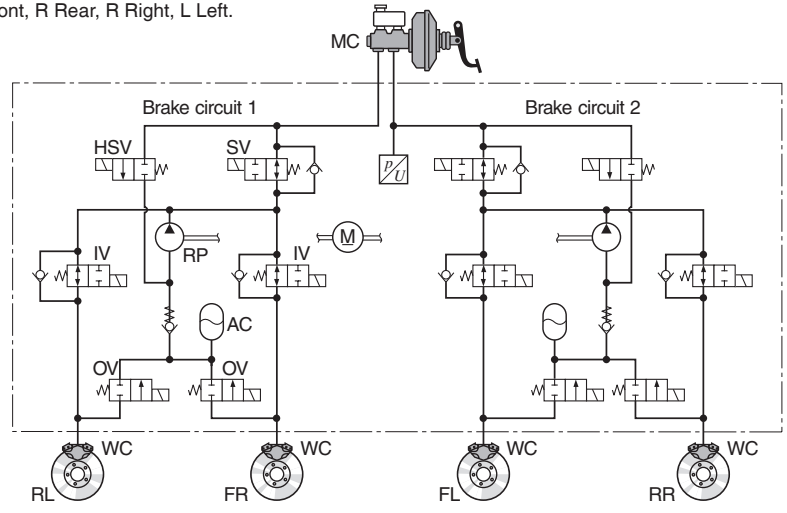
3 Engine ECU,
4 Electronically activated throttle valve,
5 Steering-angle sensor,
6 Brake booster with brake master cylinder,
7 Hydraulic unit with add-on ECU,
8 Yaw sensor with integrated lateral-acceleration sensor.

Hydraulic unit

The hydraulic unit (also called the hydraulic modulator), as in ABS or ABS/TCS systems, forms the hydraulic connection between the brake master cylinder and the wheel-brake cylinders. It converts the control commands of the ECU and uses solenoid valves to control the pressures in the wheel brakes. The hydraulic circuit is completed by bores in an aluminum block. This block is also used to accommodate the necessary hydraulic function elements (solenoid valves, plunger pumps and reservoir chambers).



ESC systems require twelve valves irrespective of the brake-circuit configuration (Figure 9). In addition, a pressure sensor is usually integrated which measures the driver's deceleration command by way of the brake pressure in the brake master cylinder. This increases the performance of vehicle stabilization in partially active maneuvers. Pressure is modulated during ABS control (passive control) using ESC hydraulics in the same way as described for the ABS system.

But because ESC systems must also actively build up pressure (active control) or increase a brake pressure input by the driver (partially active control), the return pump used for ABS is replaced by a self-priming pump for each circuit. The wheel-brake cylinders and the brake master cylinder are connected via a changeover valve open at zero current and a high-pressure switching valve.

An additional non-return valve with a specific closing pressure prevents the pump from drawing unwanted brake fluid from the wheels. These pumps are driven by a DC motor based on demand. The motor drives an eccentric bearing located on the shaft of the motor.

Three examples of pressure modulation are shown in Figure 10. In order to build up pressure independently of the driver (Figure 10c), the switchover valves are closed and the high-pressure switching valves opened. The self-priming pump now pumps brake fluid to the relevant wheel or wheels in order to build up pressure. The inlet valves of the other wheels

remain closed. To reduce the pressure, the outlet valves are opened and the high-pressure switching valves and switchover valves return to their original position (Figure 10b). The brake fluid escapes from the wheels into the low-pressure reservoirs, which are run empty by the pumps. Demand-based control of the pump motor reduces noise emission during pressure generation and regulation.

Figure 10: Pressure modulation in the ESC hydraulic unit

For partially active control (Figure 10a), the high-pressure switching valve must be able to open the suction path of the pump against higher differential pressures (> 0.1 MPa). The first stage of the valve is opened via the magnetic force of the energized coil; the second stage via the hydraulic area difference. If the ESC controller detects an unstable vehicle state, the switchover valves (open at zero current) are closed and the high-pressure switching valve (closed at zero current) is opened. The two pumps then generate additional pressure in order to stabilize the vehicle. When the intervention is finished, the outlet valve is opened and the pressure in the controlled wheel discharged to the reservoir. As soon as the driver releases the brake pedal, the fluid is pumped from the reservoir back to the brake-fluid reservoir.

Monitoring system

A comprehensive safety-monitoring system is of fundamental importance for reliable ESC functioning. The system used encompasses the complete system together with all components and all their functional interactions. The safety system is based on safety methods such as, for example, FMEA (Failure Mode and Effects Analysis), FTA (Fault Tree Analysis) and error-simulation studies. From these, measures are derived for avoiding errors which could have safety-related consequences. Extensive monitoring programs guarantee the reliable and punctual detection of all sensor errors which cannot be prevented completely. These programs are based on the well-proven safety software from the ABS and TCS systems which monitor all the components connected to the ECU together with their electrical connections, signals, and functions. The safety software was further improved by utilizing the possibilities offered by the additional sensors, and by adapting them to the special ESC components and functions.

The sensors are monitored at a number of stages. In the first stage, the sensors are continuously monitored during vehicle operation for line break, signal implausibility (“out-of-range” check), detection of interference, and physical plausibility. In a

second stage, the most important sensors are tested individually. The yaw-rate sensor is tested by intentionally detuning the sensor element and then evaluating the signal response. Even the acceleration sensor has internal background monitoring. When activated, the pressure-sensor signal must show a predefined characteristic, and the offset and amplification are compensated for internally. The steering-angle sensor has its own integrated monitoring functions and directly delivers a message to the ECU in the event of error. In addition, the digital signal transmission to the ECU is permanently monitored. In a third stage, analytical redundancy is applied to monitor the sensors during the steady-state operation of the vehicle. Here, a vehicle model is used to check that the relationships between the sensor signals, as determined by vehicle motion, are plausible. These models are also frequently applied to calculate and compensate for sensor offsets as long as they stay within the sensor specifications.

In case of error, the system is switched off either partially or completely depending on the type of error concerned. The system's response to errors also depends on whether the control is activated or not.

Further names for driving-dynamics control

Aside from ESP® and the neutral designation ESC for Electronic Stability Control there are further names used by vehicle manufacturers for driving-dynamics control. Examples are Dynamic Stability Control (DSC), Vehicle Stability Assist (VSA), Vehicle Stability Control (VSC), Dynamic Stability and Traction Control (DSTC), Controllo Stabilità e Trazione (CST).

Special driving-dynamics control system for commercial vehicles

Function

Heavy commercial vehicles essentially differ from passenger cars in their much greater mass combined with higher centers of gravity and in additional degrees of freedom resulting from trailer operation [7]. They can thus assume unstable states that extend far beyond the skidding familiar to passenger cars. Such states include, as well as the jackknifing of multiple-stage vehicle combinations, caused for example by trailer sliding, overturning caused by high lateral acceleration. A vehicle-dynamics control system for commercial vehicles must therefore, in addition to providing the stabilization functions familiar to passenger cars, also prevent jackknifing and overturning.

Requirements

The following requirements, in addition to those for passenger cars, can be derived from the extended functions of driving-dynamics control for commercial vehicles:

- Improvement in directional stability and response of a vehicle combination (e.g. articulated road train or articulated-train combination) at physical driving limits in all operating and laden states. This includes preventing jackknifing on vehicle combinations.
- Reduced risk of overturning for a vehicle or vehicle combination in both quasi-stationary and dynamic vehicle maneuvers.

These requirements implemented in commercial-vehicle ESC lead, as is the case with passenger cars, to a significant improvement in driving safety. For this reason, European law will from 2011 require the gradual introduction of a driving-dynamics control system for heavy commercial vehicles (from 7.5 t) (integral part of ECE-R 13 [11]).

Application
In the meantime, commercial-vehicle ESC has become available for virtually all vehicle configurations (except all-wheel-drive vehicles):
– vehicles with the wheel formulas 4×2, 6×2, 6×4 and 8×4,
– combinations of tractor unit and semitrailer (articulated vehicle or simply semitrailer unit),
– combinations of rig and drawbar trailer (articulated road train),
– multiple trailer combinations (Eurokombi), e.g. combinations of rig, dolly and semitrailer or semitrailer unit with additional center-axle trailer or tractor unit with B-link and semitrailer.

Operating principle
Driving-dynamics control for commercial vehicles can be divided according to requirements into the two function groups described in the following.

Stabilizing the vehicle in the event of imminent skidding or jackknifing
Directional stabilization of a commercial vehicle is initially performed according to the same principles as for a passenger car. The controller compares current vehicle motion with vehicle motion desired by the driver, taking into account physical driving limits. The physical model of motion in the horizontal plane – for a single vehicle characterized by three degrees of freedom (longitudinal, lateral and yaw motion) – is however extended for an articulated vehicle to include the articulation angle between the rig and the trailer (an additional degree of freedom). There are further degrees of freedom involved for combinations with fifthwheel trailers.

To calculate the vehicle motion desired by the driver, the ECU uses simplified mathematical-physical models (single-track vehicle model, [8]) to determine the nominal yaw velocity of the rig. The parameters that are encountered in these models (characteristic vehicle speed v_{ch}, wheelbase l and steering ratio i_L) are either parameterized at the end of the vehicle assembly line or adapted to the vehicle's behavior during vehicle operation with the aid of special adaption algorithms (e.g. Kalman filters or recursive least-squares estimators, [9]). "Online" adaptation of parameters is particularly important in commercial vehicles, because the variety of variants and loads is much greater than for passenger cars.

Parallel to this, ESC calculates current vehicle motion from the measured variables available for yaw rate and lateral acceleration plus the wheel speeds. A significant deviation between the current vehicle motion and the motion expected by the driver leads to a control fault that is transformed by the actual controller into a corrective nominal yaw moment.

The level of the nominal yaw moment for a commercial vehicle depends on the control fault, the current vehicle configuration (wheelbase, number of axles, operation with or without trailer etc.) and the laden state (mass, center of gravity in the linear direction, etc.). As these parameters are variable, they are continuously determined by ESC. This is achieved, for example, in the laden state with the aid of an estimation algorithm that uses the signals from the engine management (engine speed and engine torque) and the vehicle linear motion (wheel speeds) to permanently identify the current vehicle mass.

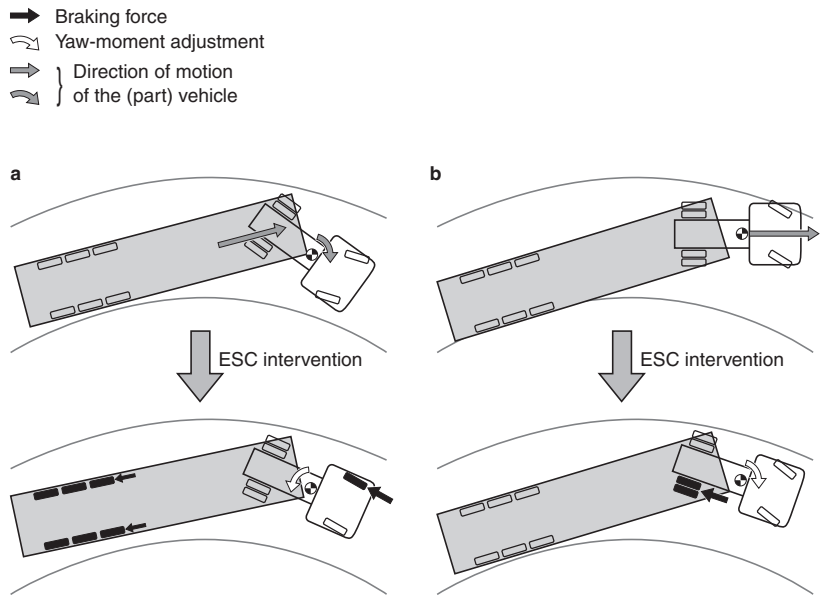
On the basis of the current driving situation, the nominal yaw moment by braking individual or several wheels and of the trailer is transformed in a suitable manner. This is depicted by way of example in Figure 11a and in Figure 11b for a clearly defined oversteer and understeer situations respectively.

In addition to these clearly defined situations, there are other critical dynamic situations in which other wheels or wheel combinations are braked depending on the desired stabilization effect. Thus, for example in the case of sharper understeer, the entire vehicle is braked along similar lines to Enhanced Understeering Control (EUC) in passenger cars.

Because of the high center of gravity of commercial vehicles, skidding and jackknifing by such vehicles primarily occur at low-to-medium coefficients of friction at which the tire static-friction limit is already exceeded at an early stage. At high coefficients of friction, laden commercial vehicles, on account of their high center

of gravity, normally start to overturn before the static-friction limit of the tires is reached.

Reducing the risk of overturning
The overturning limit (lateral-acceleration limit) of a vehicle depends not only on the height of the center of gravity but also on the chassis systems (axle suspension, stabilizers, springs, etc.) and the type of payload (fixed or moving) [10].



The situation which causes a commercial vehicle to overturn is, aside from a relatively low overturning limit, an excessive cornering speed. ESC makes use of this scenario to reduce the probability of the vehicle overturning. As soon as the vehicle approaches the overturning limit, it is slowed down by reducing engine torque and, if necessary, also applying the brakes. The overturning limit is determined here depending on the load of the vehicle and the load distribution, whereby the laden state of the vehicle is estimated "online".

Depending on each driving situation, the overturning limit that is determined is modified. Thus, the overturning limit in high-speed dynamic situations (e.g. obstacle-avoidance maneuvers) is reduced in order to permit early intervention. In very slow maneuvers, on the other hand (e.g. negotiating tight hairpin bends on uphill stretches), it is increased in order to prevent unnecessary and disruptive ESC intervention.

Determining the overturning limit is based on various assumptions regarding the height of the center of gravity and the dynamic response of the vehicle combination with a known axle-load distribution. This covers the largest portion of the usual vehicle combinations.

In order to ensure stabilization even in the case of strong deviations from these assumptions (e.g. extremely high centers of gravity), ESC additionally detects the lift of the wheels on the inside of a bend. This is achieved by monitoring the wheels

Figure 11: Principle of ESC braking intervention on semitrailers
a) Vehicle oversteering,
b) Vehicle understeering.

for implausible rotation speed. If necessary, the entire vehicle combination is then heavily decelerated by brake intervention.

A trailer wheel lifting on the inside of a bend is indicated by the trailer's electronically controlled braking system (ELB) via the CAN communication line (ISO 11992 [13]) by activating the ABS controller. For combinations with trailers equipped with ABS only, wheel-lift detection on the inside of a bend is limited to the tractor unit (rig).

System design

On the European market, the electronically controlled braking system ELB has come to the fore as the standard for brake control in heavy commercial vehicles. ESC is based on this system, extending it to include regulation of the driving dynamics. To do so, ESC uses the ELB capability of generating varying braking forces for each individual wheel independently of driver action.

The very different general conditions for commercial vehicle brake systems in North America mean that purely ABS or ABS/TCS systems are used as standard. An ESC based on ABS/TCS is therefore used for these and similar markets. Here, ESC uses the method already applied with TCS on the drive axle to generate braking force individually for each wheel independently of the driver by means of a TCS valve and the downstream ABS valves. In addition, for ABS-based ESC, the driver brake command must be measured by means of pressure sensors, which would otherwise not be possible during an ESC intervention on account of the function of the TCS valve.

Sensor systems

Like passengers cars, commercial vehicles use a combined yaw-rate and lateral-acceleration sensor and a steering-wheel-angle sensor as driving-dynamics sensors for ESC. Each of these sensors contains a microcontroller with a CAN interface for analyzing and safely transmitting the measured data.

The steering-wheel-angle sensor is usually mounted immediately below the steering wheel and it measures the angle of rotation of the steering wheel. This is then converted in the ECU into a wheel steering angle.

In order to pick up the lateral acceleration as close as possible to the center of gravity of the rig, the combined yaw-rate and lateral-acceleration sensor is usually mounted in the vicinity of the center of gravity.

Even though commercial vehicles essentially use the same sensors as passenger cars, the yaw-rate and lateral-acceleration sensor must have a much more robust design to cope with the rougher ambient conditions, particularly on the commercial-vehicle frame.

Electronic control unit (ECU)

The ESC algorithms are run together with the other algorithms for brake control (e. g. ABS and TCS) in the brake control unit. This control unit is constructed using conventional circuit-board technology with correspondingly powerful microcontrollers.

A CAN bus connects the ESC sensors with the control unit. The nominal brake pressures and wheel slip values of the ESC are then implemented by the relevant braking system for each wheel and for the trailer. In addition, the braking system transmits the requested engine torque via the vehicle CAN bus (usually standardized as per SAE J 1939 [14]) to the engine ECU for implementation.

Moreover, relevant information is also transferred from the engine and retarder to the braking system via the vehicle CAN bus. Essentially, this involves current and requested engine torque and speed, retarder torque, vehicle speed, and information from various control switches and any trailer that may be coupled.

Safety and monitoring functions

The extensive possibilities for ESC intervention in the handling characteristics of the vehicle and vehicle combination require a comprehensive safety system to ensure proper system functioning. This extends not only to the basic ELB or ABS/TCS system respectively, but also to the additional ESC components, including all sensors, ECUs and interfaces.

The monitoring functions used for ESC are essentially based on the functions used in passenger cars and are adapted to the characteristics of commercial vehicles.

There is also mutual monitoring of the microcontrollers distributed in the overall system. This means that the brake control unit contains a main computer and a monitoring computer that mainly performs plausibility checks alongside minor functional tasks. Furthermore, the corresponding algorithms permanently check memory and other internal computer hardware components to detect any defects that occur at an early stage.

The occurrence of faults results, depending on the nature and significance of the fault, in the shutdown of individual function groups through to a complete switching to "backup mode", in which the brakes are controlled by purely pneumatic means (fail-silent response). This ensures that incorrect sensor signals cannot cause implausible and possibly dangerous operating states in braking operations.

The occurrence of a fault is indicated to the driver by suitable means (e.g. warning lamp or display) so that suitable action can be taken.

Furthermore, any faults that occur are assigned a time stamp in the control unit and stored in the fault memory. The workshop can evaluate these with the help of a suitable diagnosis system.

Automatic brake-system operations

The supplementary functions described here utilize except for the pneumatic-mechanical brake assistant the driving-dynamics control infrastructure. This comprises the sensors, the actuators and the ECU.

Brake-assistant operations
Investigations into driver braking behavior in the 1990s showed that car drivers differ in the way that they respond to braking situations. The majority – the "average drivers" – do not brake hard enough when faced with an emergency situation, in other words, they require an unnecessarily long braking distance (Figure 1). This can be remedied by a system first launched in 1995, the brake assistant. Its main purposes are as follows:
– It interprets a certain rate of pedal movement (rapid application of the brakes) that fails to apply maximum braking force as an intention by the driver to carry out full braking. In this case, it generates the braking pressure required to achieve full braking effect.
– It allows the driver to "cancel" full braking operation at any time.

Figure 1: Comparison between braking with and without brake-assistant operations
A longer braking distance is required without a brake assistant than with a brake assistant.
1 "Average driver",
2 Experienced driver,
3 "Average driver" with brake assistant.
t_v Delay time for braking results in longer braking distance.

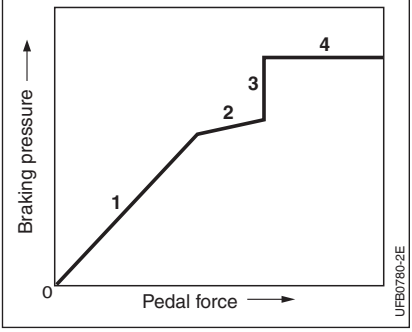
– The behavior of the brake booster and, therefore, the pedal feedback, is not altered under normal braking conditions.
– The basic braking-system function is not diminished if the brake assistant fails.
– The system is designed to prevent accidental activation.

Pneumatic brake assistant
This system requires a modified brake booster which increases the level of amplification according to the rate of pedal movement and pedal force. This results in faster and greater buildup of pressure in the wheel brakes.

In an alternative version, the brake booster is extended to include an electronically activated valve. This enables an ECU to influence the pressure difference between the brake-booster chambers and thus the boosting of the braking force. This provides better opportunities for optimizing the trigger threshold and response characteristics.

Hydraulic brake assistant
The hydraulic brake-assistant operation uses the driving-dynamics control hardware. A pressure sensor detects the driver's braking intention; the ECU analyzes the signal on the basis of the defined triggering criteria, and initiates an appropriate brake-pressure build-up in the hydraulic system. The upstream brake booster is a standard unit and does not require any modification.

As a general observation, it should be stated that it is an absolute requirement that all brake-assistant system variants referred to are used in conjunction with an antilock braking system (ABS) or a driving-dynamics control system due to the actively generated rapid brake-pressure rise beyond the wheel-lock limit.



Automatic brake-pressure increase at the rear wheels

This is a function which provides the driver with additional brake servo assistance for the rear wheels if the front wheels are controlled by the ABS system. This function was introduced because many drivers do not increase the pedal force at the start of ABS control even though the situation would require this. Once ABS control has been initiated on the front wheels, the wheel pressures at the wheels on the rear axle are increased by way of the return pump of the hydraulic modulator until these too have reached the lockup-pressure level and ABS control is initiated (Figure 2). The brake application is therefore at the physical optimum. The pressure in the rear axle wheel-brake cylinders can then exceed the pressure in the brake master cylinder, also during ABS control.

The cutoff condition is fulfilled when the wheels on the front axle are no longer under ABS control or when the pressure in the brake master cylinder falls below the cutoff threshold.

Figure 2: Automatic brake-pressure increase

1 Brake-pressure increase by brake booster,
2 Further brake-force increase by pedal force,
3 Brake-pressure increase by driving-dynamics control hydraulic modulator,
4 ABS control range.

Automatic brake-pressure increase with forceful pressing of brake pedal

This function provides the driver with additional brake servo assistance. It is activated if the maximum possible vehicle deceleration is not achieved even if the driver forcefully presses the brake pedal to the point that would normally cause the lockup pressure to be reached (primary pressure over approx. 80 bar). This is the case, for example, at high brake-disk temperatures or if the brake pads have a considerably reduced coefficient of friction.

When this function is activated, the wheel pressures are increased until all wheels have reached the lockup pressure level and ABS control is initiated (Figure 2). The brake application is therefore at the physical optimum. The pressure in the wheel-brake cylinders can then exceed the pressure in the brake master cylinder, also during ABS control.

If the driver reduces the desired level of braking to a value below a particular threshold value, the vehicle deceleration is reduced in accordance with the force applied to the brake pedal. The driver can therefore precisely modulate the vehicle deceleration when the braking situation has passed. The cutoff condition is fulfilled if the primary pressure or vehicle speed falls below the respective cutoff threshold.

Brake-disk wiper

This function ensures that, in the event of rain or a wet road, the splash water is cyclically removed from the brake disks. This is achieved by automatically setting a low brake pressure at the wheel brakes. In this way, the function helps to ensure minimum brake-response times when driving in wet conditions. Evaluated signals from the windshield wipers or rain sensor are used to detect wet conditions.

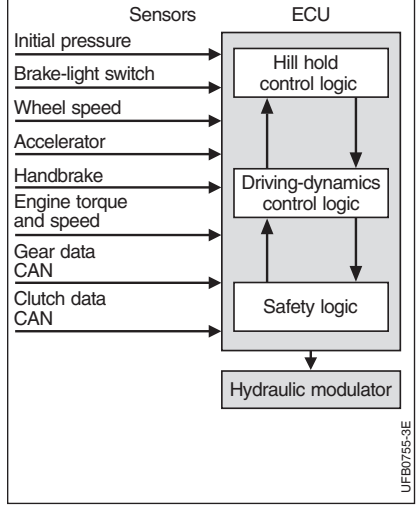
The pressure level is adjusted so that the vehicle deceleration cannot be perceived by the driver. Actuation is repeated at a defined interval for as long as the system detects rain or a wet road. If required, just the disks at the front axle can be wiped. The wiping procedure is terminated as soon as the driver applies the brakes.

Automatic prefill
This function reduces the total braking distance in emergency situations whereby the driver operates the brake pedal immediately after the accelerator pedal is released. This is achieved by prefilling and thereby preloading the brake system after release of the accelerator pedal, which means that in the subsequent brake operation the pressure build-up is considerably more dynamic. Accordingly, high vehicle deceleration sets in earlier.

Prefilling of the brake system is adjusted by the return pump of the hydraulic modulator. The brake shoes are then firmly applied to the brake disks. If there is no operation of the brake pedal directly after a rapid release of the accelerator, the pressure in the brake system is reduced again. This does not impair driveability.

Electromechanical parking brake
The electromechanical parking brake (EMP) generates the force for applying the parking brake by electromechanical means. The function of the hand- or foot-operated parking-brake lever is performed by a control knob with an electric-motor-and-transmission combination. When the driver operates the control knob, the electric motor (actuator) is activated when the system detects that the vehicle is at a standstill. When the vehicle is parked on a level surface, the holding forces are set lower than when the vehicle is fully laden and parked on a gradient. Active wheel sensors are used to detect that the vehicle is parked (i.e. stationary). As an option, it is also possible for the road gradient to be detected by a tilt sensor.

The parking brake is released by means of the same control knob. However, various safety regulations and requirements have to be met, e.g. to prevent inappropriate or inadvertent release of the parking brake by children or animals (see also Parking brake, Passenger-car brake system).



Controlled braking with hydraulic modulator
If the electromechanical parking brake is activated while driving, the vehicle must be safely decelerated to a stop. The brake pressure required for this is built up by the return pump of the hydraulic modulator. The driving-dynamics control system ensures safe braking even on slippery or wet road surfaces. When the vehicle has come to a stop, the electromechanical parking brake assumes the function of keeping the vehicle stationary.

The driver must press the activation knob of the automatic parking brake continuously during the deceleration phase.

Hill hold control
This system simplifies hill starts. It prevents the vehicle from rolling back after the driver has released the brake pedal. This is particularly helpful on heavily laden vehicles with manual transmission and vehicles that are towing trailers. There is no need to operate the parking brake. The function also works when performing a hill start in the reverse direction.

The system detects the driver's intention to pull away (Figure 3). After the brake pedal is released, there is approximately two seconds to start pulling away. The

Figure 3: Hill hold control

brake is released automatically here if the drive torque is greater than the torque resulting from downgrade force.

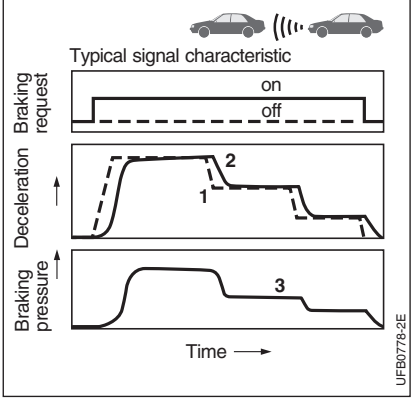
Low-speed traction control is based on the driving-dynamics control hardware and additional sensors: a tilt sensor detects the road gradient, a gear switch detects whether the driver has shifted to reverse gear, and a clutch switch recognizes whether the driver has depressed the clutch pedal.

Automatic braking on hill descent – hill descent control

This system is a convenience function which assists the driver on offroad descents with gradients of approximately 8 to 50 % by automatically operating the brakes. The driver can then concentrate fully on steering the vehicle and is not distracted by the need to operate the brakes at the same time. The brake pedal does not have to be operated.

When this system is activated, e.g, by pressing a button or switch, a preset speed is maintained over the extent of the specified brake pressure. If required, the driver can vary the predetermined speed by pressing the brake and accelerator pedal or using the control buttons of a speed control system.

The system remains active until it is switched off by pressing the button or switch again, i.e. it is not automatically deactivated.



Automatic brake application for driverassistance systems

This function is an additional function for active brake application with adaptive cruise control (ACC), i.e. for automatic vehicle-to-vehicle ranging. The brakes are applied automatically without the driver pressing the brake pedal as soon as the distance to the vehicle in front falls below a predetermined distance (Figure 4). This is based on a hydraulic brake system and driving-dynamics control.

The function receives a request to decelerate the vehicle by a desired amount (input). This is calculated by the upstream ACC system. Automatic brake intervention maintains vehicle deceleration by means of appropriate brake pressures which are adjusted with the aid of the hydraulic modulator.

Motorcycle Stability Control

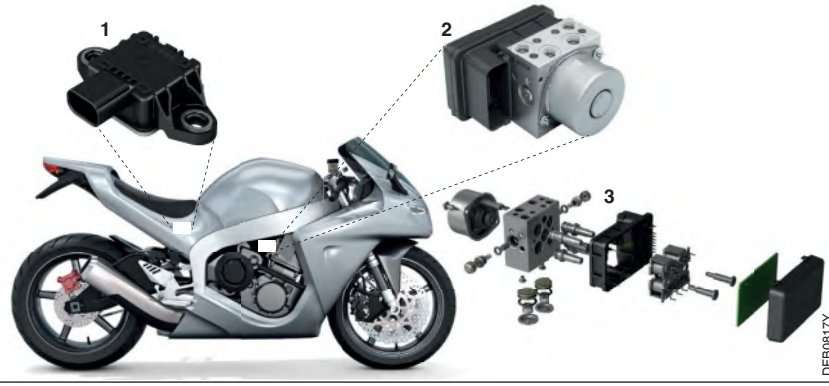
Application

Motorcycle Stability Control (MSC) improves two-wheeler safety in all critical riding situations – particularly in turns/curves. Here MSC coordinates all the functions relevant to riding dynamics such as, for example, the Antilock Braking System (ABS, see Figure 1), the electronically Combined Brake System (eCBS), anti-stoppie control, Motorcycle Traction Control (MTC), and wheelie control taking account of the current riding situation and the current road friction-coefficient conditions.

The ABS riding-dynamics control of a motorcycle is similar in some points to that of a passenger car (see Wheel-slip control systems). Therefore the riding-dynamic particulars of two-wheelers will be discussed especially in the following.

Riding physics of a two-wheeler

Maintaining equilibrium



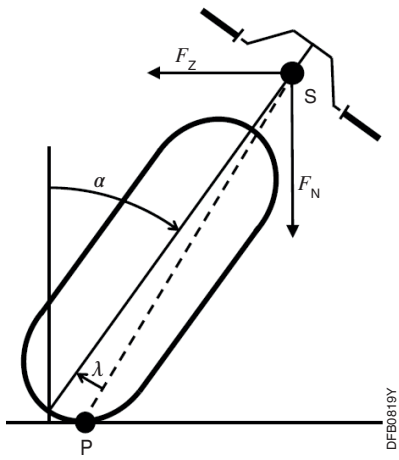
A two-wheel vehicle is in a state of unstable equilibrium and is prone to falling over. When moving it is 100% dynamically stabilized by the gyroscopic forces of the turning wheels [1] and via the castor offset. A moving two-wheeler thus becomes stable from a certain speed.

Because a two-wheeler can tilt about the longitudinal axis, it must maintain equilibrium. Figure 2 shows the equilibrium of forces between gravity and centrifugal force when cornering. In the case of a real tire the wheel contact point is laterally offset. As a result, more inclination through the angle λ is required than for a very thin tire. The wider the tire, the greater the necessary inclination at the same speed and for the same curve radius.

Self-stabilization

If the motorcycle tilts towards the inside of the curve, gyroscopic effects on the turning front wheel induce a steering moment in the direction of the inclination [1]. As a result the motorcycle rides a tighter radius, whereupon the rising centrifugal

Figure 1: MSC vehicle components
1 Inertial sensor unit,
2 ABS hydraulics with ECU (assembly)
3 ABS hydraulics (exploded view).



force rights the motorcycle again. The righting motion turns the front wheel back to the initial position. The castor offset on the front wheel brings about a similar effect. The distance between the point of intersection of the steering axis with the road and the wheel contact point is called the castor offset. When the lateral component of the wheel downforce increases, this results in a corresponding torque towards the inside of the curve on the steering (see Figure 3). The stability of a two-wheeler increases with the speed and the resulting increasing gyroscopic effects. Likewise, a greater castor offset provides for better straight-ahead stability.

To ride a stationary curve, the rider must apply a steering moment to the outside of the curve to compensate the steering moment caused by gyroscopic effects and castor offset. If the rider lets go of the handlebars, the two-wheeler rights itself and rides straight ahead again.

This produces the decisive difference as the rider specifies the desired curve radius. In a passenger car the steering wheel is turned without greater consideration of the steering torque to the corresponding steering angle. In contrast, the rider on a two-wheeler specifies the curve radius via the steering moment and the two-wheeler adjusts the associated steering angle itself accordingly by means of self-stabilization. Here the two-wheeler and the steering angle alway oscillate about the position of equilibrium somewhat. In addition, as determined by the geometry, the self-adjusting steering angle decreases as the inclination increases.

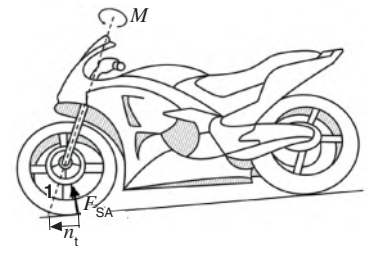
S Center of gravity,
P Wheel contact point,
F_Z Centrifugal force,
F_N Gravity (normal force),
α Inclination angle,
λ Angle to tire center plane.



Inclination estimation

Important riding-dynamic variables of a two-wheeler are the inclination (roll angle) and the pitch angle because a motorcycle leans far into the curve and tends to roll over when subjected to heavy braking and acceleration. To determine these two angles an inertial sensor unit with three acceleration sensors and three yaw sensors was developed (Figure 1); this sensor unit enables changes in angle to be sensed quickly.

The inclination and the pitch angle are calculated in accordance with ISO 8855 [2] from the direction in which Earth's gravity points when viewed from the vehicle. The direction components of the gravity vector $g = (g_x, g_y, g_z)$ are calculated by means of the following two methods:

Figure 3: Self-stabilization via the castor offset of a motorcycle leaning to the right

1 Steering axis.
M Steering moment,
F_{SA} Lateral component of wheel downforce,
n_t Castor offset.

1. Determination of the gravity vector from accelerations
When the vehicle is stationary the three acceleration sensors directly measure the components of the acceleration due to gravity. When the vehicle is moving, further components brought on by the change of speed and the centrifugal forces are added. The measured accelerations must be corrected by these components in order to obtain the gravity vector. Because the acceleration signals are for the most part disrupted more strongly by engine vibrations or road irregularities, the vector obtained in this way $g = (g_x, g_y, g_z)$ must be filtered with a low-pass filter to determine the angle precisely. This worsens the signal dynamics, but the value is long-term stable for this.

2. Rotation of the gravity vector by integration of the measured rotational movement
The rotational movement of the motorcycle about each axis is measured by three yaw sensors in the form of angular velocities. From this the change of direction of $g = (g_x, g_y, g_z)$ is calculated in each calculation cycle. The direction vector obtained in this way has good dynamics because it follows the yaw rates without further filtering. However, measuring errors or disturbances are also added up. As a result, when considered over a longer period of time, the direction of the vector would deviate ever further from the real Earth's gravity.

Correcting the g vector from method 2 with that from method 1 combines the advantages of both methods. The resulting angles dynamically follow each change and are at the same time also long-term stable.

Motorcycle ABS

Many accidents resulting in serious injury could be avoided if the rider braked fully without decelerating prior to the collision. MSC was therefore developed with the objective of enabling the rider to perform drastic braking in every situation without resulting in an accident.

Function of ABS
Just like in a passenger car, the antilock braking system (ABS) is intended to stop the wheels from locking. On a motorcycle particular attention is paid to the front wheel because here the greatest braking force can be applied and at the same time the front wheel is crucial to riding stability.

Usually the wheel slip is the most important variable for the ABS controller. However, the vehicle speed must be determined for this purpose. This poses a particular challenge when it comes to two-wheelers. Thus, for example, the rear wheel is lifted up in the event of a “stoppie” in response to heavy braking with the result that the rear-wheel speed no longer matches the driving speed. From the remaining front-wheel speed the vehicle speed must simultaneously be estimated and the wheel slip calculated. Because both these variables can no longer be reliably determined in such a situation, motorcycle ABS uses as well as the slip additional indicators, such as for example wheel deceleration, to detect wheel instability.

Rear-wheel lift-up control
A rider who brakes heavily on two wheels decelerates primarily with the front wheel. Due to the dynamic wheel-load distribution in combination with a high center of gravity, the wheel load shifts sharply towards the front wheel – often even resulting in the rear end lifting up. Rear-wheel lift-up control was developed to make stable braking possible. This function evaluates the slip and deceleration values of both wheels. If the rear wheel threatens to lift up while braking, the function adapts the pressure in the front-wheel brake circuit to keep the rear wheel on the ground and avoid rollovers.

Using the progression of the rear-wheel speed, it is in fact possible to detect when the rear wheel has lifted up, however this process does not distinguish whether the wheel hovers just a few millimeters above the ground or whether a rollover is already imminent. Here the pitch-angle and pitch-rate information from the inertial sensor helps to detect the situation and intervene with optimal control.

Braking in a turn/curve

Normal motorcycle ABS is optimized to as short a braking distance as possible during straight-ahead riding. The high brake-slip values necessary for this purpose could cause a side-slip in a curve because the tire is no longer able to apply the side control force. If the tire slips, gravity from Figure 2 is predominant and the front wheel swings in due to the castor offset towards the inside of the curve, drastically increasing the angle between direction of travel and wheel. The resulting Friction between tire and road brakes the wheel to such an extent that it locks, even if the brake pressure were reduced in this situation to 0 bar. A fall is virtually inevitable. It is therefore essential when cornering not to exceed the critical slip value.

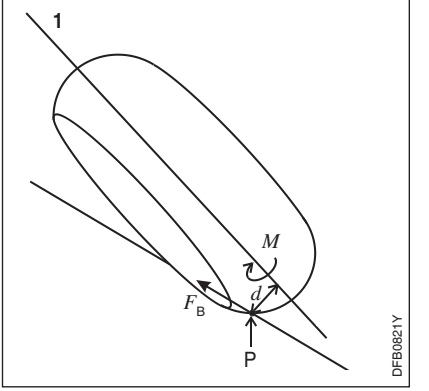
Steering moment under braking conditions

A second critical point in any braking at an inclination on the front wheel is the steering moment under braking conditions. Because the tire when inclined in no longer centrally touching the road, a longitudinally acting braking force brings about a steering moment which turns the wheel towards the inside of the curve (Figure 4). The tighter curve radius allows the centrifugal force to increase and the motorcycle rights itself and ultimately rides a wider radius than at the start. If the rider fails to correct this already at the initial-braking stage, the motorcycle may unintentionally stray onto the oncoming carriage way or leave the road.

Gradient control

Both unintentionally high brake slip in a curve and a sudden jump in the steering moment under braking conditions can be effectively brought under control by an inclination-dependent gradient control of the brake pressure. The slowly rising brake pressure gives the rider time to counteract the building steering moment under braking conditions. In addition, the slowing vehicle requires a certain righting moment because the motorcycle must be upright again at the latest when stationary.

With more slowly increasing brake pressure the brake slip as well builds up under controllable conditions and does not overshoot the limit range.



A proficient rider starts with a low brake pressure when braking in a curve and then increases this with decreasing speed and inclination. Gradient control is optimally set in such a way that it is not perceived even by professional racing riders. Only in a drastic-braking situation does it show its potential.

Further adaptations in a curve

Similarly to passenger cars, the ABS control thresholds and control parameters are adapted on a curve-dependent basis in

Figure 4: Steering moment under braking conditions

1 Steering axis.
P Wheel contact point,
M Steering moment under braking conditions,
F_B Braking force,
d Distance to center.

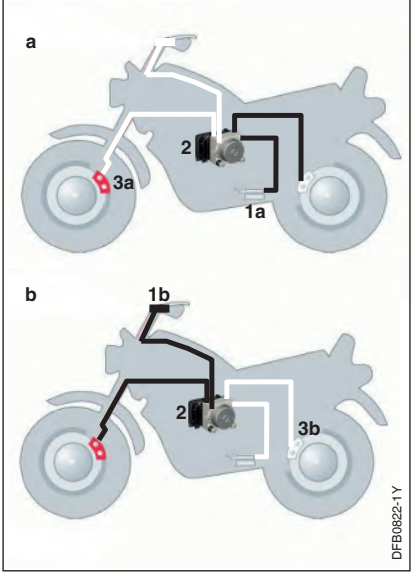
order to achieve an optimal combination of stability and braking distance. Furthermore, high ABS brake-pressure modulations must be avoided at an inclination on the front wheel because these could lead to dangerous handlebar vibrations due to the steering moment under braking conditions.

Electronically controlled braking-force distribution

To improve riding safety particularly for heavy motorcycles, Bosch has developed "ABS enhanced". This facilitates a combined braking system in the form of electronically controlled braking-force distribution (eCBS, electronically Combined Brake System). Weighing just 1.5 kg and with a volume of 1.2 liters, it is the world's smallest and lightest ABS with eCBS.

Concept of the combined braking system

With a combined braking system both wheels can be braked, even though the rider only applies the front or the rear brake (Figure 5). Using the measurement of the rider brake pressure and further parameters such as for example the speed, the system calculates the optimal braking-force distribution in each braking situation. In phase 1 in Figure 5 the rider applies the brake, in phase 2 the nominal pressure on the other wheel is calculated according to the brake pressure specified by the rider, and in phase 3 brake pressure is finally built up on the other wheel by activating the valves.



This enables very short braking distances to be achieved without a loss of stability, even if the rider, for example when panic braking, is only braking with the rear wheel. Optimization of braking-force distribution likewise reduces pitching and smooths abrupt vehicle movements, allowing the physical limits to be exploited to better effect. This makes "ABS enhanced" a safe and comfortable motorcycle-braking system.

Operating principle

The rider brake pressure is measured at the master cylinder for the eCBS function. According to the vehicle-specific braking-force distribution characteristic the systems calculates the target pressure at the other, unbraked wheel and actively builds up the brake pressure there by means of a pump. Because the target pressure is built up electronically, the brake pressure is not as in conventional, mechanical systems limited by the rider pressure. This electro-hydraulic approach offers a higher degree of freedom in the optimization of braking-force distribution to the specific riding situation. Thus, for example depending on the rear-wheel pressure, more brake pressure can be built up at the front at high speed than at low speed. Furthermore, if a speed threshold is undershot, the eCBS function can be deactivated completely so as to

Figure 5: Combined braking system – basic concept and purpose

a) Electronic pressure build-up at the front brake caliper,
b) Electronic pressure build-up at the rear brake caliper.

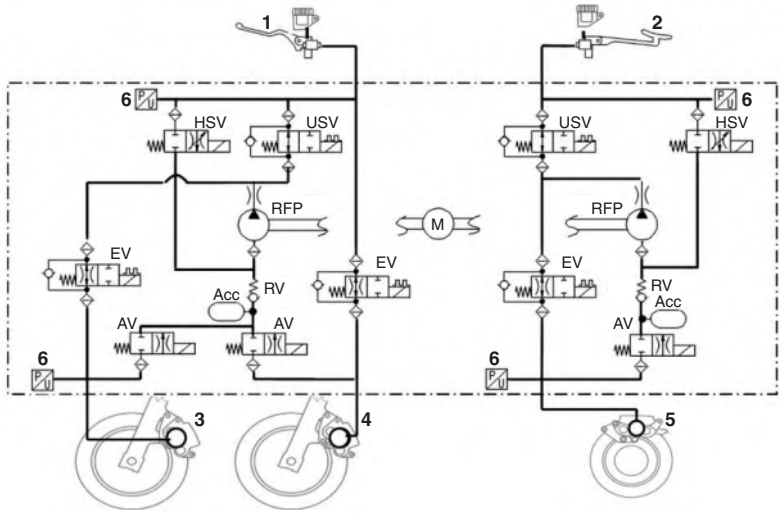
3a Brake pressure is built up at the front wheel by activating the valves and the pump,
3a Brake pressure is built up at the rear wheel by activating the valves and the pump.



avoid the comfort problems familiar from conventional systems when braking in a curve at low speed. Not least, in contrast to conventional systems, no additional hardware components are required – the complete eCBS function is already featured in “ABS enhanced”.

System design of the combined braking system
The combined braking system is available as a 2- and a 3-channel version. In the 2-channel version there is a separate brake circuit for the front wheel and one for the rear wheel. Both are independent of one another. Thus, for example for the active build-up of pressure at the front no brake fluid from the rear brake circuit is used and vice versa. In addition to the inlet (IV) and outlet valves (OV), which use a basic ABS, two additional valves per brake circuit are required – a switchover valve (SV) and a high-pressure switching valve (HSV).

The technical concept for the 2-channel system becomes apparent from Figure 6 (the figure shows a 3-channel hydraulic system, the third channel is explained later): When the rider brakes at the rear, the target pressure at the front is calculated for optimal braking-force distribution. For the active pressure build-up the high-pressure switching valve is opened and the suction pump delivers brake fluid. At the same time, energizing the changeover valve regulates its throughflow, which adjusts the desired pressure difference between master cylinder and brake caliper.

“ABS enhanced” as a 3-channel system
When the rider simultaneously brakes at front and rear, the 2-channel system has certain disadvantages with regard to the handle feel:
– If only the rear brake is applied, the system also brakes at the front wheel. If now the rider also brakes at the front,

Figure 6: Combined braking system – 3-channel hydraulic schematic
1 Brake handle, 2 Brake pedal,
3 Brake caliper 1 On front wheel, 4 Brake caliper 2 On front wheel,
5 Brake caliper on rear wheel, 6 Pressure sensors.
IV Inlet valve, OV Outlet valve,
HSV High-pressure switching valve, SV Switchover valve,
RP Return pump (suction pump), M Pump motor,
NRV Non-return valve, Acc Accumulator volume.

the brake handle feels hard. This could irritate the rider.
– If the rider is already braking lightly at the front and then applies the rear brake, the combined braking system builds up additional brake pressure at the front. In this case the connection between the brake-fluid reservoir and the brake line is already closed. The volume displacement required for the pressure build-up leads to the brake handle being drawn in.

Although both effects also occur at the rear brake circuit, the influence there on braking comfort is less pronounced because the sensitivity at the pedal is lower.

One way of solving the comfort problems of the 2-channel system is to equip the front brake with two calipers, with each being supplied by its own channel. The capacity for active pressure build-up is only implemented for one of the two calipers. When the combined braking system builds up pressure on the front wheel when the brake pedal is pressed, one caliper remains depressurized. Figure 6 shows the associated hydraulic schematic of the 3-channel system.
– If the rider now additionally applies the brake, the previously unactuated caliper through its elasticity provides for a natural braking feel.
– Due to the fact that, as shown in Figure 6, pressure is only actively built up at the left caliper of the front wheel, less brake-fluid volume is needed to achieve a particular deceleration (because for example there is only clearance at one caliper). As a result the handle reaction is reduced to an acceptable level.

Motorcycle Traction Control

Traction control regulates traction slip at the driven wheel by reducing the drive torque. This can prevent the rear wheel from breaking away sideways in a curve and optimizes the transmission of traction force to the road surface. Because the radii, the contours, and the widths of motorcycle tires are different on the front and rear wheels, the effective tire rolling circumferences depend to varying degrees on the inclination. Consequently, knowledge of the inclination angle brings a decisive advantage when calculating the wheel-slip values and in the performance capability of traction control.

Above all for Enduro motorcycles there is from slick through road tires right down to massive-bar offroad tires a wide range of possible tire combinations which can be used on all manner of surfaces such as dry asphalt, cobblestone pavement, and sand. Therefore Motorcycle Traction Control permits for the most part a wide adjustment range for adaptation to meet demand.

Anti-wheelie control

Anti-wheelie control controls the engine torque in such a way as to prevent the front wheel from lifting up in an uncontrolled manner and at the same time to guaranteed the maximum possible acceleration.

Using the progression of the front-wheel speed, it is possible to detect when the front wheel has lifted up. However this process does not distinguish whether the wheel hovers just a few millimeters above the ground or whether a rollover is already imminent. Here the pitch-angle and pitch-rate information from the inertial sensor helps to detect the situation and intervene with optimal control.

Integrated driving-dynamics control systems

Overview

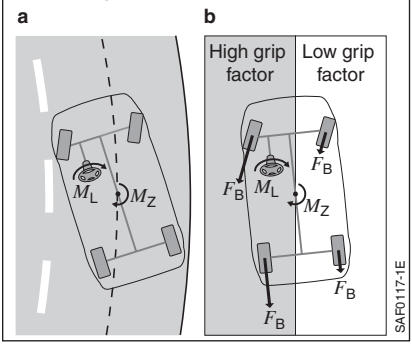
In addition to the brakes and engine, as used by the driving-dynamics control system (Electronic Stability Control, ESC), there are other actuators in the chassis and in the drivetrain which are used to purposefully influence driving dynamics. The functional combination of actuators relevant to driving dynamics is referred to by different names by the various automobile manufacturers and suppliers: Vehicle Dynamics Management (VDM), Integrated Chassis Control (ICC), Integrated Chassis Management (ICM), and Global Chassis Control (GCC).

Primary uses
The functions are used primarily in the fields of directional stability, agility and reducing "driver workload", i.e. the efforts exerted by the driver to operate and control the vehicle.

Improving directional stability
In critical driving situations, these functions take on stabilization tasks which are normally performed by the driver himself. Typical examples are the oversteer situation or braking on roads with different grip factors on the left and right sides of the vehicle (μ split).

Increasing agility
Some of these functions improve the acceleration response of the lateral-dynamic response of the vehicle to steering inputs by the driver. These make the vehicle more agile, i.e. it responds more spontaneously and dynamically to driver inputs.

Reducing the effort to control/operate the vehicle
An improved response by the vehicle to movements of the steering wheel and automatic stabilization interventions relieve the driver's workload, the steering effort in particular being reduced.



Functions

Driving-dynamic driver steering recommendation
Function
This function utilizes electrical power steering as the actuator. An additional, driving-dynamically motivated steering torque is superimposed on the steering-servo torque of the power steering in order to provide the drive with a steering recommendation.

Limitation of supplementary steering torque
The driving-dynamic supplementary steering torque is limited, depending on the vehicle, to values of approximately 3 Nm so that the driver can oversteer the steering recommendation at any time.

Driving-dynamics applications
The steering recommendation is activated in different driving situations. In a oversteer situation, a steering torque is introduced in the countersteer direction (Figure 1a). In the event of understeer, the function motivates the driver not to increase the steer

Figure 1: Driving-dynamic driver steering recommendation with supplementary steering torque
a) Oversteer,
b) Braking on road with different grip factors.
M_L Supplementary steering torque,
M_Z Yaw moment based on intended driver reaction,
F_B Braking force.

angle further, since the side-force potential on the front wheels is already exhausted and further steering may even reduce the side force.

When braking or accelerating on roads with different grip factors on the left and right sides of the vehicle (μ split), the driver is assisted in compensating the vehicle yaw motion by countersteering (Figure 1b).

Active steering stabilization on the front axle

Function

This function intervenes via the angle-superimposing steering actuator of the override steering directly in the vehicle movement. An additional steering angle adjusted by an electric motor is added to the driver's steering angle in an override gearbox.

Driving-dynamics applications

The function operates, for example, in an oversteering driving situation. Yaw-rate control with automatic steering-angle intervention returns the excessively high yaw-rate value to its setpoint value.

During braking on roads with different grip factors, the function provides for compensation of the yaw motion. Since yaw compensation is automatically triggered and happens much faster than the steering operation of a typical driver, the measures in driving-dynamics control for yaw-moment build-up delay can be reduced. The braking distance is also reduced.

A further benefit can be achieved in the event of understeer and starting on roads with different grip factors.

Demands on the sensor system

Because of the high positioning rate of an override steering system, the sensor signals must be monitored with low fault latencies, i.e. a fault must be signaled quickly. This means that the inertial sensor system must have a redundant design.

Active steering stabilization on the rear axle

Function

In vehicles with rear-axle steering, the primary function controls the rear-axle steering angle as a function of the steering-wheel angle and the driving speed. At low speeds, the rear wheels are steered in the opposite direction to the front wheels, which improves vehicle maneuverability.

At high speeds, the rear wheels are steered in the same direction as the front wheels. In this way, the yaw motion is less intensely excited during obstacle-avoidance maneuvers. This increases directional stability considerably.

Driving-dynamics applications

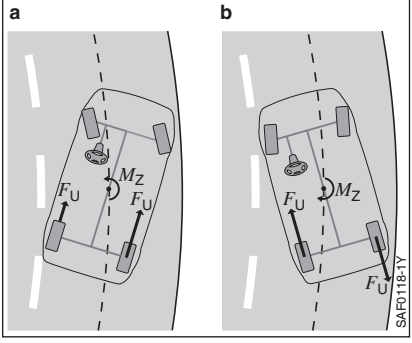
The associated functions act in situations similar to active front-axle steering interventions. The effectiveness of oversteer interventions is crucially dependent on the current utilization of the side-force potential on the rear wheels.

When braking on roads with different grip factors, it is necessary on account of the reduction of load on the rear axle to make interventions with larger angles in order to suppress the yaw motion. On the other hand, braking can take place without a considerable attitude angle.

Demands on the sensor system

The functions for rear-axle steering likewise require a redundant inertial sensor system, since the positioning rate of a steering actuator on the rear axle is comparable with the override steering.

Torque distribution in the longitudinal direction for four-wheel drives



Function

In vehicles with four-wheel drive, interaxle differential locks or transfer cases within the framework of their basic function improve the traction and, with it, the accelerating performance of the vehicle, whereby the wheels of both axles transfer tractive forces.

Driving-dynamics applications
In situations where the grip factor is not fully utilized by traction, the self-steering properties can be altered by shifting the tractive forces between the front and rear axles. The more tractive force an axle transfer, the more the side-force potential on the wheels of this axle is weakened. Shifting the tractive force to the front axle increases the understeer tendency, while shifting it to the rear axle reduces the understeer tendency. Through dynamic control of drivetorque distribution, lateral-dynamic agility can be increased without the vehicle tending towards oversteer.

Wheel-torque distribution in the lateral direction
Function
Functions based on a "torque-vectoring actuator" make a significant contribution to increasing agility. The actuator permits an extensively free shift of the wheel torque between the left and right wheels on an axle. In this way, the total turning force excluding friction losses is not reduced in the actuator meaning that this intervention is virtually neutral with regard to the driving speed.

Figure 2: Wheel-torque distribution in the lateral direction
a) Understeer,
b) Oversteer.
F_U Wheel peripheral force (driving, braking),
M_Z Yaw moment based on intervention.

Driving-dynamics applications
In an understeering driving situation, the drive torque of the wheel on the outside of the curve is increased and the drive torque of the wheel on the inside of the curve is decreased. In this way, an additional yaw moment turning into the curve acts on the vehicle (Figure 2a). The understeer tendency decreases; the vehicle's lateral-dynamic agility increases.

When accelerating on roads with different grip factors, the drive torque is specifically directed to the wheel with a high grip factor. Brake interventions by the traction control system on the wheel with a low grip factor are dispensed with to a large extent. This increases the mean acceleration on roads with different grip factors.

Even in an oversteering situation, the brake interventions are partly replaced by a wheel-torque shift (Figure 2b). In this way, the speed loss can be reduced by brake interventions of the driving-dynamics control in the event of mild oversteer. In critical oversteering situations, the brakes still intervene, since in this case the speed loss is desired to alleviate the driving situation.

Replacement of wheel-torque distribution by brake and engine-control interventions
The understeer interventions by means of a torquevectoring actuator can be emulated by brake interventions on the wheels on the inside of the curve. The engine torque is increased to compensate the deceleration by the one-sided brake intervention. This produces an effect similar to understeer intervention with a torque-vectoring actuator. This only requires a hydraulic modulator with a long service life and low noise generation instead of an additional torque-vectoring actuator.

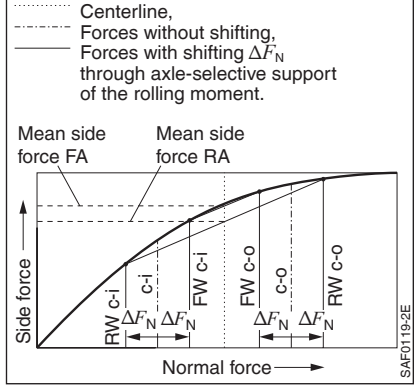
Influencing self-steering properties through roll stabilization
Function
In line with their comfort-oriented basic function, systems for roll stabilization serve to compensate the rolling motion of the vehicle body when cornering.

Driving-dynamics applications
Where the roll-stabilization system has a two-channel design with separate activation of the actuators on the front and rear axles, there is an additional option for influencing the self-steering properties. The roll-compensating torques can – within the framework of the performance of the individual channels – be actively distributed between the front and rear axles. This results in a change of the wheel downforces.

The effect on the self-steering properties is based on the degressive increase in the lateral forces with the normal forces (Figure 3). When the rolling moment is extensively supported over the rear axle, the normal force at the rear on the wheel on the outside of the curve increases dramatically; the associated side force, however, increases only underproportionally. The side force on the rear axle is weakened, and the understeer tendency decreases. As a countermove, the understeer tendency increases when the rolling moment is extensively supported over the front axle.

Influencing self-steering properties through variable vibration dampers
Function
The use of variable dampers for adaptive damping of the vertical movement of the vehicle body has become significantly widespread. Pitching and rolling motions which are caused by driver inputs such as braking and steering or by road-surface defects, as well as vertical movements caused by road-surface defects, can be noticeably reduced.

Driving-dynamics applications
It is also possible with limited effect to influence the self-steering properties. The action mechanism corresponds to influencing the self-steering properties through roll stabilization. However, the function only has a transient effect during a rolling motion of the vehicle body, since a damper movement is a prerequisite for damping forces. The damping forces can be modulated by adjusting the damping hardness so that the wheel downforces can be semiactively distributed as described above.



System architecture

Allocation of functions to ECUs
The actuators in the chassis and in the drivetrain are generally activated not only by functions of the integrated driving-dynamics control systems, but also first and foremost by basic functions which are very closely connected with the actuator. Examples of such basic functions include servo assist in an electrical power-steering system or variable steering ratio in an override steering system.

The basic functions are characterized by moderate networking with other vehicle systems. Because of their close connection to the actuator, they are usually integrated into the associated ECU, which also activates and monitors the actuator.

On the other hand, the functions of the integrated drivingdynamics control systems are highly networked, in particular with driving-dynamics control (ESC) and other chassis control systems. They calculate a setpoint driving-dynamic value for the actuator, which is transmitted via a data bus to the ECU. An arbitration with the setpoint values of the basic functions is performed in the ECU.

Figure 3: Side force as a function of normal force with a constant slip angle
Reduction of understeer tendency by shifting of normal wheel forces.
FA Front axle, RA Rear axle,
FW Front wheel, RW Rear wheel,
c-i Inside of curve, c-o Outside of curve.

The ECU for driving-dynamics control (ESC) or a central ECU of the "Chassis" functional area is suitable for use as the integration platform for the functions of the integrated driving-dynamics control systems (Figure 4).

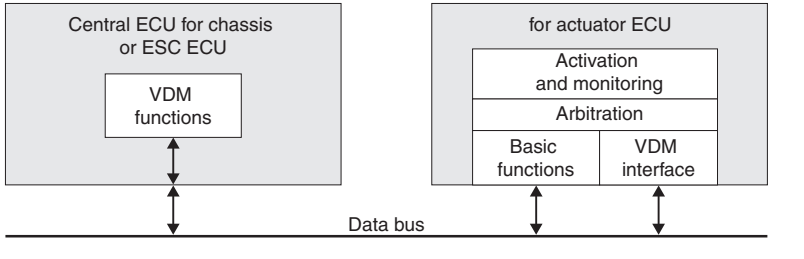
Interaction of various functions

Various functions and actuators are increasingly being installed in a single vehicle. This calls into question a function structure which guarantees good interaction of the individual functions and which above all prevents mutual interference.

The original trend observed of implementing a separate controller for each actuator is reaching its limits. However, fully bringing together all the algorithms in a central controller limits flexibility in the distributed development and in the use of ECU resources.

A more promising compromise is bringing together all the controllers which utilize a related positioning principle, since interventions with a related positioning principle require particularly intensive coordination.

The following are mentioned as positioning principles and allocated positioning systems:



– wheel torque: driving-dynamics control, controllable differential locks, torque vectoring,
– steering angle: override steering (front axle) and rear-axle steering,
– normal force: roll stabilization, adjustable shock absorbers.

The driving-dynamic steering-torque recommendation plays a special role. It must be matched in terms of its effect on the driver with functions for override steering.

Figure 4: System architecture for implementing functions of integrated driving-dynamics control (VDM)

Vehicle bodies, passenger cars

Introduction

The vehicle body or the body shape determines the external shape of a vehicle and is itself essentially determined by the vehicle purpose or the use and the addressed customer group, but also by social, technological, and design trends. Design trends and the combination of body-shape archetypes have consistently given rise to new body shapes. One example of this is the Sports Utility Vehicle (SUV), which developed in the USA from the “station wagon” (estate car) and the classic off-road vehicle. Even new drive concepts, such as for example the electric drive, influence the realized body shapes.

Vehicle body and vehicle concept, described by the essential main dimensions and the positioning of the main components and the occupants, are closely interlinked. For this reason, first the body shapes and then the development of the vehicle concept or the vehicle architecture will be discussed in the following. To conclude, the effects of current technological trends such as for example automated driving and virtual product development on vehicle conception and vehicle bodies will be described.

Milestones in automobile history

The history of the automobile (or passenger car) has been marked by many individual discoveries, which will only be briefly described here. New product and process technologies have consistently led to innovations and trend reversals in the development of the automobile.

In 1886 Carl Benz and Gottlieb Daimler, independently of each other, built the first motor carriages with an internal-combustion engine and thereby initiated the triumphal advance of motorized private transport. However, by the end of the 19th century it had still not been decided which drive would gain acceptance in the automotive industry.

Already in 1834 Thomas Davenport in the USA built the first electrical DC motor and demonstrated its operation using an electrically powered model locomotive which was equipped with a non-rechargeable battery. In 1837 Davenport in the USA was awarded a patent for his electric motor. At the same time and independently in 1834 Moritz Hermann von Jacobi also developed an electric motor with a power output of approximately 15 W. In 1835 the two Dutchmen Sibrandus Stratingh and Christopher Becker constructed an electric motor which was used to drive a small model vehicle – the first demonstrable use of an electric motor. In 1881 the first electrical three-wheeler was demonstrated by Gustave Trouvé at the International Exposition of Electricity in Paris, i.e., already five years before the first automobile with internal-combustion engine. In 1882 Werner Siemens ran on a test track in Berlin the “Electromote”, the forerunner of today's trolley buses. In 1888 Andreas Flocken developed the first electric car from Germany with pneumatic tires and electric headlamps and a top speed of 15 km/h. In 1897 electric taxis were introduced in New York and by 1899 already 90 % of all the taxis in that city were electrically powered.

Up to the first decade of the 20th century automobiles with steam drives were

also built as alternatives to the internal-combustion engine drive and the electric drive. Examples include the White Touring Car from the White Motor Corporation and the Stanley Steam Car from the Stanley Motor Carriage Company.

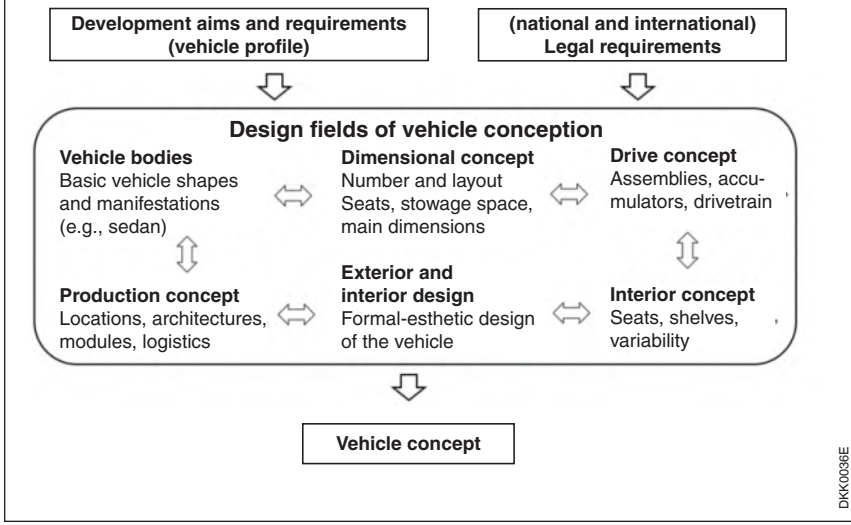
Only with the invention of the electric starter in 1909 by Kettering in the USA and through further development in 1914 by Bosch in Germany (patent in 1914 to Bosch) and due to the rapid expansion of a filling-station network for mineral-oil-based fuels was the internal-combustion engine able to gain acceptance as the dominant drive for automobiles and push electric and steam vehicles into niche markets.

The invention of the pneumatic tire in 1888 by Dunlop in the UK and the invention of the steering wheel in 1900 by Packard in the USA are further milestones on the road to today's automobile. In 1914 Ford introduced assembly-line production with the Model T. As a result, automobiles could be produced in large numbers and were able to conquer the roads [1].

Not only the drive technology but also the configuration of the drive has influenced the automobile body shapes. The rear-wheel drive is the oldest form of drive and refers to a vehicle with a powered rear axle irrespective of the layout of the engine. In the standard drive the engine is housed in the front end and drives the rear axle through a propeller shaft with cardan universal joints via the differential. This makes it necessary to have a transmission or center tunnel and gives rise to weight and installation-space disadvantages. On the other hand, the standard drive facilitates the separation and splitting of the steering function and the drive function to one axle each and thereby results in better weight distribution. The rear axle is also powered in the rear-wheel drive. Here the rear engine, transmission, and drive axle form a complete drive unit at the rear of the vehicle. A front-wheel drive in conjunction with a front engine is generally referred to as a front-wheel drive. Further drive configurations are the all-wheel drive with two powered axles, the rear-wheel drive with mid engine, and the rear-wheel drive with transaxle configuration. The front-wheel drive and the standard drive have predominantly gained acceptance today.

Since the 1990s the electrification of the drive has experienced a renaissance. However, this was initially confined to concept vehicles and pilot tests, e.g., on the island of Rügen (1992 – 1996). With the foundation of the National Platform for Electric Mobility in Germany in 2010 electromobility based on lithium-ion-battery technology gathered significant pace again. In 2012 Tesla with its Model S launched the first luxury sedan with electric drive and frunk (front trunk, i.e., luggage compartment at the front of the vehicle) onto the market. Today electrification of the drive and the trend towards automated vehicles are opening up new possibilities for fashioning vehicle body shapes.

In more recent developments body shapes have become increasingly diversified. Each era has had its preferred body shapes. Thus in the 1980s Chrysler with the Chrysler Voyager popularized the family van or people carrier (Chrysler Minivan 1985). In the 1990s through to the first decade of the 21st century the Minivan experienced a revival as an automobile body shape with optimized space utilization and a high roof line. Mercedes-Benz with the A-Class brought onto the market a family sedan in the compact segment with an allowance for alternative drives in the vehicle floor with the look of a Minivan (one-box design). Towards the mid-1990s the Sports Utility Vehicle (SUV) arrived on the German market in the form of the Toyota RAV 4. Starting with large vehicles, the SUV in the 2000s conquered further segments extending down to compact vehicles [2]. In 2021, according to the Federal Motor Transport Authority (KBA) in Germany, SUVs held a market share of around 25 % of passenger-car sales.



Definitions

Vehicle architecture
The vehicle architecture constitutes the totality of the components and systems of a vehicle family which facilitates a derivation of all the planned derivatives and body shapes of that vehicle family. Legal requirements, market and customer requirements, functional requirements, ergonomic requirements, safety requirements, production requirements, and economic requirements are all taken into account in the definition of vehicle architecture. The focus in vehicle architecture is on the concept-determining modules, components, and systems.

Vehicle concept
"The vehicle concept the structural design of a product idea with which the fundamental feasibility is safeguarded" [3]. The vehicle concept describes the vehicle in its essential main dimensions (inside and outside) and the positioning of the main components and the occupants (driver and passengers) in the vehicle. Over the years different body shapes have developed in response to the arrangement of the drive components. The vehicle concept ensures the technical feasibility of the arrangement of the assemblies and components and compliance with statutory provisions. This relates to the regulations covering crashes, e.g., deformation travel, and covering ergonomics, e.g., the accessibility of operating and control elements and outward visibility [4]. The design fields of the vehicle conception integrate various subconcepts, such as for example the drive concept, the interior concept, the production concept, and the formal-esthetic design of the vehicle (see Figure 1). The emphasis here is on the definition and design of body manifestation, basic vehicle shape, and future variants [3].

Vehicle body
The vehicle body defines the external shape of a vehicle and is established by the German standards DIN 70010 (System of road vehicles) and DIN 70011 (Bodies for passenger cars; terms and definitions) and the international standard ISO 3833 (Road vehicles – Types – Terms and Definitions). The standards differ from each other in the details. The vehicle body

Figure 1: Design fields of vehicle conception

or the body shape is determined by the vehicle purpose and the addressed customer group.

Vehicle package
"The package is the gradually refined elaboration of the design during the development of the vehicle with the aim of constantly check the technical feasibility of the planned product and the dimensional interaction of all the assemblies and components" [3]. This entails as a matter of priority the optimal use of the installation spaces in the vehicle. The different conflicts of aims, space requirements, and functional dependencies are weighed up and carried over into an arrangement that satisfies all the components geometrically and physically. This arrangement of all the components in the vehicle is called the vehicle package or package.

Vehicle body and vehicle segments

The vehicle body or the body shape is primarily determined by the vehicle purpose and the addressed customer group. Styling trends, social trends, and statutory provisions as well have consistently given rise to new body shapes. Historically, new vehicle body shapes have frequently come about as the result of elements from existing body shapes being put together in new ways. This is shown particularly in the so-called "cross-over body shapes", such as for example the Sports Utility Cabriolet (SUC), which combines a Sports Utility Vehicle (SUV) with a cabriolet or convertible. Elements from SUVs can be found today in many hybrid body shapes. The German Federal Motor Transport Authority (KBA) has defined vehicle segments for the carriage of persons and goods [5], which are already featured elsewhere (see Complete motor-vehicle system). This classification has been used to explain the vehicle body shapes and vehicle segments in Figures 2a, 2b, and 2c. Also customary internationally are still further classifications of vehicles into segments which follow a similar logic, e.g., the vehicle segments of the EU Commission or the vehicle-size categories of the NHTSA (National Highway Traffic Safety Administration) in the USA and other.

Figure 2a shows how the classic body shape of the sedan, which was previously the dominant body shape, has continued to diversify starting out from the three basic shapes of notchback, squareback, and station wagon/estate.

The development of the SUV body shape from the classic off-road vehicle with elements of sedan-like body shapes is an example of the creation of new body shapes. SUVs are characterized by a high seat position, increased ground clearance, an at least disengageable all-wheel drive, and a characteristic body shape based on an off-road vehicle. Over time SUVs have been able to gain acceptance as an alternative to the high-capacity sedan (Family Van) and establish itself as a new body shape across all vehicle-size categories [2]. This development continues and results, for example by borrow-

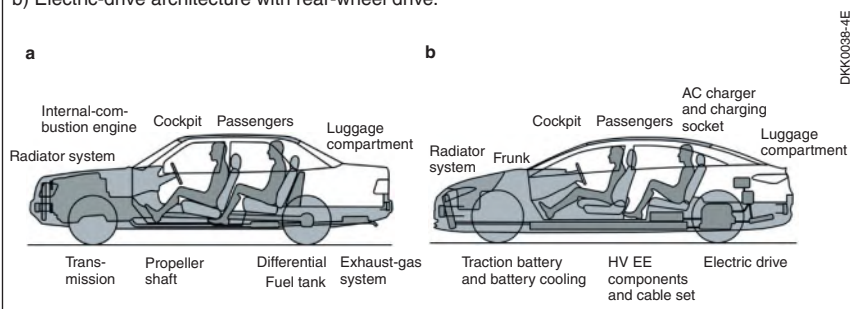
ing from other classic body shapes like the Coupé, in the new body shape of the Sports Utility Coupé. An example of an SUV Coupé is the Mercedes-Benz GLE. There is a trend, particularly in electric vehicles, towards SUV Coupés. Examples of SUV Cabriolets (SUCs) are the Range Rover Evoque Convertible and the VW T-Roc Convertible.



There are other relevant body shapes which are depicted in Figure 2c. These are, firstly, the emotive body shapes sports car and supercar and, secondly, the practical body shapes like the Multi-Purpose Vehicle (MPV) and the high-capacity sedan, the high-capacity van (minibus), and the pickup as a cross-over from the SUV and the light-duty truck.

Whereas the high-capacity sedan, e.g., the Renault Espace, is a family car with plenty of room and a variable-folding seating concept which is derived from a passenger-car architecture, the high-capacity van is a high vehicle derived from a light-utility-van architecture which is often characterized by removable seats mounted on continuous rails. The VW Bulli minibus was definitive of the high-capacity van. Today the segment is widely diversified.

Vehicle systems

Each vehicle package comprises the same system groups. These are the groups occupants, interior and stowage space, drivetrain, body structure, suspension and chassis, and wheels and tires (Figure 3). Each of these system groups can take on different manifestations depending on the functional objectives of the vehicle. Each of the vehicle systems has, through further development of the requirements, the potential to generate new body shapes.

Figure 3: Main components and systems of a passenger car (examples)
The drive determines the architecture and the dimensional concept.

b) Electric-drive architecture with rear-wheel drive.

Interface management in complete-vehicle development

The complete-vehicle conception and thus also the design of the vehicle body are characterized by the interdisciplinary cooperation of a number of technical disciplines and their interfaces. This is shown among others in the diverse requirements imposed on the vehicle concept and the package (Table 1) [3].

The first disciplines involved in the vehicle concept are complete-vehicle design, vehicle design (styling), and vehicle aerodynamics. But also further functions like drive, body design (body structure), and vehicle safety determine the vehicle concept. Here complete-vehicle design has an integrating function along the vehicle-conception process.

From a design viewpoint, the vehicle design can be divided into three types:
- the one-box design (e.g., a box-body light-utility truck or an MPV, e.g., Renault Espace),
- the two-box design (e.g., the square-back sedan, hatchback, e.g., VW Golf, station wagon or SUV),
- and the (classic) three-box design of the notchback sedan (e.g., Mercedes-Benz E-Class) [3].

The vehicle-design type constitutes the basis for all the design and constructive considerations with regard to styling, surface, and the like [6]. But also the drivetrain and the drive assembly with its peripheral components (e.g., accessories) determine via the vehicle package its interior and exterior design [6].

The complete-vehicle conception with its main functions of dimensional conception, ergonomics, and packaging embodies the "technical knowledge" in vehicle-body development. It is responsible for complying with the statutory provisions and integrating the requirements from design, aerodynamics, vehicle safety among others.

The vehicle aerodynamics and the design fashion the shape of the vehicle iteratively with different targets. The vehicle design process focuses on the design of the exterior and the interior. Here holistic considerations relating to the product environment, the customers, their use cases, and general design trends leave their mark. The vehicle design process is shown in Figure 4. Premises and an initial profile are elaborated on the basis of an initial analysis. Potential customers are described in the form of "personas" (fictitious customers representative of a particular target group). This is followed by an initial idea generation (brainstorming). The ideas are visualized in the form of sketches and a first technical dimensional concept and package are created in 3D. This is followed by the concept phase, in which the 3D designs are further elaborated and in part converted into hardware (1:4 clay models, 3D models). Methods of digital shape verification (VR, Powerwall) are used in the concept on a supporting basis. In the detailing phase a 1:1 clay model and a seat box are created in parallel to the design of the digital 3D model. The shapes found are returned by model scanning to the digital world. A model verification is performed in parallel

Table 1: Vehicle-concept and package requirements

	Requirements

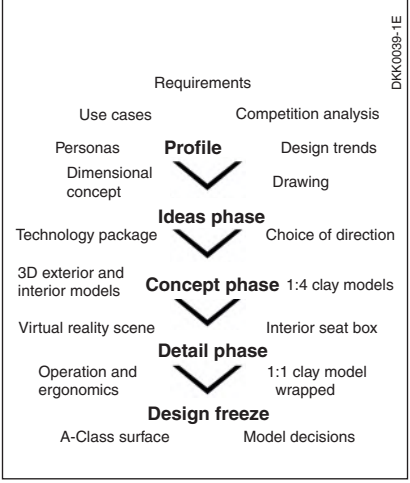
	Economic efficiency: – Use of funds (investments) – Product costs – Total cost of ownership (TCO)

by comparison with the technical "hard points" (e.g., dimensions of technical assemblies or lines of sight prescribed by law). This is followed by the so-called surfacing (Strak) phase (construction of class-A free-form surfaces), in which the surfaces are optimized from an optical and design perspective.

The most important target variable of vehicle aerodynamics is aerodynamic drag, supplemented by the output at the rear end, the aeroacoustics (responsible for wind noises), and the avoidance of contamination. From the aerodynamics perspective vehicles are blunt bodies which move with minimal ground clearance above the road surface [7]. The flow around the vehicle is three-dimensional and characterized by turbulent boundary layers. Flow separations must be avoided as far as possible because they result in increased flow resistance. Behind the vehicle a dead-water zone is created which is trailed by a wake. In the case of passenger cars powerful longitudinal vortices may also be created which interfere with the dead-water zone and the wake and contribute substantially to the flow resistance [7]. To reduce the energy demand of a vehicle and with it the fuel or energy consumption the vehicle's body shape is aerodynamically optimized in the direction of low c_d values (drag coefficients) and thus retroacts on the design of the vehicle.

The other drag-determining variable, the cross-sectional area of the vehicle, is determined by the body type (see Vehicle segments) and the number and posture of the occupants. The determination of openings for the cooling-air flows to deliver efficient thermal management for the drive and for further assemblies and components and to ventilate the passenger compartment constitutes further designs fields of vehicle aerodynamics [7].

Process of vehicle-concept development



Vehicle concept

From the perspective of vehicle development the vehicle concept is at the start. It has the greatest influence on the vehicle body shape. Vehicle body shape and vehicle package, i.e., the accommodation of the assemblies and components in the vehicle and the interior design for the driver and the passengers are closely interlinked [3]. The vehicle concept comprises the following subconcepts ([3], [8], [1], [6]):

- drive concept and assembly position (front-, rear- or all-wheel drive, internal-combustion engine, hybrid or electric drive, front- or transversal installation of the drive assembly, etc.),
- interior concept (number of seats, comfort features, e.g., legroom, headroom, and stowage-space volumes),
- chassis concept (steered and rigid axles, suspension, wheels, and tires),
- thermal management and air-conditioning concept (heat recovery and heat utilization, active air conditioning, heat pump, thermal accumulators among others).

The drive concept and the chassis concept form the chassis and can be characterized as a drive platform which can be

Figure 4: Vehicle design process

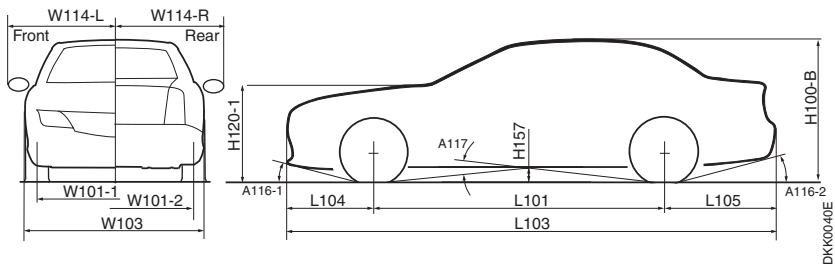
used across a number of body variants. Volume manufacturers today develop body variants for model families which use common concepts and components. These are called the vehicle architecture. The interior concept and the drive concept have the greatest interactions with the sought-after body shape.

On the basis of the general vehicle concept – consisting of the subconcepts drive concept, chassis concept, body concept among others – the main dimensions of the vehicle such as vehicle length, vehicle width, and vehicle height as well as the interior dimensions are defined [9]. Selected external dimensions as per SAE or ECE are shown in Figure 5.

In the interior an empirical relationship between interior height and interior length can be demonstrated. In taller vehicles the occupants are seated in a more upright position and consequently the vehicle interior can theoretically have a shorter design [9]. Limits to this correlation are presented by the legroom and kneeroom of the occupants. Selected internal dimensions are shown in Figure 6.

The path from the first strategic considerations to the finished vehicle concept covers a number of steps. The first vehicle package should be kept simple and only show the essential concept features. With regard to the vehicle body, the first so-called "hard points" are defined. These are definitions of the main dimensions which are set for legal, strategic, design or technical reasons. The vehicle proportions are defined by few boundary conditions which are set in the vehicle profile, such as for example the number of occupants, the drive type and drive position, the wheel and tire sizes and the size of the luggage compartment, the ground clearance, and the sought-after crash-safety level. These definitions are referred to in the following as functional vehicle objectives [1].

Conception steps



Step 1

The design process starts with the idea generation for design and package (see Interface management and Complete-vehicle development) and is geared towards the functional objectives for the vehicle concept. Even initial considerations regarding the body structure and the doors, gates, and lids have some bearing on the initial design. Further elaboration of the vehicle body in conducted from the inside outwards.

Step 2

In the second step the occupants of the first seat row (driver, front passenger) are positioned in the vehicle. The height-dimension chain is developed from the ground and takes into account the sought-after ground clearance H157 (closely correlated with the selected vehicle segment), the package of assemblies in the vehicle floor (e.g., energy storage devices), and the segment-specific sitting posture of the occupants in the vehicle. The sitting posture is determined by the seat reference point (R point) or the associated H30 dimension, the heel point,

Figure 5: Selected external dimensions as per SAE or ECE
(Front/rear view and side view.)

and the position of the steering wheel. With regard to the driver's sitting posture, statutory provisions must be observed (Figure 7), such as for example forward visibility, but also functional and ergonomic considerations have a bearing on the choice of seat position, such as for example the aerodynamics of the resulting vehicle body and the ergonomics of the entry/exit. Digital human models representing specific percentiles of the height distribution of potential customers are used in the validation of the requirements [10]. It has proven worthwhile for layout purposes to validate the requirements with a tall 95th percentile man (95 % of men are shorter or of equal height) and a short 5th percentile woman (fewer than 5 % of women are shorter) ([4], [1]).

Step 3

In the third step the rear passengers are positioned. Here today – depending on the vehicle segment – one or two rear-seat rows are conceivable. The number of passengers in the rear who sit next to each other determine the vehicle width at the height of the respective seat row. For example, two individual seats, two full seats and one emergency seat or three full seats are conceivable in the rear. Leg-room, headroom, and shoulder room of the rear passengers are verified with digital human models.

Entry/exit simulations or trials with test subjects can be used to validate and optimize the first conceptional definitions in the course of the vehicle-concept development.

Step 4

In the fourth step the final decision regarding the drivetrain is made and this is located in the vehicle layout. Depending on the drive type, this concerns the components driving machine (internal-combustion engine, e-machine with inverter), energy storage device (fuel tank, traction battery), and miscellaneous components of the drivetrain (e.g., drive shafts) [1]. The choice of drive type, the number of powered axles, and the position of the drive have concept-determining effects on the vehicle proportions and are thus characteristic of specific vehicle segments. New

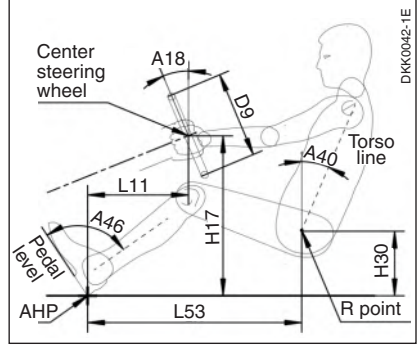
R point: Seat reference point,
AHP: Accelerator heel point.



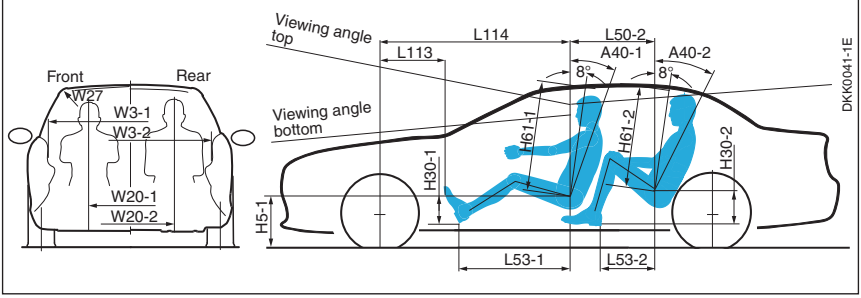


Figure 6: Selected internal dimensions as per SAE or ECE
(Front/rear view and side view.)

drive types or drive configurations result if necessary in new vehicle body shapes.

Step 5
In the fifth step the position of the occupants is established in the y-direction (vehicle width), having regard to the packaging of the drivetrain, the crash behavior, and the comfort requirements. This definition is crucial to the feeling of space and comfort in the interior, but also to the safety of the passengers in the event of a side collision. In this phase a rough package of the occupants and all the essential assemblies should verify the rough dimensional concept in the essential dimensions [1]. In practice the individual steps can also take place on account of project-specific settings in a different order. Statutory provisions with regard to width and height of the vehicle body must be verified and observed.

Step 6
In the sixth step the installation spaces are defined for the payload. Depending on the requirements profile the length of the overhangs is influenced by the required load-compartment space and in turn gives rise to segment-specific body shapes, e.g., station wagon. New drive concepts here open up new stowage-space options, such as for example the so-called frunk (front trunk). In the development of vehicle architectures different variants are conceivable in a vehicle model. The position of the powered axle(s) in relation to the position of the main drive has concept-relevant consequences, e.g., the need for a propeller shaft to direct the power flow from the drive to the powered axle. This requires installation space in the interior (so-called tunnel) and in the underbody area as well as appropriate ground clearance.

Steps 7 and 8
In the next steps 7 and 8 the wheelbase and the wheel and tire dimensions are finally established. The distance between the vehicle axles determines the weight distribution and the package efficiency as well as the comfort of the occupants. Here the benefit dimensions of the vehicle and also the sought-after price positioning (volume market vs. premium market) must be observed. Low-priced subcompact-size cars are generally built as compactly as possible. This produces a short vehicle length, but also a relatively confined vehicle interior. For premium vehicles the wheelbase is chosen in such a way as to create a generous feeling of space. Particularly in electric vehicles with long ranges the battery installed in the underbody is decisive for the wheelbase. Boundary conditions such as the turning circle also have a bearing on the dimensioning of the wheelbase. The ground-clearance requirements are also verified in this step.

Step 9
In the ninth step the respective track of the front and rear axles is established. Particularly in the rear area there are here conflicts of aims between the space requirement of the passengers and the axles, wheels and tires on the one hand and the aerodynamics, which can be improved by reducing the vehicle width at the rear, and the stylistic body design of the vehicle.

Step 10
In the tenth and last conception step the vehicle (cross-)sections are established at the height of the axles, at the height of the driver and front passenger, at the height of the rear passengers, and if necessary in the area of the luggage compartment [1]. In an iterative harmonization process between technology and design the optimal shaping of the vehicle exterior is established in the field of conflict of different requirements. The exterior surfaces are influenced by the body structure, the arrangement and function of the doors, gates, and lids (door concept), and the interior layout (interior concept).

Sectional elaboration of the vehicle concept

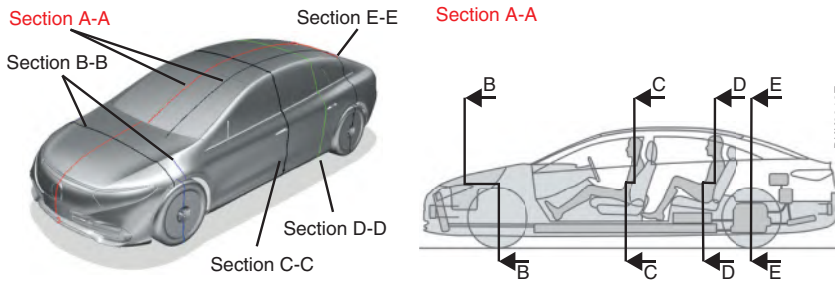
Installation-space sections
The sections through the vehicle divide the vehicle installation space into sections which can be elaborated with segment- and body-specific targets (Figure 8) [1]. Alternatively, digital 3D package rough models are used for the first design.

Section 1
The first section up to the vehicle bulkhead (after the front axle) is characterized for example for a front-wheel drive by the package of the drive assembly and the design of the crash structures. The position of the drive assembly (longitudinal or transversal) and the crash structure necessary to satisfy the front-collision requirements are the determining issues in this installation-space section.

Section 2
The front passenger compartment is the next installation-space section, which is essentially characterized by the needs and requirements of the driver's cockpit and the driving posture of the driver and the front passenger [6]. Here statutory provisions (regarding visibility) and the accessibility of the operating and control elements are concept-determining. An upright driving posture results in a high vehicle architecture and enables the wheelbase to be shortened ([1], [6]).

Section 3
The next section at the height of the B-pillar to the end of the vehicle interior de-

Figure 8: Concept-relevant sections through the vehicle



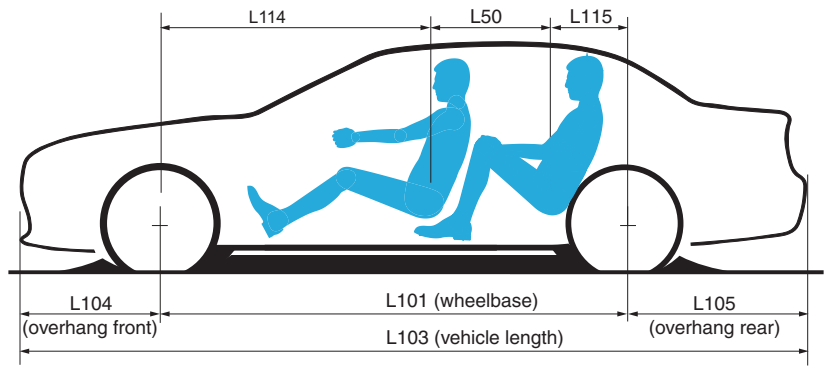


Figure 9: Dimension chain in longitudinal direction to define the vehicle length

scribes the rear passenger compartment. The number of rear seat rows, the sitting posture of the rear passengers, and their legroom and kneeroom determine the length of the wheelbase and thus also the vehicle length.

Section 4
The luggage compartment is the fourth and last installation-space section. It is determined by the required load-compartment space, the packaging of a fuel tank or a traction battery or if necessary a spare wheel, and the required crash length in the event of a rear impact.

Vehicle length
The four installation-space sections result in the vehicle length, which for its part is subject to segment-specific and legal restrictions. The dimension chain in the x-direction is shown in Figure 9.

Vehicles should adhere to the customary garage dimensions and length restrictions, for example for carriage on motorail trains or ferries. A generous vehicle length furthermore entails additional weight, additional costs, and driving-performance limitations. Therefore the complete-vehicle conception aims to minimize the vehicle length by adhering to all the requirements.

Current trends of vehicle-concept development

New technological and social developments influence vehicle conception. This changes the process of vehicle conception through new methods and tools and can also result in new body shapes.

Electrification of the drivetrain
The transition to electromobility means that a traction battery of a size commensurate with the range requirements of the customers must be accommodated in the vehicle. The battery modules can be installed in a distributed arrangement in the vehicle or as a large battery pack, e.g., in the underbody. In fuel-cell vehicles hydrogen accumulators must be incorporated aside from a smaller high-voltage battery and the e-machine(s) together with inverter. Energy storage devices, such as for example high-voltage batteries and hydrogen tanks, are today usually accommodated in the underbody. If in future the volumetric energy densities of energy storage devices increase due to technological advances, the installation-space situation will ease and lower architectures will be easier to implement.

Automated driving
Automated driving is one of the trends for the 21st century. This carries with it new installation-space demands for powerful computers and sensors, e.g., lidar sensors, video cameras among others, which are required for highly automated driving. On the other hand, highly automated driving could open up the opportunity to deliver the vision of accident-free driving. Technologies like drive-by-wire (electronic accelerator and brake pedals) and steer-by-wire (electronic steering) play a significant role on the road to automated driving. The automation of all driving functions leads via driver-assistance systems, which support the driver, to autonomous driving, which relieves the person completely of the driving function and responsibility and thus in future will make possible driverless transport systems on public roads ([11], [12]).

Digitalization of vehicle development
Increasing digitalization in vehicle developing opens up to vehicle constructors and designers new opportunities to develop vehicles digitally from the outset. This ranges from modern tools for quickly sketching and designing vehicle surface models through data-driven development, which makes possible in connection with "machine learning" the development of intelligent vehicle systems. The digital transformation of the vehicle-development process makes possible the collaborative integration of representatives of different specialist departments and divisions, even beyond corporate boundaries and national borders [13].

Virtual reality (VR)
VR tools – including headsets for augmented and mixed reality – used to be classed with video games and films. Today they accelerate vehicle development and enable vehicle-concept teams around the world to completely refashion vehicles and mobility experiences. Form finding for new vehicle models and the presentation of innovative vehicle concepts can take place in a virtual future, be experienced immersively, and be discussed and further developed with decision makers. Furthermore, VR tools play an increasingly more important role in the functional verification of vehicle concepts. Here the tools are used in a so-called mixed reality, where physical structures (hardware) and VR elements complement one another, or even in a purely virtual environment.

In future algorithms and expert systems will support subproblems of vehicle development, such as for example the choice of wheels and tires. The incipient states are already being tested. The future vision would be a completely AI-supported (Artificial Intelligence) vehicle-design process.

Vehicle bodies, commercial vehicles

Classification of commercial vehicles

Commercial vehicles are used for the safe and efficient transportation of persons and freight. In this respect, the degree of economic efficiency is determined by the ratio of usable space to overall vehicle volume, and of payload to gross vehicle weight. Dimensions and weights are limited by legal regulations.

A wide variety of vehicle types meet the demands of local and long-distance transportation, as well as the demands encountered on building sites and in special applications (examples in Figure 1). Commercial vehicles can basically be subdivided into the following categories: light utility vans, medium- and heavy-duty trucks, buses, tractor units, construction and agricultural machines, and special vehicles (e.g., piste basher, airfield fire truck).

Due to the wide diversity of vehicle types, the process of calculating the dimensions of the body structures (unitized body, cab, chassis, etc.) takes on a major importance right from the earliest stages of design. Building on experience with comparable vehicles, benchmark designs (volume-sales units, worst-case configurations) are defined by simulation and calculation with the aid of gradually refined complete-vehicle models using FEM (finite-element method) or MBS (multiple-body simulation). In this way, the rigidity, operational integrity, and vibration, acoustic and crash characteristics, etc. of relevant body-structure variants can be obtained to a substantial degree by computational means, even before testing starts. Structural calculations also take account of the requirements of (international) statutory safety standards.

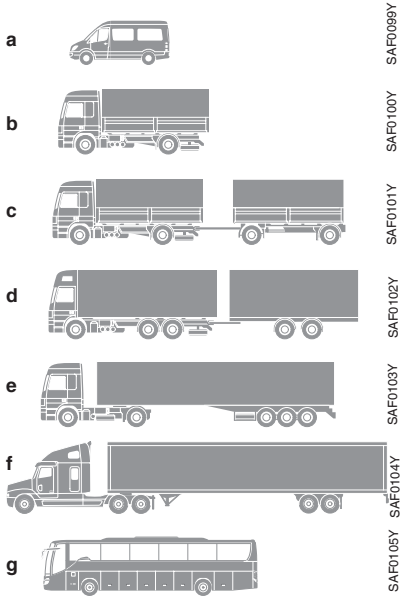

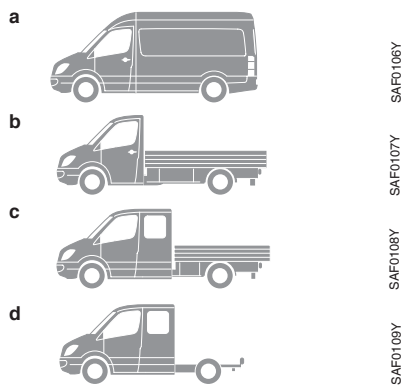

Figure 2: Overview of light utility vans
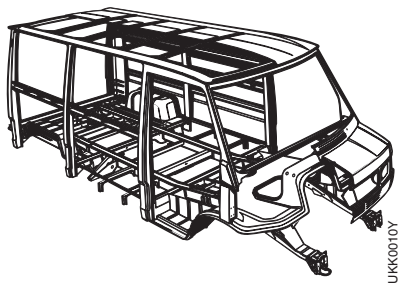
(Examples).
a) Panel van, b) Flatbed van,
c) Twin cab, d) Chassis.

Light utility vans

Areas of application
These are light utility vans (2 to 7 t) used in the transportation of persons and in local freight distribution. Light utility vans with more powerful engines are also increasingly deployed in pan-European long-distance transport duties involving high mileages (express delivery services, overnight courier services). In both cases, stringent demands are made on the vehicle in terms of agility, performance, user-friendliness, and safety.



Body-structure variants of light utility vans
The design concepts are based on front-mounted engine, front or rear-wheel drive, independent suspension, or rigid axle and, with overall weights of over 3.5 to 4 t, twin tires on the rear axle.

The product range includes enclosed-body multipurpose panel vans and platform-body vehicles, as well as low-bed and high-bed platform trucks with special superstructures and crew cabs (examples in Figure 2).

Up to approximately 6 t overall weight, the bodies form an integral load-structure unit together with the chassis (Figure 3). The body and chassis frameworks consist of sheet-metal pressed elements and flanged profiles similar to passenger cars.

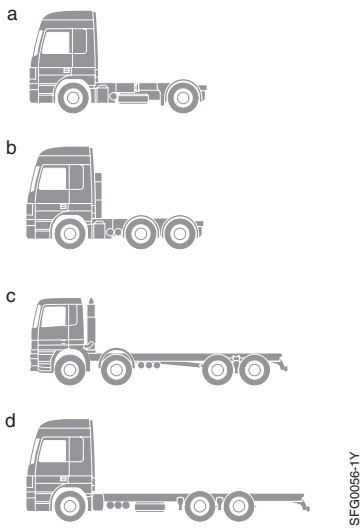
Light utility vans with platform bodies have a ladder-type frame with open or closed side members and cross-members as the primary load-bearing structure (similar to trucks, next section, Figure 5). These open designs also serve to build up box or recreational-vehicle bodies.

Figure 3: Light utility van, load-bearing unit

Medium- and heavy-duty trucks and tractor units

Body
Trucks are divided into four essential subtypes: long-distance transport vehicles, delivery vehicles, construction vehicles, and special vehicles. What all these vehicles have in common is a supporting frame structure on which a resiliently mounted cab is located and which constitutes a body which is connected with shear strength to the frame. The maximum dimensions and maximum permitted vehicle weights are subject to statutory provisions, which sometimes differ significantly from country to country. The maximum dimensions with regard to overall and semi-trailer lengths are stipulated for example in Europe by Directive 96/53/EU [1], the new version of which 2015/719/EU [2] is currently being technically elaborated. In the NAFTA zone, however, only the semi-trailer length, but not the overall length, is subject to restriction.

Equipped with a front-mounted engine, the drive is provided via one or more dual-tire rear axles. In individual cases, the rear axle is fitted with single tires. Four-wheel drive with an additional transfer case including interaxle-differential lock is also used for construction-site applications (off-road) with high traction requirements. The powered axles in this case have as standard axle-differential locks in their differentials and interaxle-differential locks for tandem-axle assemblies.



Chassis
Designations
The type of truck chassis (Figure 4) is given its designation in accordance with the convention N×Z/L, where N denotes the number of wheels or wheel pairs, Z the number of driven wheels or wheel pairs, and L the number of steered wheels (twin wheels count as one wheel pair). If L is not specified (e.g., 4×2), the vehicle has two steered front wheels.

Wheel suspension
Truck chassis have pneumatic- or leaf-spring-suspension rigid front and rear axles. Independent wheel suspensions are only used occasionally. Pneumatic

suspensions reduce the body acceleration to improve driving comfort, protect the load, and reduce strain on the road. They also facilitate the raising and lowering of swap bodies and the attachment and removal of semitrailers. These applications are usually used with 4×2 and 6×2 chassis for long-distance transport and delivery traffic.

Tandem-axle assemblies
For construction-site use or in the case of increased traction requirements the chassis are equipped with several powered axles (e.g., 4×4, 6×4, 6×6, 8×4, 8×8). In this case, the rear axles are combined to form a tandem-axle assembly. For the most part a steel-spring suspension is used, but pneumatic suspensions are also featured on the rear axles for road-based applications (e.g., building-material or low-loader transport) with the previously mentioned advantages. The axle load in a tandem-axle assembly is compensated in the case of the steel spring mechanically by pivoted mounting (center mounting) between the axles. In the case of non-combined pneumatically sprung single axles, the axle load is normally compensated pneumatically by altering the spring stiffness of the pneumatic suspension of the single axles.

Figure 4: Truck chassis
(Examples).
a) 4×2 (four wheels, two of which driven),
b) 6×2/4 (six wheels, two of which driven, four steered),
c) 8×6/4 (eight wheels, six of which driven, four steered),
d) 6×2 (six wheels, two of which driven).

Leading and trailing axles
Three-axle vehicles (6×2) are fitted with either a leading or a trailing axle (nonpowered axles in front of or behind the driven axle) to increase the payload capacity. If the chassis is fitted with a leading axle, this is mounted as an additional axle in front of the powered rear axle and provided with pneumatic suspension.

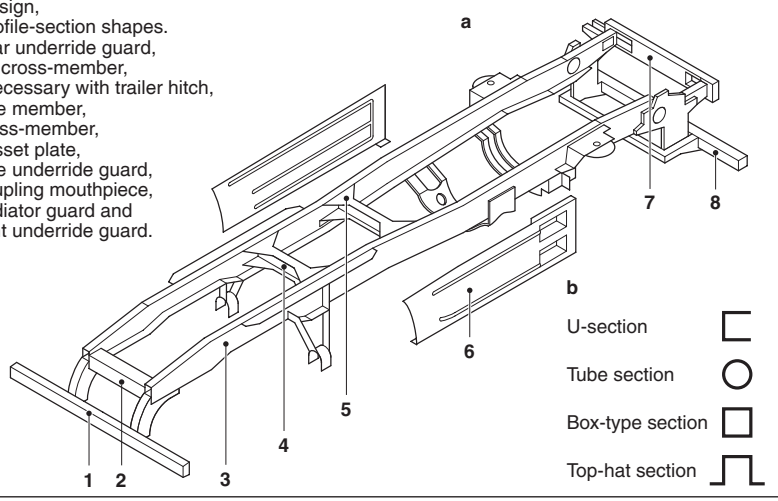
These leading axles usually have a steered design in order to avoid constraints when cornering, deliver a small turning circle, and thereby increase the maneuverability of the complete vehicle. The steering was effected in the first designs by a steering linkage branched from the steering axle, but is now equipped as a rule with electro-hydraulic steering because this does not require a linkage that takes up valuable space.

It is possible to equip the leading axle with a smaller wheel/tire size differing from the powered axle, but in this case the bearing loads of the leading axle are lower (4 to 5 t instead of a possible 7.5 to 9 t). There is also the combination of the leading axle with a lifting device. Then, when the vehicle is driving empty or with a low load, the axle is lifted from the driving position via a further air-spring bellows operating in the axially centered direction. This decreases rolling resistance and consequently reduces fuel consumption and also tire wear. Both these factors help to improve the vehicle's economic efficiency.

In the case of chassis designs with a trailing axle, this axle is mounted behind the powered rear axle. It is as a rule provided in on-road vehicles with pneumatic suspension and fitted with single tires, and in this case usually has a bearing load of 7.5 t. This variant can also be steered. Where trailing axles were still rigid when they began to be used in the late 1960s with the emergence of swap-body artic-

ulated road trains, steered trailing axles came to the fore with the desire for improved maneuverability against the backdrop of the increased use of three-axle chassis in delivery traffic. In view of the space conditions the trailing axle here is as a rule fitted with electro-hydraulic steering so that these variants can be flexibly used with different chassis and wheelbases. The use of a steered trailing axle offers, with a corresponding vehicle configuration, the combination of the load capacity of a three-axle chassis with the maneuverability of two-axle vehicle, which affords considerable benefits in economic terms. The trailing axles are also designed to be liftable virtually across the board with the previously mentioned advantages.

Where 6×2 chassis are operated on dirt roads or outside Europe, there are twin-tire rigid trailing axles with a bearing load of 9 to 10 t. As a rule, these are not designed to be liftable, but liftable variants are possible.



For special chassis the multiple fitment of leading and trailing axles or even the use of powered leading or trailing axles is conceivable. These chassis variants are conceived as special constructions and constitute technical challenges in that each axle must be assigned a different steering angle for the wheels so that the vehicle runs without excessive tire wear when cornering and complies with the turning-circle requirements. Combining a number of leading and trailing axles can thus also produce five- to eight-axle chassis which make possible gross vehicle weight ratings of over 60 t, for example for the mounting of concrete pumps or lifting work platforms with a working height of up to 112 m.

Chassis frame

The chassis frame is the commercial vehicle's actual load-bearing element. It is designed as a ladder-type frame, consisting of side members and cross-members (Figure 5). The vehicle body is bolted onto and the driver's cab is positioned on the chassis frame (Figure 6). The dimensions of the members are chosen to suit the required severity of application and load capacity (light- and heavy-duty commercial vehicles), but also in line with cost and weight considerations. The choice of profile sections (number and thickness) determines the level of torsional stiffness. Torsionally flexible frames are preferred in medium- and heavy-duty trucks because they allow the suspension to cope better with uneven terrain. Torsionally stiff frames are more suitable for light-duty delivery vehicles.

Figure 5: Ladder-type frame for a truck

a) Design,

if necessary with trailer hitch,
3 Side member,
4 Cross-member,
5 Gusset plate,
6 Side underride guard,
7 Coupling mouthpiece,
8 Radiator guard and
front underride guard.

Apart from the force introduction points, critical points in the chassis-frame design are the side- and cross-member junctions (Figure 7). Special gusset plates or pressed cross-member sections form a broad connection basis. The junctions are riveted, bolted, and welded. U- or L-shaped side-member inserts provide increased frame flexural strength and reinforcement at specific points.

The chassis frame also serves to accommodate by means of a variety of holders a wide range of add-on components such as fuel tanks, battery-device holders, compressed-air tanks, exhaust-gas system, or spare wheel. The configuration varies here, depending on the application profile required. Special mounted installations such as, for example, loading cranes or platform lifts are likewise mounted on the chassis frame for corresponding applications.

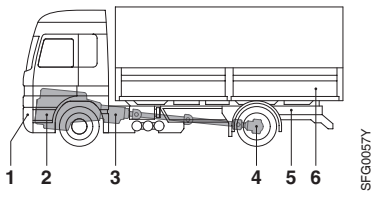

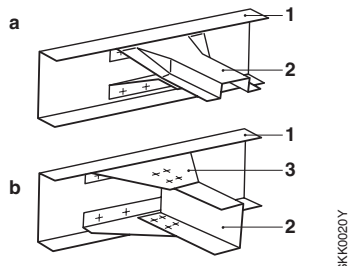

Figure 7: Junctions
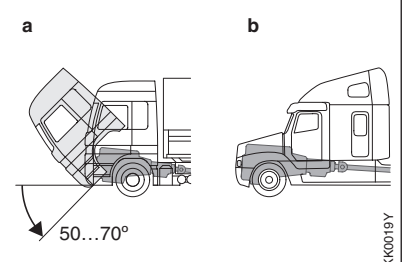
a) Cap cross-member, b) U-cross-member.
1 Side member, 2 Cross-member, 3 Gusset plate.



Driver's cab
There are a variety of cab designs available depending on the vehicle concept. In delivery vehicles and for public-service use, low, convenient entrances are an advantage, whereas in long-distance transport applications, space and comfort for example with a level floor are more important. Modular design concepts allow for short, medium and long cab versions while retaining the same front, rear and doors.

The cab is connected to the chassis frame by the cab mounting. A distinction is made here between comfort and standard mountings with different spring-and-damper combinations or transverse leaf-spring links with natural frequencies of 1 to 6 Hz.

From the design-concept viewpoint, a distinction must be made between cab-over-engine (COE) and cab-behind-engine (CBE) vehicles (Figure 8). In the case of cab-over-engine (COE) vehicles, the bulkhead and steering system are positioned right at the front of the vehicle. The engine is located under the cab (in the case of a level floor) or underneath an engine tunnel between the driver and the co-driver. The entrance is positioned in front of or above the front axle. A mechanical (by pretensioned torsion bars) or hydraulic cab-tipping mechanism provides access to the engine.

In cab-behind-engine (CBE) vehicles, the engine/transmission assembly is mounted ahead of the cab firewall under

Figure 8: Driver's cab
a) Cab over engine,
b) Cab behind engine.

a steel or plastic hood which is usually tiltable for reasons of accessibility. The driver enters the cab behind the front axle.

The standards required of the driver's cab with regard to aerodynamics, choice of materials, corrosion or equipment must be viewed as the same as the standards required of an automobile body. This means that, to save fuel and consequently CO_2 emissions, the aerodynamic drag of firstly the cab and secondly the entire truck-trailer must be reduced. Both the tractor vehicle and the trailer or the semitrailer must be included in the analyses for this purpose. Field tests show that including the semitrailer in the optimization of the complete-vehicle aerodynamics can achieve fuel savings of between 2 % and 4.5 %.

Body structures

Specific body structures such as flatbeds, box vans, dump-truck deep-beds, tankers, and concrete mixers permit the economical and efficient transportation of a wide variety of freight and materials. The body and load-bearing chassis frame are joined sometimes by means of auxiliary frames with non-positive or positive attachments. Special design features (e.g., sprung mountings in the forward body area) are required to connect the chassis frame (which usually has low torsional strength) to a rigid body (e.g., box-type). For off-road vehicles the torsional flexibility of the chassis frame must not be limited by a rigid body structure. Three-point mountings of the body structure are therefore used. For these vehicles coil instead of leaf springs are also used in the chassis to achieve large spring deflections.

Articulated road trains and semitrailer rigs are used in long-distance transport (Figure 1). As the size of the transportation unit increases, the costs relative to the freight volume decrease. Load volume is increased by reducing the empty spaces between the cab, body, and trailer (high-capacity road train, Figure 1d). Advantages of semitrailer rigs lie in the greater uninterrupted loading length of the cargo area and possible shorter inoperative times of the tractor units. Measures to improve aerodynamics, such as front and side panels on the vehicle and specially adapted air deflectors from the cab to the body, are applied to minimize fuel consumption.

The use of longer heavier vehicles which do not exceed the gross weight rating of 40 t but extend the overall road-train length to 25.25 m (instead of 16.50 m for semitrailers and 18.75 m for articulated road trains) can generate additional economic benefits. These longer heavier vehicles are used for light but bulky transported goods, e.g., for molded parts for the automotive industry, or in the transport of consumer goods.

Buses

The bus market offers a specific vehicle for practically every application. This results in a wide range of bus types, which differ in their overall dimensions (length, height, width) and appointments (depending on the application) (Figure 9).

Bus types

Microbuses

Minibuses carry up to approx. 20 passengers. These vehicles have been developed from light utility vans weighing up to approximately 4.5 t.

Mini- and midibuses

Buses which can carry up to approximately 25 persons are called mini- or midibuses. The transition from minibus to midibus is fluid. These vehicles have for the most part been developed from light utility vans weighing up to approximately 7.5 t. They are occasionally built on ladder-type chassis of light-duty trucks, or a unitized integral structure is used. A modified suspension design and special measures carried out on the body (e.g., flexible mountings) result in optimum ride comfort and low noise levels.

City buses

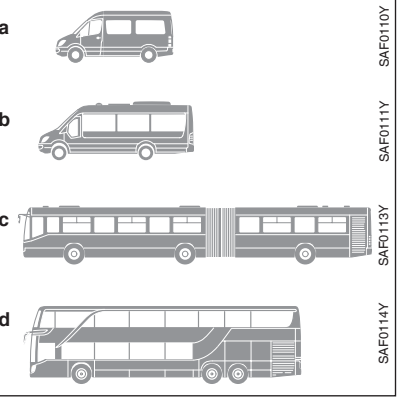
City buses are equipped with seating and standing rooms for scheduled routes. The short intervals between stops in suburban passenger transportation operations require rapid passenger turnover. This is achieved by wide doors that open and close swiftly, low boarding heights (approx. 320 mm) and low floor heights (approx. 370 mm).

Main specifications for a standard municipal-service bus:

– Vehicle length approx. 12 m,
– Permissible total weight 18.0 t,
– Number of seats 32 to 44,
– Total passenger capacity approx. 105 persons.

The use of double-decker buses (length 12 m carrying up to approximately 130 passengers), three-axle rigid buses (length up to 15 m carrying up to approximately 135 passengers), and three-axle articulated buses (length up to approximately 18 m carrying 160 to 190 passengers) provides increased transport capacity.

Now articulated buses with an overall length of almost 21 m and a total weight of 32 t are used in large numbers as city buses. These make use of an additional steered trailing axle which increases the bus' weight capacity and at the same time improves the maneuverability despite the greater overall length.



Intercity/overland buses

Depending on the application (standing passengers are not permitted at speeds over 60 km/h), low-floor designs featuring low boarding and floor heights (as in city buses) or higher floors and small luggage compartments (already very much like tour buses) are used. Intercity buses come in lengths of 11 to 15 m as rigid vehicles or in lengths of 18 m as articulated vehicles.

Tour buses (coaches)

Tour buses are designed to provide comfortable travel over medium and long distances. They range from the low, two-axle standard bus through to the double-decker luxury bus. Tour buses come in lengths of 10 to 15 m. Articulated buses were only occasionally used in intercity-bus applica-

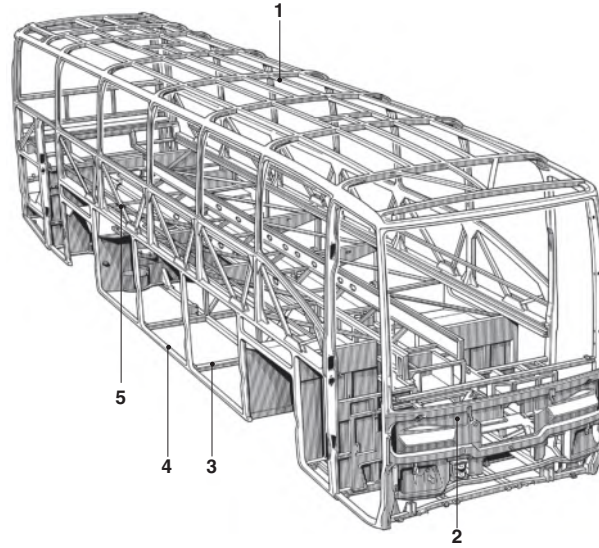
Figure 9: Overview of buses
(Examples).
a) Microbus,
b) Mini- and midibus,
c) City bus,
d) Tour bus.

tions and did not gain acceptance. Double-deckers, on the other hand, are frequently used as intercity buses, particularly on long-distance bus routes which are operated with tour buses.

Trailer operation
Buses with trailers are increasingly being used. This applies to all applications, i.e., city and intercity/overland buses, as well as to tour buses.

In city-bus applications trailers are specially approved to carry passengers and at peak times are hitched to the towing vehicle to meet passenger demand. This type was used up until the 1960s, but disappeared very quickly with the emergency of articulated buses. Since around 2010 the city-bus/trailer combination has been back in favor so as to provide a flexible response to passenger fluctuations depending on the time of day on the outskirts of big cities.

With intercity/overland buses trailers serve to transport luggage or to carry bicycles in vacation regions so as to be able to offer an attractive and flexible means of transport for changing to local public transport.



In the case of tour buses, particularly double-deckers, which in view of their design can offer minimal luggage space, the luggage trailer is a good solution as an economical and comfortable means of travel. The approval of trailers for cruising speeds identical to buses without trailers (max. 100 km/h) entails no drawbacks in terms of travel times, increasing the attractiveness.

Body
Lightweight design based on a unitized body has gained acceptance as standard (integral construction). The body and base frames, which are firmly welded together, consist of pressed grid-type support elements and rectangular tubes (Figure 10).

In the case of the chassis structure, the body is positioned on a supporting ladder-type frame (similar to trucks). Except for mini- and midibuses, this design is not commonly encountered in Europe.

Chassis systems
The vertically or horizontally mounted engine drives the rear axle. Here the engine together with the transmission is not – in contrast to trucks – installed at the front

Figure 10: Unitized bus body
1 Body framework,
2 Pressed parts,
3 Base frame,
4 Rectangular tube,
5 Grid-type support elements.

and then connected with a long propeller shaft to the powered axle, but instead the engine/transmission unit is installed at the rear end of the bus. This also applies to articulated buses, in which the last axle is powered. Pneumatic suspension on all axles permits ride-level stabilization and a high degree of ride comfort. Intercity buses and tour buses are mainly equipped with independent suspension on their front axles. Disk brakes, frequently supported by retarders, are used on all axles.

Alternative drives
In view of the increasing sensitivity of users and operators of commercial vehicle, increasing endeavors are being made to produce alternative drives for commercial vehicles. The advantage of vehicles with alternative drives is that they comply with CO_2 legislation, avoid break-in restrictions, and satisfy the demands of society in general. These demands on the one hand relate to eliminating the dependence on petroleum fuels, whose days as fuels are numbered. They relate on the other hand to reducing the emission of CO_2 as a combustion product that contributes substantially to the greenhouse effect.

Both light utility vans and buses can be equipped for urban operation with a natural-gas, a battery-electric, or a fuel-cell drive. Likewise, battery drives are also available for heavy trucks in local goods and delivery traffic. A future development task is to come up with the best complete-vehicle concept for an electric truck and in so doing bring into line the general design of the battery with regard firstly to range, installation space, weight, and costs, and secondly to the demands of daily operation (charging cycle, charging time, useful load, ease of use).

Active and passive safety in commercial vehicles

Active safety comprises all the systems and measures which help to avoid an accident. Passive safety is intended to limit the consequences of accidents and to protect other road users. Systematic recording of accidents, accident tests with complete vehicles, and intensive computer optimization help to devise safety measures.

Active safety
A minimum of active safety systems is redefined on a regular basis by legislative bodies. Where the antilock braking system (ABS) was developed to the stage of series production for trucks back in 1980, it gained acceptance in all trucks at a later stage as the result of appropriate legal requirements. This also applies to driving-dynamics control (Electronic Stability Control, ESC) and the active brake assistant.

The availability of a comprehensive package of active-safety systems is a necessary precondition for the application of high automated or autonomous driving, a epoch-making change in truck operation.

Passive safety
Requirements
Generally, the effectiveness and strength of occupant restraint systems has to be demonstrated. Therefore, the dimensioning of commercial-vehicle body structures must take account of aspects, such as the strength and rigidity of seat-belt anchor points on the seats and of the related body structures (seat rails, floor, frame, etc.).

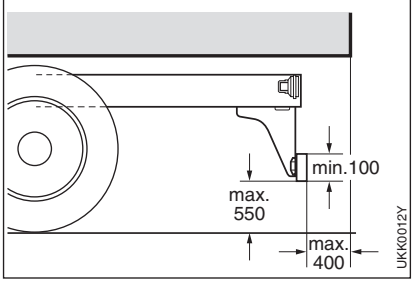
In the event of a collision, the driver's cab and the passenger cabin must maintain the amount of room necessary for occupant survival, while at the same time deceleration must not be excessive. Depending on vehicle design, there are a variety of solutions to this problem. In light utility vans, front-section design is energy-absorbing as in passenger cars. In spite of shorter deformation paths and higher levels of released energy, the physiologically permissible limits are not exceeded in virtually all passenger-car

crash-test standards (legal requirements and rating tests). In light utility vans, there must also be features which prevent injury to occupants by uncontrolled movement of the payload. The static and dynamic strength of such features (partitions, cages and nets, securing eyes) has to be demonstrated mathematically or by testing.

In the case of trucks, the side members extend up to the front fender and can absorb high linear forces. Such passive-safety measures are based on accident analyses and are intended to improve the structural design of the cab. Static and dynamic stress and impact tests at the front and rear of the cab, as well as on its roof, simulate the stresses involved in a frontal impact and in accidents in which the vehicle overturns, rolls over, or in which the cargo moves. They are described in the Regulation ECE R29 [3], but the passing of these tests as a condition of type approval is only required in a few European countries.

Statistical analyses have proved that the bus is the safest means of passenger transportation. Static roof-load tests and dynamic overturning tests provide evidence of body strength. The use of flame-retardant and self-extinguishing materials for the interior equipment of the vehicle minimizes the risk of fire.

As road traffic involves many different kinds of vehicles, collisions between light and heavy vehicles cannot be avoided 100 % without the use of active-safety systems or the communication of vehicles with each other (V2V, vehicle to vehicle; V2X, vehicle to infrastructure). As a result of the differences in vehicle weight, and incompatibility in terms of vehicle geometry and structural stiffness, the risk of injury in the lighter vehicle is greater.



The change in speed Δv during a central plastic impact for front-end or rear-end collisions between two vehicles (vehicle 1 and vehicle 2) is defined as

$$\mu = \frac{m_2}{m_1}: \ \Delta v_1 = \frac{\mu v_r}{1+\mu}, \ \Delta v_2 = \frac{v_r}{1+\mu},$$

with the masses m_1 and m_2 of the vehicles involved and the relative speed v_r prior to the impact.

Side, front and rear underride guards help to reduce the danger of the lighter vehicle driving under the heavier vehicle. In other words, they serve to protect other road users (Figure 11).

Figure 11: Rear underride guard for trucks

Lighting equipment

Functions

Ever since the invention of the automobile, it has been accompanied by vehicle lighting. Initially candles, then petroleum and carbide lamps were used to provide lighting; today, these lamps would be classed as position or marker lamps. Only with the introduction of automotive electrics in the form of the Bosch alternator in the Adler vehicle (1913) were manufacturers able to introduce systems which generated good ranges and lived up to being called "headlamps". Further significant milestones have been

– the introduction of the asymmetrical low-beam pattern, characterized (RHD traffic) by an extended visual range along the right side of the road (1957),
– the introduction of new headlamp systems featuring complex geometrical configurations (PES, Poly-Ellipsoid System, free-form surfaces, facetted reflectors) offering efficiency-level improvements of up to 50 % (1985),
– the "Litronic" headlamp system with gas-discharge lamps (xenon lamps with luminous arc) which supplied more than twice the light generated by comparable halogen units (1990),
– adaptive front-lighting systems (AFS) with moving, dynamic PES modules (Poly-Ellipsoid System) or static, activated reflectors for turning (2003).

Lighting at the vehicle front end
The primary function of the headlamps at the vehicle front end is to illuminate the roadway so that the driver can detect traffic conditions and recognize any obstacles and hazards in good time. They also serve to identify and mark out the vehicle to oncoming traffic. The turn-signal lamps serve to show the driver's intention to change direction or to indicate a hazardous situation.

The headlamps and lights at the front end include the following:

– low-beam headlamps
– high-beam headlamps
– fog lamps
– auxiliary driving lamps
– turn-signal (direction-indicator) lamps
– parking lamps
– position/clearance lamps (for wide vehicles)
– daytime running lamps (if required by law in individual countries).

Lighting at the vehicle rear end
Lights are turned on at the vehicle's rear end in accordance with the lighting and weather conditions and indicate the vehicle's position. They also indicate how the vehicle is moving and in which direction, e.g., whether the brakes are applied or the driver is intending to change direction, or whether a hazardous situation exists. The reversing lamps illuminate the roadway while the vehicle is reversing.

The lamps and lights at the rear end include the following:

– stop lamps,
– tail lamps,
– rear fog warning lamps,
– turn-signal (direction-indicator) lamps,
– parking lamps,
– clearance lamps (for wide vehicles),
– reversing (backup) lamps,
– license-plate lamps.

Lighting in the vehicle interior
In the vehicle interior, priority over all other functions is given to the ease and reliability with which the switch elements can be reached and operated, and to provide the driver with sufficient information on the vehicle's operating states (while distracting him/her from driving as little as possible). These priorities dictate effectively illuminated instrument panels and discrete lighting for various control clusters (such as the sound and navigation systems), where they satisfy a prime requirement for relaxed and safe vehicle operation. Optical and acoustic signals must be prioritized according to their urgency and then relayed to the driver.

Regulations and equipment

Approval codes and symbols, Europe/ECE
Automotive lighting equipment is governed by national and international design and operating regulations, according to which the equipment in question must be manufactured and tested. For every type of lighting equipment, there is a special approval code and symbol which has to be legibly displayed on the equipment concerned. The preferred locations for approval codes and symbols are places that are directly visible when the hood is open, such as the lenses of headlamps and other lights, and the headlamp unit components. This also applies to approved replacement headlamps and lights.

If an item of equipment carries such an approval code/symbol, it has been tested by a technical inspectorate (e.g., in Germany the Lighting Technology Institute of Karlsruhe University) and approved by a licensing authority (in Germany the Federal Road Transport Office). All volume-production units which carry the approval code/symbol must conform in all respects to the type-approved unit. Examples of approval symbols:

(E1) ECE approval mark, [e1] EU approval mark.

The number 1 following each letter indicates the type-approval test carried out and the award of approval according to ECE (Economic Commission for Europe) Regulations for Germany with Europe-wide recognition. In Europe, installation of all automotive lighting and visual signaling equipment is governed not only by national guidelines but also by the higher European directives (ECE: whole of Europe, EU, New Zealand, Australia, South Africa and Japan). In the course of the ongoing union of Europe, the implementation regulations are being increasingly simplified by the harmonization of directives and legislation.

Right-hand-drive or left-hand-drive traffic
The ECE Regulations apply by analogy to driving on the right or left. The technical requirements for lighting are mirrored around the central perpendicular of the test screen (see Figure 4). According to the Vienna Global Treaty of 1968, when traveling in countries which drive on the other side of the road, all road users are obliged to adopt measures to prevent increased glare of oncoming traffic at night due to the asymmetrical light pattern. This can be achieved either by self-adhesive strips obtainable from the vehicle manufacturer or two-way switches in the headlamps (in the case of PES).

Regulations for the USA
In the USA, lighting equipment is governed by regulations that are very different from those in Europe. The principle of self-certification compels each manufacturer as an importer of lighting equipment to ensure, and in an emergency to furnish, proof that its products conform 100 % with the regulations of FMVSS 108 [27] (Federal Motor Vehicle Safety Standard) laid down in the Federal Register. There is therefore no type approval in the USA. The regulations of FMVSS 108 are partly based on the SAE industry standard (Society of Automotive Engineers).

Upgrading and conversion
Vehicles imported to Europe from other regions must be modified to comply with European directives. This applies in particular to the lighting equipment. Identical components available for the European market can be used as direct replacements. Other solutions, such as retail products or, in certain cases, retention of the original equipment, require an engineer's report. In Germany, Article 22a of the StVZO (Road Traffic Licensing Regulations) [1] requires "Approximation Certificates" for lighting equipment. Such certificates are issued by the Lighting Technology Institute of Karlsruhe University.

Subsequent alterations to type-approved headlamps, bases, and sockets invalidate the type approval and consequently the general operating license of the vehicle.

Light sources

With regard to automotive light sources, a distinction is made between thermoluminescent radiators (thermal radiators) and electroluminescent radiators. The outer electron shells of atoms of certain materials can absorb varying levels of energy by excitation (energy input). The transition from higher to lower levels may lead to the emission of electromagnetic radiation.

Thermoluminescent radiators
In the case of this type of light source, the energy level of the crystal system is increased by adding heat energy. Emission is continuous across a broad wavelength range. The total radiated power is proportional to the power of 4 of the absolute temperature (Stefan-Boltzmann law). The distribution-curve maximum is displaced to shorter wavelengths as temperature increases (Wien's displacement law) [38].

Filament lamps
Filament lamps, with tungsten filament (fusion temperature 3,660 K), are also thermal radiators. The evaporation of the tungsten and the resulting blackening of the bulb restrict the service life of this type of lamp.

Halogen lamps
A halogen filling (iodine or bromine) in the lamp allows the filament temperature to rise to close to the melting point of the tungsten. Close to the hot bulb wall, the evaporated tungsten combines with the filler gas to form tungsten halide. This is gaseous, light-transmitting and stable within a temperature range of 500 K to 1,700 K. It reaches the filament by means of convection, decomposes as a result of the high filament temperature, and forms an even tungsten deposit on the filament. In order to maintain this cycle, an external bulb temperature of approx. 300 °C is necessary. To achieve this, the bulb, made of fused silica (quartz), must surround the filament closely. A further advantage of this measure is that a higher filling pressure can be used, thereby providing additional resistance to tungsten evaporation.

Electroluminescent radiators
Gas-discharge lamps
Gas-discharge lamps are electroluminescent radiators and distinguished by their higher luminous efficiency. A gas discharge is maintained in an enclosed, gas-filled bulb by applying a voltage between two electrodes. The atoms of the emitted gas are excited by collisions between electrons and gas atoms. The atoms excited in the process give off their energy in the form of luminous radiation.

Examples of gas-discharge lamps are sodium-vapor lamps (street lighting), fluorescent lamps (interior illumination) and D lamps for motor-vehicle applications (Litronic).

Light-emitting diodes
A light-emitting diode or LED is an electroluminescent lamp. Thanks to their robustness, high energy efficiency, fast reaction time, and compact construction, LEDs are used as illuminators or displays in a wide range of applications. They are used in motor vehicles in the passenger compartment to provide illumination, as displays or for display backlighting. In the exterior areas LEDs are fitted in particular in auxiliary stop lamps and tail lamps. With a further increase in their luminous efficiency, they can increasingly be used in lamps and main functions at the front end of the vehicle.

Motor-vehicle bulbs

Replaceable filament bulbs for motor-vehicle lighting must be type-approved in accordance with ECE R37 [10], replaceable gas-discharge light sources in accordance with ECE R99 [19]. Other light sources which do not comply with these regulations (LEDs, neon tubes, special bulbs) are permitted, but can only be installed as a fixed component part of a lamp or as a "light-source module".

Bulbs complying with ECE R37 are generally available in 12 V versions, some bulbs also in 6 V and 24 V versions (Table 1). To help avoid mix-ups, different bulb types are identified by different base shapes. Bulbs of differing operating voltages are labeled with this voltage in order to avoid mix-ups in the case of identical bases. The bulb type suitable in each case must be indicated on the equipment.

A voltage increase in halogen lamps of 10 % results in a 70 % reduction in service life and a 30 % increase in luminous flux (Figure 1, [39]).

The luminous efficiency (lumens per watt) represents the bulb's photometrical efficiency relative to its power input. The luminous efficiency of vacuum bulbs is 10 to 18 lm/W. The higher luminous efficiency of halogen lamps (22 to 26 lm/W) is primarily a consequence of increasing the filament temperature. Gas-discharge bulbs provide a luminous efficiency in the order of 85 lm/W for substantial improvements in low-beam performance.

LEDs today achieve a luminous efficiency in the range of 50 lm/W (LEDs with high power consumption) or 100 lm/W (LEDs with low power consumption). An increase in luminous efficiency of up to 25 % is expected in the next few years.

Main-light functions

Low beam

The main light for driving at night is provided by low-beam headlamps. The creation of the characteristic light-dark boundary was one of the technological milestones in lighting technology.

The "dark above/bright below" distribution pattern resulting from the light-dark boundary furnishes acceptable visual ranges under all driving conditions. This configuration reduces glare, to which approaching traffic is exposed, within reasonable limits, and at the same time it supplies relatively high luminous intensity in the area below the light-dark boundary.

The light distribution pattern must combine maximum visual ranges with minimum glare effect. These demands are supplemented by other requirements affecting the area directly in front of the vehicle. For instance, the headlamps must provide assistance when cornering, i.e., the light distribution pattern must extend beyond the left and right-side extremities of the road surface.

With the asymmetrical low-beam pattern the light-dark boundary in the right area slopes upwards so that the right side of the road is better illuminated. This prevents oncoming traffic from being dazzled. This is mirror-inverted in left-hand-drive vehicles.

High beam
High-beam headlamps illuminate the road to the maximum range. This creates a high luminous intensity, depending on the distance, acting on all objects in the space reserved for traffic. High-beam headlamps are therefore only permitted when they do not dazzle oncoming traffic (glare).

The high traffic density on modern roads severely restricts the use of high-beam headlamps.

Installation and regulations
Designs
Global regulations mandate two headlamps for low beam and at least two (or the option of four) high-beam units for all dual-track vehicles. The light color is white.

Dual-headlamp system
The dual-headlamp system (Figure 2a) uses lamps with two light sources (halogen double-filament bulbs (H4), US sealed beam) for high and low beams using shared reflectors (see Reflection headlamps). In headlamps with gas-discharge bulbs the dual function is achieved by focusing or defocusing the xenon burner in a shared reflector (see Bi-Litronic "Reflection"). In bi-xenon projection systems a screen is moved out of or into the beam path (see Bi-Litronic "Projection").

Figure 2: Headlamp systems
a) Dual-headlamp system,
b) Quad-headlamp system,
c) Quad-headlamp system with additional fog lamps.

Quad-headlamp system
Two of the headlamps in a quad-headlamp system provide both high and low beam, while the second pair only provides high-beam illumination (Figure 2b). The light functions of projection and reflection systems can be used in any combination. The low-beam headlamps can additionally be combined with the fog lamps (Figure 2c).

Important definitions of device design
Grouped design
A single housing, but with different lenses and bulbs. Example:
– Multiple-compartment rear-lamp assemblies containing different individual light units.

Combined design
A single housing and bulb assembly with more than one lens. Example:
– Combined tail lamp and license-plate lamp.

Nested design
Common housing and lens, but with individual bulbs. Example:
– Headlamp assembly with nested position lamp.

Main-light functions for Europe

Regulations and directives for Europe
The most important regulations and directives are laid down in ECE R112 [20], ECE R113 [21], ECE R48 [12], 76/756/EEC [24], ECE R98 [18], and ECE R123 [23].
- ECE R112: Headlamps for asymmetrical low beam and/or high beam that are fitted with filament bulbs or LED modules (cars, buses, trucks).
- ECE R113: Headlamps for symmetrical low beam and/or high beam that are fitted with filament bulbs, gas-discharge light sources or LED modules (motorbicycles, motorcycles).
- ECE R48 and 76/756/EEC: for attachment and application.
- ECE R98: Headlamps with gas-discharge lamps as per ECE R99.
- ECE R123: Adaptive front-lighting systems (AFS) for motor vehicles.

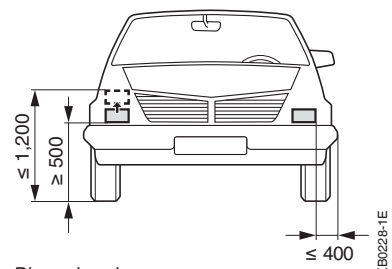
The installation regulations described in the following refer to passenger cars.

Low beam
Regulations prescribe 2 white-light low-beam headlamps for multiple-track vehicles (Figure 3).

Automotive headlamp performance is subject to technical assessment and verification before they are put into volume production. Among the requirements are minimum luminous intensity, to ensure adequate road-surface visibility, and maximum intensity levels, to prevent glare (see measurement points and luminous intensities for headlamps, Figure 4 and Table 2).

Homologation testing is carried out under laboratory conditions using test lamps manufactured to more precise tolerances than those installed in production vehicles. The lamps are operated at the specified test luminous flux for each lamp category. The laboratory conditions apply across the board to all headlamps, but only take limited account of the specifics of individual vehicles, such as headlamp fitted height, vehicle power supply, and adjustment.

High beam
A minimum of two and a maximum of four headlamps are prescribed for the high-beam mode. The prescribed instrument-cluster high-beam indicator lamp is blue or yellow in color.



The high beam is usually generated by a light source located at the focal point of the reflector (Figure 5). This causes light to be reflected outward in the direction of the reflector axis. The maximum luminous intensity achievable by the high beam is largely a function of the reflector's illuminated area.

In quad-headlamp systems, in particular, roughly paraboloid high-beam reflectors can be replaced by units with complex geometrical configurations designed to supply a "superimposed" high-beam pattern. The calculations employed to design these units seek to achieve a high-beam distribution that harmonizes with the low-beam pattern (simultaneous activation). The pure high beam is "superimposed" as it were on the low-beam projection. The annoying overlap area close to the front of the vehicle is done away with in this case.

High-beam light distribution pattern is defined in the regulations and guidelines together with stipulations governing the low beams.

The maximum approved luminous intensity, a composite of the intensity ratings of all high-beam headlamps installed on the vehicle, is 430,000 cd. This value is indicated by identification codes located adjacent to the homologation code on

each headlamp. 430,000 cd corresponds to the figure 100. The luminous intensity of the high beam is indicated by the number, e.g., 25, stamped next to the round ECE approval mark. If these are the only headlamps on the vehicle (no auxiliary driving lamps), then the composite luminous intensity is in the range of 50/100 of 430,000 cd, i.e., 215,000 cd.

Auxiliary driving lamps
Auxiliary driving lamps are used to complement the effectiveness of the high beam in standard high-beam headlamps.

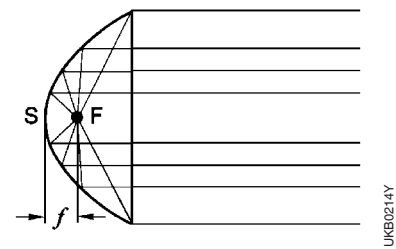
Auxiliary driving lamps are mounted and aimed in the same way as standard headlamps, and the underlying lighting technology is the same. Auxiliary driving lamps are also subject to the regulations governing maximum luminous intensity in vehicle lighting systems, according to which the sum of the reference numbers of all headlamps fitted to a vehicle must not exceed 100. For older headlamps without approval number, the number 10 is used for general assessment purposes.

Low- and high-beam switching
All high-beam headlamps must extinguish simultaneously when the low beams are switched on. Dimming (gradual deactivation) is permitted, with a maximum dimming period of 5 seconds. A 2-second response delay is required to prevent the dimming feature from activating when the headlamp flashers are used.

When the high-beam headlamps are switched on, the low-beam units may continue to operate (simultaneous operation). H4 bulbs are generally suitable for short periods of use with both filaments in operation.

Main-light functions for the USA

Regulations and directives
The national standard is the Federal Motor Vehicle Safety Standard (FMVSS) No.108 [27] and the SAE Ground Vehicle Lighting Standards Manual (Standards and Recommended Practices) to which it refers.



The regulations governing installation and control circuits for main headlamps are comparable in parts to those in Europe. Since 5/1/1997, however, headlamps with light-dark boundaries have also been authorized in the USA, but these require manual adjustment. It is now possible to develop headlamps which conform to legal requirements in both Europe and the USA.

As in Europe, dual- and quad-headlamp systems are used in the USA. The fitting and use of fog lamps and additional high-beam headlamps, however, are subject to a variety of, in some cases, widely diverging, local laws passed by the 50 individual states.

Up to 1983 only sealed-beam headlamps were permitted in the USA.

Low beam
The light-pattern requirements in America differ to a greater or lesser degree from the European system depending on the design type. In particular, the minimum glare levels are higher in the USA, and the maximum low-beam width is closer

Figure 5: Parabolic reflector
F Focal point, S Vertex of the parabola, f Focal length.

to the vehicle. The basic setting is generally higher (see measurement points in Figure 6 and Table 3).

High beam
The designs for high-beam headlamps are the same as in Europe. Differences exist in the required dispersion width of the light pattern, and there is a lower maximum figure on the axis of the high-beam headlamp.

Designs
Sealed-beam design
In this design, which is no longer used, the aluminized glass reflector and the lens must be sealed gas-tight on account of the light sources that are not encapsulated.

21	4D, 20R	≥ 300

The whole unit is sealed and filled with an inert gas. If a filament burns through, the entire light source must be replaced. Units with halogen lamps are also available.

The limited range of available sealed-beam headlamps on the market severely restricted the freedom of design for vehicle front ends.

Vehicle headlamp aiming device (VHAD)
This design involves replaceable-bulb headlamps which are adjusted vertically with the aid of a spirit levels integrated in each headlamp, and horizontally by means of a system comprising a needle and dial. In fact, this is equivalent to "on-board aiming".

Headlamps for visual aim (VOL / VOR)
These systems have been in use since 1997. These are replaceable-bulb headlamps whose low beam has a light-dark boundary line which allows visual aiming of the headlamps (as is standard in Europe).

Either the left horizontal light-dark boundary (VOL, visual optical aim left; VOL mark on the headlamp) or, as is more often the case in the USA, the right horizontal light-dark boundary (VOR, visual optical aim right; VOR mark on the headlamp) is used. What is notable about the US systems is the position of the light-dark boundary, which is much closer to the horizon (inclination depending on type 0.4 to 0 %). This increases the potential dazzling risk of such systems.

There is no horizontal aiming with this type of headlamp.

Definitions and terms

Photometrical terms and definitions
Headlamp range
This is the distance at which the light beam continues to supply a specified luminous intensity – mostly the 1 lux line at the right side of the road (LHD traffic).

Geometric range of a headlamp
This is the distance to the horizontal portion of the light-dark boundary on the road surface (see Headlamp leveling control, Table 4). A low-beam inclination of 1 %, or 10 cm/10 m, results in a geometric range equal to 100 times the headlamp's fitted height (as measured between the center of the reflector and the road surface).

Visual range
The visual range is the distance at which an object (vehicle, object, etc.) within the luminance distribution of the human visual field is still visible.

The visual range is influenced by the shape, size, and reflectance of objects, the road-surface type, headlamp design and cleanliness, and the physiological condition of the driver's eyes. Due to the large number of influencing factors, it is not possible to quantify this range using precise numerical definitions. Under extremely unfavorable conditions (with RHD traffic, on the left side of a wet road surface) the visual range can fall to below 20 m. Under optimum conditions, it can extend outward to more than 100 m (with RHD traffic, on the right side of the road).

Disability: glare
This is the quantifiable reduction in visual performance that occurs in response to light sources emitting glare. An example would be the reduction in visual range that occurs as two vehicles approach one another.

Discomfort: glare
This condition occurs when a glare source induces discomfort without, however, causing an actual reduction in visual performance. Discomfort glare is assessed according to a scale defining different levels of comfort and discomfort.

Headlamp technology
Reflector focal length
Conventional reflectors for headlamps and other automotive lamps are usually parabolic in shape (Figure 5). The focal length f (distance between the vertex of the parabola and the focal point) is 15 to 40 mm.

Reflector illuminated area
This is the parallel projection of the entire reflector opening on a transverse plane. The standard reference plane is perpendicular to the vehicle's direction of travel.

Effective luminous flux, efficiency of a headlamp
The first of the above is the portion of the light source's luminous flux that is capable of supplying effective illumination via its reflective or refractive components (for instance, as projected on the road surface via the headlamp reflector). A reflector with a short focal length makes efficient use of the filament bulb and has high efficiency because the reflector extends outward to encompass the bulb, allowing it to convert a large proportion of the luminous flux into a useful light beam.

Angles of geometric visibility
These are angles that are defined relative to the axis of the lighting device, at which the illuminated area must be visible.

Technical design variations of headlamps

Components
Parabolic reflector
Reflectors direct the light from the light source either directly onto the road (reflection system) or into an intermediate plane which is further projected by a lens (projection system, see PES headlamps). The reflectors are made of plastic, die-cast metal or sheet steel.

Plastic reflectors are manufactured by injection molding (thermosetting plastics), which offers a considerably better precision of geometry reproduction than the deep-drawing of sheet-steel reflectors. The geometric tolerances that can be achieved lie in the range of 0.01 mm. The base material requires no corrosion-proofing treatment.

The die-cast metal used is usually aluminum, or occasionally magnesium. The advantages are high thermal resistance and the ability to produce shapes with a high degree of complexity (shaped bulb holders, screw holes and bosses).

The surfaces of thermosetting plastic and die-cast metal reflectors are given a smooth finish by spray painting or powder-based paint before a layer of aluminum 50 to 150 nm thick is applied. An even thinner transparent protective coat prevents the aluminum from oxidizing.

Sheet-steel reflectors are manufactured using deep-drawing and punching dies. A powder-based paint is then applied. This process hermetically seals the sheet steel and gives it excellent surface smoothness. The base coat created in this way is, like other reflectors, coated with aluminum.

Free-form reflectors
Furthermore, reflectors in stages and any desired facet distributions can also be implemented. The geometrical configurations of free-form reflectors are generated using complex mathematical calculations (HNS, Homogeneous Numerically Calculated Surface). Here, the low mean focal length f is defined relative to the distance between the reflector vertex and the center of the filament. Typical values range from 15 to 25 mm.

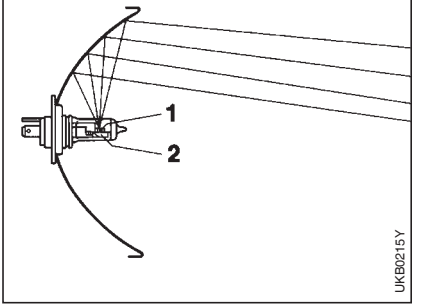
In the case of reflectors partitioned with steps or facets, each partition can be created with its own mean focal length *f*.

Diffusing lenses
A large proportion of contoured diffusing lenses is manufactured using high-purity glass (free of bubbles and streaks). During the lens molding process, high priority is given to surface quality in order to prevent undesirable upward light deflection in the final product – this would tend to create glare for oncoming traffic. The type and configuration of the lens prisms depend on the reflector and the desired light distribution pattern.

Cover lenses
The clear cover lenses used on modern headlamps are usually made of plastic. Besides reducing weight, plastic lenses provide other advantages for automotive applications, including greater freedom in headlamp and vehicle design. Since around 2007 multicolor plastic lenses (2-component lenses) have also been used in which the edge area is sprayed in a different color, usually black or gray. The advantage here is that the spray tools are designed in such a way that no inner slides are needed and therefore no separating lines are created on the visible surface. Light dispersion from the edge areas is also avoided.

There are several reasons why plastic cover lenses should not be cleaned with a dry cloth:
– Despite the scratch-proof coating, rubbing with a dry cloth can damage the surface of the lens.
– Rubbing with a dry cloth can produce an electrostatic charge in the lens, which can then allow dust to build up on the inside of the lens.

Conventional reflection headlamps
For conventional headlamp systems with virtually parabolic reflectors (Figures 5 and 7), the quality of the low beam increases in direct proportion to the size of the reflector. At the same time the geometric range increases as a function of installation height.



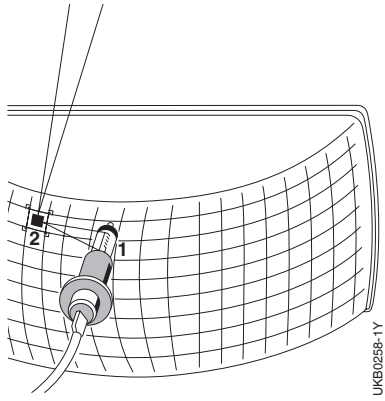
These factors must be balanced against the aerodynamic constraints according to which the vehicle's front-end profile must be kept as low as possible. Under these circumstances, increasing the size of the reflector results in wider headlamps.

Reflectors of a given size, but with different focal lengths, also perform differently. Shorter focal lengths are more efficient and produce wider light beams with better close-range and side illumination. This is of particular advantage during cornering.

Specially developed lighting programs (CAL, computer-aided lighting) enable the implementation of infinitely variable reflector shapes with non-parabolic sections and of faceted reflectors.

Headlamps with facet-type reflectors
In the case of facets, the reflector surface is partitioned and each individual segment is individually optimized. The important feature of surfaces with facet-type reflectors is that discontinuity and steps are permitted at all boundary surfaces of the partition. This results in freely shaped reflector surfaces with maximum homogeneity and side illumination (Figures 8 and 9).

Figure 7: Low beam (beam-path vertical section, H4 lamp)
1 Low-beam filament, 2 Bulb cover.



PES headlamps
The PES headlamp system (poly-ellipsoid system) employs imaging optics (Figure 10) and offers greater design scope than conventional headlamps. A lens aperture area with a diameter of only 40 to 70 mm allows the generation of light patterns previously only achievable with large-area headlamps. This result is obtained using an elliptical (CAL designed) reflector in combination with optical projection technology. A screen reflected with the objective projects precisely defined light-dark boundaries. Depending on specific individual requirements, these transitions can be defined as sudden or gradual intensity shifts, making it possible to obtain any geometry required.

PES headlamps can be combined with conventional high beams, position lamps and PES fog lamps to form lighting-strip units in which the entire headlamp is no higher than approximately 80 mm.

In PES headlamps, the beam path can be configured in such a way that the surroundings of the objective are also used in the signal image. This enlargement of the signal image is used above all with small objective diameters to reduce the psychological glare for the oncoming traffic. The additional surface can also be made into a lens, a partially vapor-deposited screen or a design feature with illuminated round or rectangular gaps, or illuminated three-dimensional objects.

Xenon headlamps
Functioning principle
The headlamp system with a xenon gas-discharge lamp as its central component (Figure 11) generates high illumination-intensity levels with minimal frontal-area requirements, making it ideal for vehicles with aerodynamic styling with exceptional c_w values. In contrast with the conventional filament bulb, light is generated by a plasma discharge inside a burner the size of a cherry stone (Figure 12).

4 Lamp.

Performance
The arc of the 35W xenon bulb D2S delivers, when compared with the H7 bulb, twice the luminous flux with a higher color temperature (4200 K), i.e., the color of the light is very similar to natural sunlight. A D5S bulb with a power rating of only 25 W still delivers three times the luminous flux of an H7 bulb with the same high color temperature as a 35W xenon bulb. Maximum luminous efficiency, corresponding to approx. 90 lm/W, is available as soon as the quartz element reaches its operating temperature of more than 900 °C. Brief high-power operation at currents of up to 2.6 A (continuous operation: approx. 0.4 A) can be used to obtain "instant light". 2000 hours of service life are sufficient for the average required total duration of operation in passenger cars. As no sudden failure occurs as in the case of a filament, diagnosis and replacement in good time are possible.

Categories
At present gas-discharge lamps with the type designations D1 and D2 and since 2012 only the type designations D3 and D4 are used in the power-rating range of 35 W. In the D3 and D4 families dosing of the heavy metal mercury (approximately 1 mg) can be dispensed with. These lamps are distinguished by lower lamp voltage, a different plasma composition, and different arc geometries. The same applies to the new categories of 25W gas-discharge lamps D5, D6 and D8. The electronic control units for the individual lamp types are generally developed for a specific design type and are not universally interchangeable.

The D2 and D4-series automotive gas-discharge lamps feature high-voltage-proof bases and UV glass shielding elements. On the D1 and D3-series models, the high-voltage electronics necessary for operation are also integrated in the lamp

Figure 12: Gas-discharge lamp D5S

base. Category D5 lamps are a special case – these lamps have the advantage that both the ignition unit and the control unit are already integrated in the base of the gas-discharge lamp.

All systems feature two subcategories: S-lamps for projection-system headlamps and R-lamps for reflection headlamps with an integrated light shield for producing the light/dark boundary comparable with the bulb cover used for halogen H4 low beams. At present the D1S and D3S lamps are the type most widely used.

Electronic ballast unit

An integral part of the Litronic headlamp (contraction of Light and Electronics) is the electronic ballast unit responsible for activating and monitoring the lamp (Figure 13). Its functions include ignition of the gas discharge (voltage 10 to 20 kV), controlled power supply during the warm-up phase when the lamp is cold, and demand-oriented supply during stationary operation.

The system furnishes largely consistent levels of illumination (i.e., elimination of luminous-flux changes) by compensating for fluctuations in the vehicle system voltage. If the lamp goes out (for instance, due to a momentary voltage drop in the vehicle electrical system), re-ignition is spontaneous and automatic.

The electronic ballast unit responds to defects (such as a damaged lamp) by interrupting the power supply to help avoid injury in the event of contact.

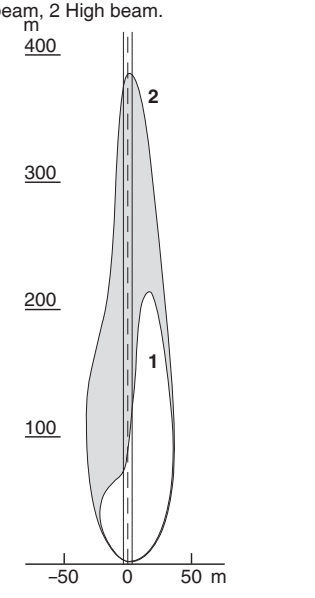
1 ECU, 1a DC/DC converter, 1b Shunt, 1c DC/AC converter, 1d Microprocessor, 2 Ignition unit, 3 Lamp socket, 4 D2S lamp, U_B Battery voltage.

Light distribution
The xenon light emitted by Litronic headlamps produces a broad carpet of light in front of the vehicle combined with a long range (Figure 14). This has made it possible to achieve substantially wider road-illumination patterns for lighting the edges of bends and wide roads as effectively as a halogen unit illuminates straight stretches of road. The driver enjoys substantial improvements in both visibility and orientation in difficult driving conditions and bad weather.

Headlamp leveling control
In accordance with ECE Regulation 48 [12], Litronic headlamps with 35W gas-discharge lamps are combined with automatic headlamp leveling control and headlamp cleaning systems. These requirements do not apply to headlamps with 25W lamps on account of the lower luminous flux of the lamps, i.e., such headlamps may also – like halogen headlamps – be operated with manual headlamp leveling control. This makes it easier to switch from halogen to 25W gas-discharge headlamps in the aftermarket sector.

Figure 15: Bi-Litronic "Projection"
1 Low beam, 2 High beam.



Bi-Litronic
Bi-Litronic systems permit both the low and high beams to be generated by the arc of a single gas-discharge lamp.

Bi-Litronic "Projection" (bi-xenon)
The Bi-Litronic "Projection" system is based on a PES Litronic headlamp (Figure 15). For the high beam the light shield for creating the light/dark boundary (for the low beam) is moved out of the light beam. With lens diameters of 70 mm, Bi-Litronic "Projection" allows the present highly compact headlamp design with combined high and low beam and at the same time outstanding luminous efficiency (Figure 16).

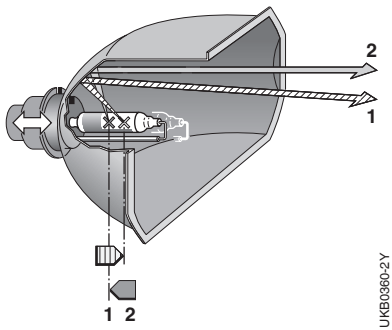
The primary advantage of Bi-Litronic "Projection" is the xenon light for high-beam operation.

Bi-Litronic "Reflection"
Both mono- and bi-xenon systems use a single DxR lamp for both headlamp functions.

Figure 16: Light distribution patterns of Bi-Litronic
1 Low beam, 2 High beam.

In the bi-xenon version, when the high-/low-beam switch is operated, an electromechanical actuator moves the gas-discharge lamp in the reflector into the appropriate position for producing the high or low beam as required (Figure 17).

LED headlamps



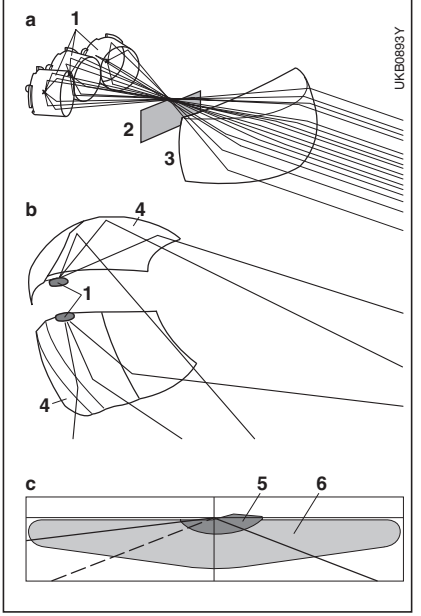
Potential for reducing energy consumption

LEDs are increasingly being used as economical alternatives in reducing CO_2 emissions and fuel consumption. The energy consumption of the main-light functions will play a significant role in future low-energy vehicles. Xenon and LED alternatives offer the levels of optimized consumption and improved road safety called for by the EU.

Today's LED systems already consume, depending on performance (luminous flux, range, side illumination), much less energy than halogen bulbs. Power consumption currently fluctuates between 28 W and 50 W per headlamp. When compared with bulb power output of approx. 65 W (for 13.2 V), this means potential savings of 30 to 70 W per vehicle.

One projection system and two reflection elements are used for the low-beam spot. The light of three multichip LEDs each with two LEDs is concentrated by three primary optical elements and imaged by a projection lens. The optical system incorporates a screen to guarantee the quality of the light-dark boundary. A reflector is positioned both above and below the lens (Figure 18).

Figure 17: Bi-Litronic "Reflection"
1 Low beam, 2 High beam.



The optical efficiency of the LED low-beam headlamp is roughly 45 %. Compared with this, the efficiency of a bi-xenon system is around 33 %. This can be explained by the nature of LEDs, which give off their light only to the half-space and do not, like conventional light sources, illuminate the entire space. Because of the higher efficiency of an LED system, less luminous flux is needed in the LEDs to deliver the same luminous flux to the road with one LED low-beam headlamp.

The better LEDs will become in future, the less power will be output by the control unit, the light performance always being kept at a constantly high level.

The first LED headlamps on the market also show the increasing role of design

Figure 18: Basic design of an LED low-beam headlamp
Interaction of projection and reflection systems.

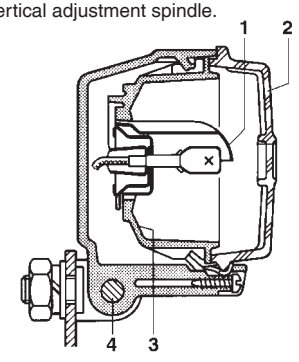
6 Basic light.

elements in headlamps. In 2008, for example, a headlamp received an internationally renowned design award for the first time.

Around 75 % of total worldwide mileage is completed during daytime hours. Great importance is therefore also attached to the energy consumption of the daytime driving lights function. A typical LED daytime driving light has an energy consumption of 14 W (0.36 g CO_2/km) per vehicle. Use of vehicle lights during the day consumes up to 300 W (7.86 g CO_2/km) (low-beam headlamps, tail lamps, position lamps, number-plate lamps, switch and instrument lighting).

Laser light
Functions in the headlamp whose light source is based on a blue laser diode (see Laser LED) are called laser light. Similarly to white LEDs the blue laser radiation is converted with a phosphor conversion into a white wavelength spectrum and diffused. The advantage of the laser-light source including converter is the five to seven times higher luminance compared with the LEDs currently used. The higher luminance is used to generate light distributions with high luminous intensities with smaller reflectors. This can be used for example to produce an auxiliary high beam which roughly doubles the range on the road. The higher luminous intensities on the road lead to improved, earlier detection of objects at great distances and represent a significant increase in safety.



Additional headlamps

Fog lamps
Fog lamps (white light) are intended to improve orientation in fog, snow, heavy rain, and dust. A beam of light with a particularly high side dispersion is generated for this purpose. This ensures that the side of the road which is close to the vehicle is particularly well illuminated. The brightness levels achieved on close objects are significantly higher. Unlike the usually dark road surface far ahead of the vehicle, these high brightness levels help drivers to find their bearings better despite the poor weather conditions.

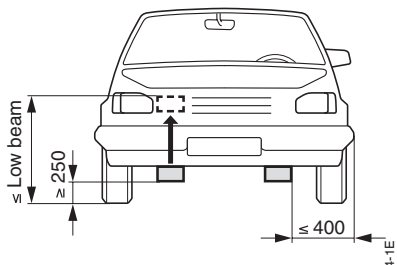
Designs
DIY and dealer-installed fog lamps are designed as individual projection units in their own housings. These are installed either upright on the fender, or suspended from it (Figure 19). Stylistic and aerodynamic considerations have led to increased use of integrated fog lamps, designed either for installation within body openings or included as a component within a larger light assembly (with adjustable reflectors when the fog lamps are combined with the main headlamps).

Present fog lamps produce white light. There is no substantive evidence that yellow lamps provide any physiological benefits. A fog lamp's effectiveness depends on the size of the illuminated area and the focal length of the reflector. Assuming the

Figure 19: Fog lamp (upright mounting)
1 Bulb cover, 2 Lens, 3 Reflector, 4 Vertical adjustment spindle.

same illuminated area and focal length, the differences between round and rectangular fog lamps from the technical viewpoint are negligible.

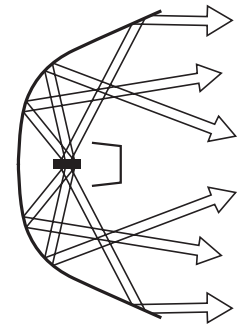
Regulations
Design is governed by ECE R19 [8], installation by ECE R48 [12] (and StVZO (Road Traffic Licensing Regulations) Article 52 [3] in Germany); two white or yellow fog lamps are permitted. The control circuit for switching the fog lamps must be independent of the high- and low-beam circuits. In Germany, the StVZO allows fog-lamp installation in positions more than 400 mm from the widest point of the vehicle's width, provided they are wired so that they can only be switched on when the low-beam headlamps are on (Figure 20).



Paraboloid with diffusing lenses
A parabolic reflector featuring a light source located at the focal point reflects light along a parallel axis (as with the high-beam headlamp), and the lens extends this beam to form a horizontal band (Figure 19). A special bulb cover prevents the beam from being projected upward.

Free-form technology
Calculation methods, such as CAL (computer-aided lighting), can be used to design reflector shapes in such a way that they scatter light directly (i.e., without optical lens contouring) and also generate (without separate shading) a sharp light-dark boundary. The fact that the lamp features pronounced envelopment of the bulb leads to an extremely high volume of light combined with maximum dispersion width (Figure 21).

PES fog lamps
This technology minimizes reflected glare in fog. The screen, the image of which is projected onto the road surface by the lens, provides a light-dark boundary with minimum upward light dispersion.



Innovations
The technical-functional importance of the fog lamp has been pushed into the background slightly by the introduction of powerful halogen, xenon and AFS systems. The emphasis is still on the demand for improved lighting in traffic situations with adverse ambient conditions. This can be solved by separate fog lamps of the type used up to now (as per ECE R19 [8]), by the poor-weather light function of AFS systems (as per ECE R123 [23]), or by combinations of the two functions.

Figure 20: Fog lamp (positioning)

Dimensions in mm

Figure 21: Fog lamp with free-form reflector (horizontal section)

Light functions

Cornering headlamps
Cornering headlamps have been approved for public use since the beginning of 2003. Whereas previously only high-beam headlamps were allowed to turn in response to changes in steering angle (1960s Citroën DS), swiveling low-beam headlamps are now also permitted (dynamic cornering headlamps or adaptive headlamps) or a supplementary light source (static cornering headlamps). This provides for a larger visual range on winding roads.

Static cornering headlamps
Static cornering headlamps are used mainly to illuminate areas close to the side of the vehicle (switchbacks, turning maneuvers). For this purpose, activating additional reflector elements is generally the most effective way.

Dynamic cornering headlamps
Dynamic cornering headlamps are used to illuminate the changing course of the road, e.g., on winding overland highways (Figure 22).

In contrast with the directly linked swiveling action of the cornering headlamps of the 1960s, modern "high-end systems" electronically control the rate of swivel and the swivel angle in response to the vehicle's speed. This optimizes "harmonization" between the headlamps and the vehicle attitude, and eliminates "jerky" headlamp movements. Headlamp positioning is performed by a positioner unit (stepping motor) which moves the basic or low-beam module or the reflector elements in response to changes in steering-wheel angle or the steering angle of the front wheels (Figure 23). Sensors detect those movements to prevent glare for oncoming traffic by means of "failsafe"

Figure 23: Cornering-headlamp modules

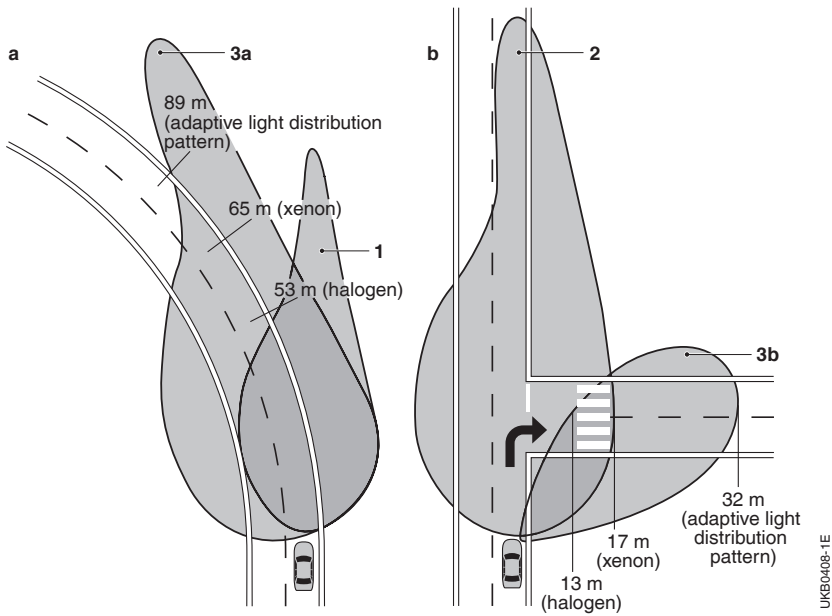
1 Turning module, 2 Basic module.



algorithms. General legal requirements specify that the headlamp beam may only be turned as far as the center line of the road at a distance of approx. 70 m in front of the vehicle to prevent glare for oncoming vehicles.

Road safety and driving convenience
The introduction of dynamic cornering headlamps is a significant improvement in the safety and convenience of driving at night (Figure 24). Compared with conventional low-beam headlamps, improvements in visual range of approximately 70 % are achieved, representing an extra 1.6 seconds of travel time. With cornering headlamps, a motorist can assess hazards better and start braking sooner. As a result, the severity of an accident can be significantly reduced. Static cornering headlamps double the visual range for turning maneuvers.

AFS functions
Expressway beam
For special driving situations, altered light patterns (AFS, adaptive front-lighting system) have been developed to enable a better view for the driver for each driving state. In the development of the expressway beam (Figure 25), special attention was paid to achieving a better range for the driver without dazzling oncoming traffic to an excessive degree. The increase in the detection distance to up to 150 m enables an extension of driving time up to the detected object of approx. 2 seconds (comparison at 100 km/h with halogen headlamps). This enables the driver to better assess a critical situation and, possibly, to initiate braking much earlier.

Poor-weather light
In the case of the poor-weather light beam, the special focus is on improving

Figure 24: Measurable improvement of visibility for driver with adaptive light distribution pattern of cornering headlamps
a) Left-hand bend, dynamic cornering headlamps, b) Right turn, static cornering headlamps.

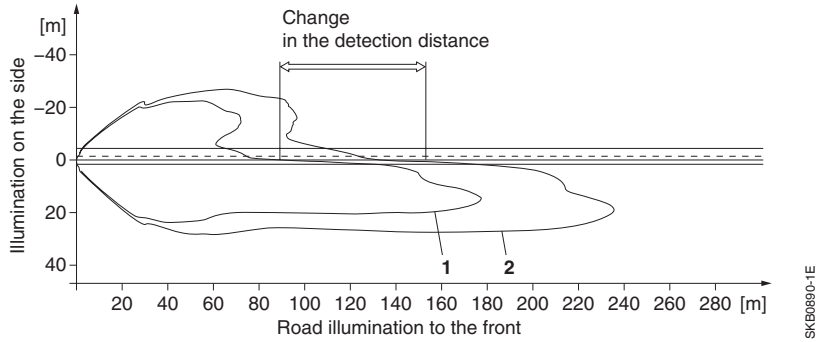
3b Adaptive light distribution pattern with static cornering headlamps.

the optical guidance on the road. Especially the zones around the sides of the road are better illuminated.

Most variants of the poor-weather light feature movement of the left cornering-headlamp module by 8° to the side and simultaneously a slight lowering or activation of the static cornering lights. This provides for very wide illumination of the road and the edge of the road. In future, component elements, for example the elements responsible for widened side illumination, will be activated sequentially. Control parameters are, for example, steering-angle information and direction-indicator actuation. The individual segments are then "quasidynamically" activated.

Light functions and driver-assistance systems

The introduction of video technology in automotive engineering makes it possible to implement camera-based headlamp functions as well. When the position of an oncoming vehicle is identified by the camera, the headlamp or the AFS system can adapt the range of the driving lights in such a way that it is increased for large distances and reduced for smaller distances (dynamic range function). This ensures optimum illumination without dazzling oncoming traffic.



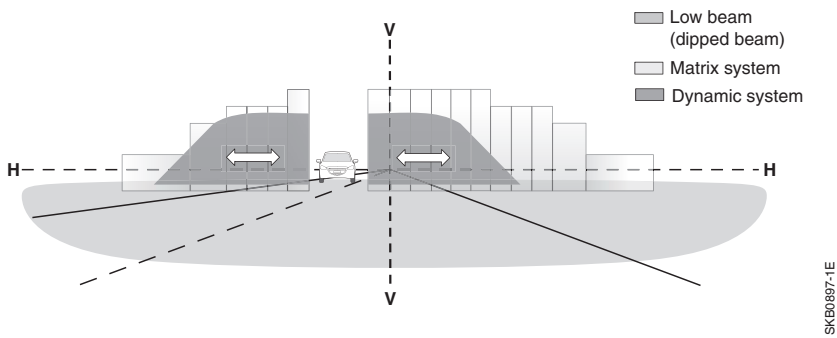
Glare-free high beam

"Glare-free high beam" is a light function which is classed as part of the high beam but in contrast to the conventional high beam can also be activated in traffic situations with preceding or oncoming traffic. This function is referred to in the international context and in the statutory provisions as Adaptive Driving Beam (ADB). Activation requires a camera and image analysis which determines the positions of the other road users quickly and precisely. Shadows in the high-beam distribution are specifically controlled with this information (Figure 26, see also High-beam assistant).

Dynamic system

This type is based on the dynamic cornering headlamps (see Figure 23). Here the left headlamp generates a partial high-beam distribution with a vertical light/dark boundary to the right side and the right headlamp generates a right partial high-beam distribution (Figure 26). In the "normal" high beam both the partial high-beam distributions are superimposed in the middle to achieve high luminous intensities in the central range. To prevent other road users from being dazzled, a shadow is generated in the corresponding position and width with the dynamic movement of both sides.

Figure 25: Metrological-functional connection between expressway beam and highway beam
1 Road illumination with highway beam, 2 Road illumination with expressway beam.



Matrix system
In realizing the glare-free high beam as a matrix system the light distribution is made up typically of 12 to 18 strips. Individual LEDs or LED arrays with individually switchable chips are used as light sources and the specific attributes such as compact shape, rapid switch-on and switch-off, and dimmability are used. Each strip is formed by an LED chip. The shadow adapted to the traffic situation is formed by the specific switching-off of individual LEDs or groups of LEDs. For "normal" high-beam distribution all the LEDs are operated and a balanced light distribution is created by means of a dimming profile.

Matrix headlamps
Three-row modules with 84 pixels are available in some vehicles as a further development of the one-row matrix systems for glare-free high beam. The shadows for fading out other road users can be positioned even more precisely with the finer pixel resolution (Figure 27). Further shadows can additionally be created for example to fade out road signs.

Matrix in the low beam
The essential difference from the one-row systems is that with this type part of the low beam is also formed with the matrix module. This enables even the dynamic cornering headlamps – without mechanical actuators – to be implemented by purely electronic means via activation of the LEDs. In addition, the specific dimmability of areas of the light distribution can be used in adverse weather light to reduce the dazzling of oncoming traffic via the reflection on the wet road.

Figure 26: Glare-free high beam (1st generation)

Installation and regulations for signal lamps

These types of lamp are intended to facilitate recognition of the vehicle, and to alert other road users to any intended or present changes in direction or motion. Uniform, distinctive colors in the red, yellow or white color range are prescribed for these lamps to denote their application. White, yellow and red lights are used to mark the positions of the vehicle at the front, the sides and the rear respectively. Stop lamps and rear fog warning lamps are also red. Yellow lights are used in most applications for turn-signal lamps. Only in the USA are red turn-signal lamps also permissible at the rear.

As projected along the reference axis, minimum and maximum luminous intensities for all lamps must remain within a range calculated to guarantee signal recognition without, however, causing glare nuisance for other road users.

Turn-signal lamps and hazard-warning flashers
(as per ECE R6 [6]).
ECE R48 and 76/756/EEC specify Group 1 (front), Group 2 (rear), and Group 5 (side) turn-signal lamps for vehicles with three or more wheels. For motorcycles, Group 2 turn-signal lamps are sufficient.

The lamps are electrically monitored. A function indicator is required inside the vehicle. The dashboard-mounted monitoring lamp may be in any color desired.

The flashing frequency is 90 ± 30 cycles per minute with a relative illumination period of 30 to 80 %. Light must be emitted within 1.5 s of lamp switch-on. All the turn-signal lamps on one side of the vehicle must flash synchronously. If one lamp fails, the remaining lamps must continue to generate visible light.

All the turn-signal lamps flash synchronously in hazard-warning mode, also operational when the vehicle is stopped. An operation indicator is mandatory.

Two lamps each (color: yellow) are prescribed for the front, the rear and the side turn-signal lamps. In the USA the color red or yellow is permitted for the rear and side turn-signal lamps (SAE J588, Nov. 1984, [33]).

Design regulations
The design requirements for Europe are set out in the ECE Regulations R6, R7, R23, R38 and R87 [6, 7, 9, 11, 16], and the installation requirements in ECE R48 [12] (Figures 28, 29 and 30).

In the USA, FMVSS 108 specifies the number, location, and color of signal lamps. The design and technical lighting requirements are defined in the relevant SAE standards.

Figure 27: Matrix headlamps (2nd generation)

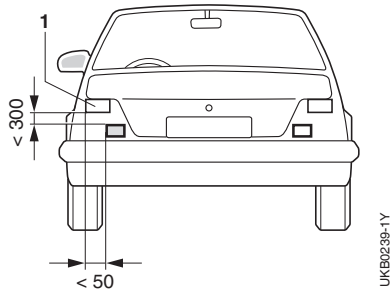

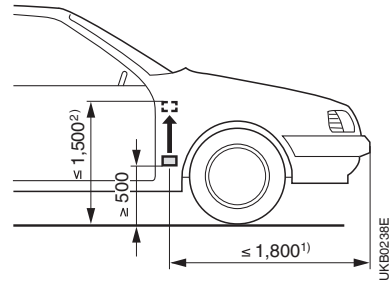

Figure 30: Positioning of side turn-signal lamps as per ECE
Dimensions in mm.
If the type of vehicle body does not permit adherence to the maximum dimensions:
[1]) or 2500 mm.
[2]) or 2300 mm.

Hazard-warning and turn-signal flashers for vehicles without trailer
The electronic hazard-warning and turn-signal flashers include a pulse generator designed to switch on the lamps via a relay and a current-controlled monitoring circuit to modify the flashing frequency in response to bulb failure. The turn-signal control stalk controls the turn signals, whereas the hazard flashers are operated using a separate switch.

Hazard-warning and turn-signal flashers for vehicles with trailer
This type of hazard-warning and turn-signal flasher differs from those employed on vehicles without trailers in the way that the function of the turn-signal lamps is controlled when they flash to indicate a change in direction.

Single-circuit monitoring
The tractor and trailer share a single monitoring circuit designed to activate the two indicator lamps at the flashing frequency. This type of unit cannot be used to localize lamp malfunctions. The flashing frequency remains constant.

Dual-circuit monitoring
Tractor and trailer are equipped with separate monitoring circuits. The malfunction is localized by means of the indicator lamp. The flashing frequency remains constant.

Tail and position lamps
(as per ECE R7 [7]).
According to ECE R48 and 76/756/EEC, vehicle and trailer combinations wider than 1,600 mm require position lamps (facing forwards). Tail lamps (at rear) are mandatory equipment on vehicles of all widths. Vehicles wider than 2,100 mm (e.g., trucks) must also be equipped with clearance lamps visible from the front and rear.

Position lamps
Two white-light position lamps are stipulated. The regulations set out in SAE J222, Dec. 1970, [29] apply in the USA.

Tail lamps
Two red tail lamps are stipulated. When the tail and stop lamps are combined in

a nested design, the luminous-intensity ratio for the individual functions must be at least 1:5. Tail lamps must operate together with the position lamps.

The regulations set out in SAE J585, Feb. 2008, [30] apply in the USA.

Clearance lamps
(as per ECE R7 [7]).
Vehicles wider than 2,100 mm require two white lamps facing forward, and two red lamps facing to the rear. They must be positioned as far outward and as high as possible.

The regulations set out in SAE J592e, [34] apply in the USA.

Side-marker lamps
(as per ECE R91 [17]).
According to ECE R48, vehicles of any length exceeding 6 m must have yellow side-marker lamps (SML) except on vehicles with cab and chassis only.

Type SM1 side-marker lamps may be used on vehicles of all categories; type SM2 side-marker lamps, on the other hand, may only be used on cars.

The regulations set out in SAE J592e] apply in the USA.

Rear reflectors
(as per ECE R3 [4]).
According to ECE R48, two red, non-triangular, rear reflectors are required on motor vehicles (one on motorcycles and motorbicycles).

Additional reflective items (red reflective tape) are permitted if they do not impair the function of the legally required lighting and signaling equipment.

Two colorless, non-triangular front reflectors are required on trailers and on vehicles on which all forward-facing lamps with reflectors are concealed (e.g., retractable headlamps). They are permitted on all other types of vehicle.

Yellow, non-triangular, side reflectors are required on all vehicles with a length exceeding 6 m, and on all trailers. These are permitted on vehicles shorter than 6 m.

Two red triangular rear reflectors are required on trailers, but are banned on motor vehicles.

There may be no light fitted inside the triangle.

The regulations set out in SAE J594, Feb. 2010, [36] apply in the USA.

Parking lamps
(as per ECE R77 [15]).
ECE R48 permits either two parking lamps at the front and rear, or one parking lamp on each side. The prescribed colors are white facing forwards and red facing rearwards. Yellow may also be used at the rear if the parking lamps have been designed as single units together with the side turn-signal lamps.

The parking lamps must be designed to operate even when no other vehicle lights (headlamps) are on. The parking-lamp function is usually assumed by the tail and position lamps.

The regulations set out in SAE J222, Dec. 1970, [29] apply in the USA.

License-plate lamps
(as per ECE R4 [5]).
According to ECE R48, the rear license plate must be illuminated so as to be legible at a distance of 25 m at night.

Across the complete license-plate, luminance must be at least 2.5 cd/m^2. The luminance gradient of $2 \times B_{min}$/cm should not be exceeded between any of the test points distributed across the surface of the license plate. B_{min} is defined as the smallest luminance measured at the test point.

The regulations set out in SAE J587, Oct. 1981, [32] apply in the USA.

As an alternative to the license-plate lamp, self-illuminating license plates will also be permitted in future.

Stop lamps
(as per ECE R7 [7]).
According to ECE R48, all cars must be fitted with two type S1 or S2 stop lamps, and one type S3 stop lamp, colored red in each case (Figure 31).

When a nested design with stop and tail lamps is used, the luminous-intensity ratio between individual functions must be at least 5 : 1.

The Category S3 stop lamp (central high-level stop lamp) must not be a combined unit incorporating any other lamp.

The regulations set out in SAE J586, Feb. 1984, [31] and SAE J186, Nov. 1982, [28] apply in the USA.

Rear fog warning lamps
(as per ECE R38 [11]).
For EU/ECE countries, ECE R48 prescribes one or two red rear fog warning lamps for all new vehicles. They must be distanced at least 100 mm from the stop lamp (Figure 32).

The visible illuminated area along the reference axis may not exceed 140 cm². The circuit must be designed to ensure that the rear fog warning lamp operates only in conjunction with the low beam, high beam and/or front fog lamp. It must also be possible to switch off the fog warning lamps independently of the front fog lamps.

Rear fog warning lamps may only be used if the visual range due to fog < 50 m, as rear fog warning lamps have a high luminous intensity that can severely dazzle drivers at the rear when there is a clear view. The required indicator lamp is yellow in color.

Reversing (backup) lamps
(as per ECE R23 [9]).
According to ECE R48, one or two white reversing lamps are permitted (Figure 33). The switching circuit must be designed to ensure that the reversing lamps operate only when reverse gear is engaged and the ignition on.

The regulations set out in SAE J593c, Feb. 1968, [35] apply in the USA.

Daytime running lamps and daytime driving lights
In the vehicle type approval the fitting and use of daytime running lamps has according to ECE R87 ([16], Figure 34) been mandatory in Europe since February 2011 for passenger cars and light commercial vehicles; since August 2012 this has also applied to all other vehicle categories.

Daytime running lamps must be automatically switched on on the vehicle when

Figure 31: Positioning of stop lamps as per ECE
Dimensions in mm.

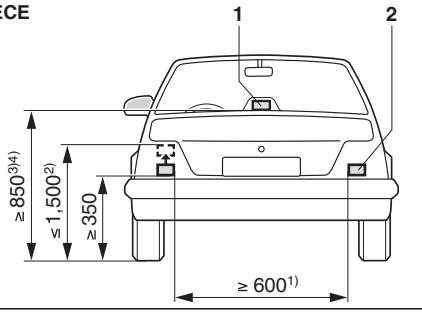
2 Two stop lamps (categories S1 and S2).
[1]) ≥ 400 mm if width < 1300 mm,
[2]) ≤ 2100 mm if compliance with max. height not possible, or
[3]) ≤ 150 mm below bottom edge of rear window,
[4]) However, the lower edge of the central high-level stop lamp must be higher than the upper edge of the main stop lamps.



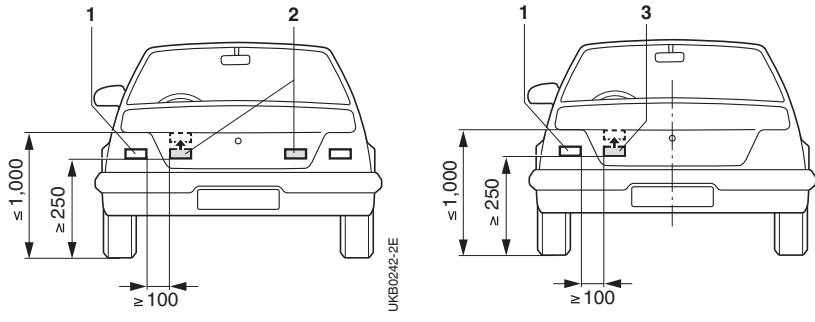


Figure 32: Positioning of rear fog warning lamps as per ECE
Dimensions in mm.
1 Stop lamp, 2 Two rear fog warning lamps, 3 One rear fog warning lamp for driving on right.

the engine is started and remain lit until either the front headlamps or fog lamps are switched on or the engine is turned off.

The regulations set out in FMVSS108 [27] apply in the USA.

Front cornering lamps
(as per ECE R119 [22]).
Two cornering lamps are permitted on the front of the vehicle which must radiate light at least 60° to the outside of the vehicle. They are used in cornering maneuvers up to a maximum speed of 40 km/h to illuminate better the destination road (e.g., side roads or garage entrances) which is usually inadequately lit by the regular headlamps. The front cornering lamps are activated via the turn-signal control stalk or when the steering wheel is turned.

Front cornering lamps typically have the same light distribution as static cornering headlamps. The switching conditions, however, are different. For the most part the same reflector is used for both the static cornering headlamps and the front cornering lamps.

The regulations set out in SAE J852, Apr. 2001, [37] apply in the USA.

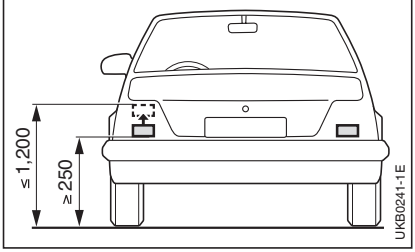
Identification lamps
According to ECE R65 [14], identification lamps must be visible from any direction, and create the impression of flashing. The flashing frequency is 2 to 5 Hz. Blue identification lamps are intended for installation on official vehicles. Yellow identification lamps are designed to warn of dangers or the transport of dangerous freight.

Technical design variations for lamps

Light color
Depending on their application (e.g., stop lamps, turn-signal lamps, or rear fog warning lamps), motor-vehicle lamps must display uniform, distinctive colors in the red or yellow color range. These colors are defined in specific ranges of a standardized color scale (color location).

Since white light is composed of various colors, filters can be used to weaken or filter out the emission of undesirable spectral ranges (colors) completely. The color-filter functions may be performed by either the tinted lenses of the lamp, or the colored glass bulb of the lamp (e.g., yellow bulb in turn-signal lamps with clear lens).

Figure 33: Positioning of reversing lamps as per ECE
Dimensions in mm.
Quantity: 1 or 2.



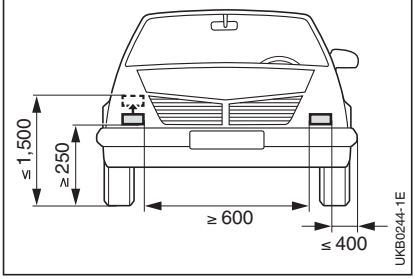


Figure 34: Positioning of daytime running lamps as per ECE
Dimensions in mm.

Filter technology can also be used to design lamp lenses in such a way that, when the lamp is switched off, the color is matched to the vehicle's paintwork. Nevertheless, existing homologation regulations are complied with when the lamp is on. Color locations have been laid down in the EU/ECE region. They correspond to a wavelength of approximately 592 nm for "yellow/orange" turn-signal lamps, for example, and to a wavelength of approximately 625 nm for "red" brake and tail lamps.

Luminous intensities

As projected along different axes, minimum and maximum luminous intensities for all lamps must remain within a range calculated to guarantee signal recognition without, however, causing glare nuisance for other road users. The same percentile basis ("unified spatial light distribution pattern") is used for most lamps. With regard to the value along the reference axis, luminous-intensity levels to the sides and above and below may be lower (Figure 35). However, these values may, depending on the installation height or for special lamps (e.g., daytime running lamps), differ from this basis.

Lamps with Fresnel optics

The light from the bulb is projected directly (without diversion) on the lens, which uses Fresnel optics to shape the beam in the desired manner (Figure 36). This concept is a highly cost-effective solution in that no vapor-deposited surface is needed. The drawbacks are low efficiency and the limited vehicle-design options.

Lamps with reflector optics

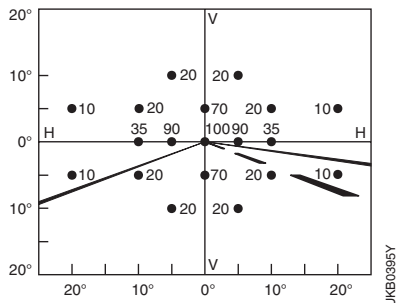
Lamps with approximately parabolic reflectors or stepped reflectors direct the light from the bulb in an axial beam, and shape the beam by means of the optical dispersion elements in the lens (Figure 37).

Lamps with free-form reflectors achieve the required beam spread or light pattern, completely or partially, by directing the light by means of a reflector. The outer lens can thus be designed as a clear lens, or supplemented by cylindrical lenses in the horizontal or vertical direction.

Designs combining both the above principles have also been successfully employed. The principle of the free-form lamp with Fresnel cap combines excellent luminous efficiency with a variety of possible stylistic implementations (Figure 38). It is essentially the reflector that shapes the light pattern. The Fresnel cap improves luminous efficiency by diverting a proportion of the light, which would not otherwise contribute to the function of the lamp, in the desired direction.

Mainly lamps with free-form reflectors are used in modern vehicle designs. These lamps offer the best opportunities of adaptation to the body shape and therefore to the available structural space,

Figure 35: ECE "lamp" test screen
Schematic diagram of spatial light distribution pattern (values in %).



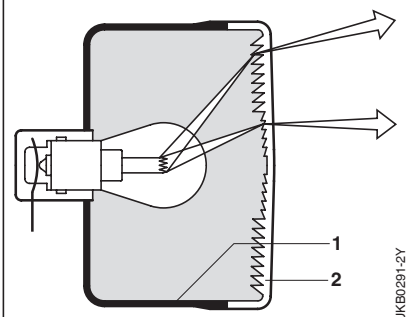


Figure 36: Lamp with Fresnel optics (principle)
1 Housing,
2 Lens with Fresnel optics.

and at the same time of meeting stylistic requirements.

Lamps with light-emitting diodes

Light-emitting diodes (LEDs) are increasingly used as the light source for lamps. LEDs have been used for years as standard in auxiliary stop lamps. The crucial factor here is the design freedom to deliver a slimline design with a number of light sources (Figures 39 and 40). In addition, LEDs in stop lamps provide an added safety aspect. An LED reaches maximum light output in less than 1 ms, whereas filament bulbs require about 200 ms to reach their nominal luminous flux. This means that LEDs emit the brake signal sooner, and this in turn reduces reaction time.

With their improved efficiency with regard to luminous flux, luminance, thermal performance and mechanical design, LEDs can also be used for functions with higher lighting requirements.

When it comes to being used as light sources in vehicle lights, LEDs differ crucially from filament and halogen lamps in that they cannot be operated directly from

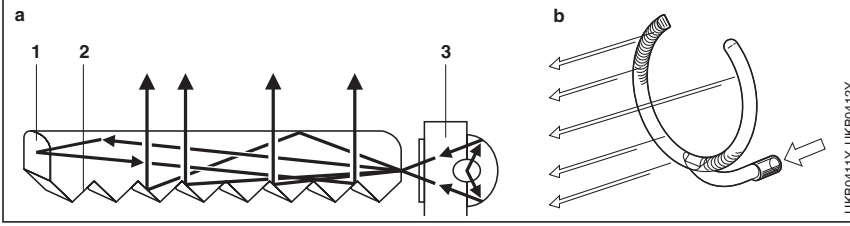
the vehicle electrical system. They require both a defined voltage, which ranges depending on the semiconductor material between 2.2 V and 3.6 V, and a defined current, by means of which the luminous intensity is adjusted. Resistor solutions can be used for activating functions with very low photometric requirements. Most applications require linear controllers or DC/DC converters. The electronics can be either integrated as individual electronics in the lamp or in a self-contained ECU, which is either mounted to the lamp or in the vehicle.

Lamps with fiber-optic technology



By using optical fibers/waveguides, the light source can be separated from the light emission point. In order to obtain the desired light pattern, special beam launchers in the optical waveguides, or optically active elements on or in front of the optical waveguide are required. Filament lamps can be used as light sources, but the high infrared levels are a drawback of these lamps. This necessitates the use of heat-resistant materials such as glass or heat shields. When using LEDs as "cold" light sources, it is possible to launch directly into transparent plastics such as PC (polycarbonate) or PMMA (polymethyl methacrylate). Lamps with fiber-optic technology are used primarily to produce stylistic elements such as narrow strips or thin rings (Figure 41).

Adaptive rear-lighting systems

Until now, rear-lighting functions were produced with a one-level circuit. Depending on the version and design, this resulted in a fixed luminous intensity that had to lie within the legal limit values to guarantee minimum visibility.

A large number of sensors (brightness, dirt, visual range, wetness, etc.) mean that the vehicle is nowadays able to ascertain the ambient parameters and lighting conditions more exactly. So that the optimal visibility (e.g., sufficient luminous intensity without excessive glare) can be achieved, rear light functions will be able to vary the luminous intensity they emit depending on the ambient conditions detected around the vehicle. For example, a stop lamp can be operated with high luminous intensity during strong sunlight and with lower values at night in order to ensure optimal detection and attribution of the driver's actions (Figure 42).

Figure 41: Lamp using fiber-optic technology (principle)
a) Design and function, b) Example.
1 Optical waveguide, 2 Beam launcher,
3 Lamp (with reflector and heat shield) or LED.

Convenience lamps

Lights for use when the vehicle is stationary are increasingly being fitted. Typical applications are the illumination of areas immediately outside the doors when the doors are open or closed, lights that identify the vehicle outline in the underbody area, or lights which identify the door handles.

Combinations of such lights with position lamps or fog lamps are referred to as "coming home" functions, which are activated when the doors are unlocked, for instance.

Headlamp leveling control

Headlamp adjustment for low and high beams

The correct adjustment of vehicle headlamps is an essential factor in nighttime road safety for both the driver of the vehicle concerned and for oncoming vehicles. If the beam is set only a fraction too low, there will be a substantial reduction in headlamp geometric range (Table 4). If the beam is set only a fraction too high, oncoming traffic will suffer much greater glare.

Installation and regulations

Headlamp leveling, Europe

Since 1/1/1998, an automatic or manual headlamp leveling control (beam-height adjustment) device has been mandatory in Europe for all first-time vehicle registrations, except in cases where other equipment (e.g., hydraulic suspension leveling) guarantees that light-beam inclination will remain within the prescribed tolerances.

Figure 42: Permitted light intensity for adaptive tail lamps

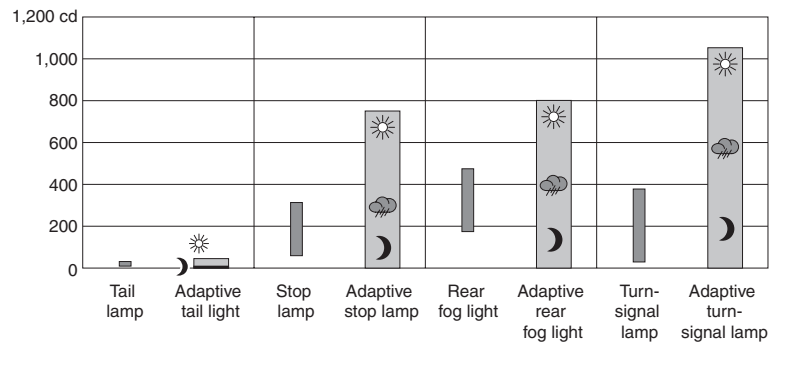


Table 4: Geometric range of the horizontal component of the low beam's light-dark boundary
Headlamp installed at height of 65 cm.

Inclination of the light-dark boundary (1 % = 10 cm / 10 m)	%	1.0	1.5	2.0	2.5	3.0
Adjustment dimension e	cm	10	15	20	25	30
Geometric range for the horizontal portion of the light-dark boundary	m	65.0	43.3	32.5	26.0	21.7

Although this equipment is not mandatory in other countries, its use is permitted.

Automatic headlamp leveling control must be designed to compensate for vehicle laden states by lowering or raising the low beam by between 5 cm/10 m (0.5%) and 25 cm/10 m (2.5%).

A manual headlamp leveling control device is operated from the driver's seat and must incorporate a detent position in the base setting; beam adjustment is also performed at this position. Units with infinitely variable and graduated control must both feature visible markings in the vicinity of the hand switch for vehicle load conditions that require vertical aiming.

Technical design variations
All design variations employ an adjustment mechanism to provide vertical adjustment of the headlamp reflector (housing design) (Figure 43). Manually operated units employ a switch near the driver's seat to control the setting (Figure 44), while automatic units rely on level sensors on the vehicle axles to monitor suspension spring compression, and relay the proportional signals to the adjustment mechanisms.

Hydromechanical systems
Hydromechanical systems operate by transmitting a fluid through the connecting hoses between the hand switch (or level sensor) and the adjustment mechanisms. The degree of adjustment corresponds to the quantity of pumped fluid.

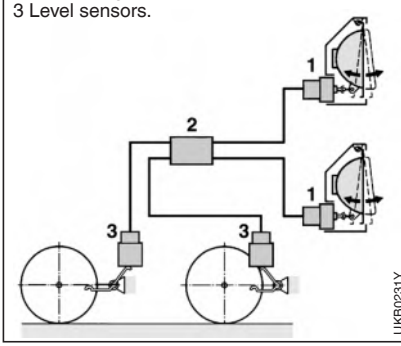
Vacuum systems
With vacuum systems, the hand switch (or level sensor) regulates vacuum from the intake manifold, and transmits it to the adjustment mechanisms to achieve varying degrees of adjustment.

Electrical systems
Electric systems employ electric gear motors as the adjustment mechanisms. They are switched either by switches in the vehicle or by axle sensors.

Headlamp adjustment

Headlamp adjustment, Europe
Regulations and procedure
Correct adjustment of motor-vehicle headlamps should ensure the best possible illumination of the roadway at the same time as minimizing glare for other traffic. The EU Directives (and therefore the requirements of Article 50 of the StVZO [2] (Road Traffic Licensing Regulations) in Germany) specify the required horizontal and vertical alignment of the headlamp beams. Low-beam glare is regarded as eliminated if the luminous intensity is not more than 1 lux at a distance of 25 m in front of each headlamp when the beam

Figure 43: Automatic headlamp leveling control (principle)
1 Adjustment mechanism,
2 Processing unit,
3 Level sensors.



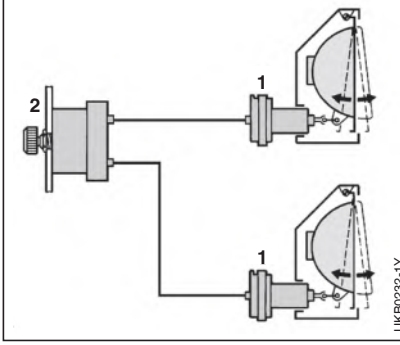


Figure 44: Manual headlamp leveling (principle)
1 Adjustment mechanism,
2 Hand switch.

is projected on a surface vertical to the road surface at the height of the center of the headlamp and above. If, however, the vehicle is subject to extreme variations in attitude due to changes in payload, the headlamps must be adjusted so that the desired aim is achieved.

ECE R48 [12] and EEC 76/756 [24] define the basic setting and the adjustment dimension required on the vehicle. For vehicle categories not covered by these directives, the regulations contained in ECE R48 or ECE R53 [13] shall apply.

Preparations for adjustment
Laden state of vehicle
- Motor vehicles excluding motorcycles: unladen, 75 kg (one person in driver's seat).
- Motorcycles: for EC (as per 93/92/ EEC [25]) unladen, without a person on the driver's seat; for ECE and StVZO (Road Traffic Licensing Regulations) unladen, 75 kg (one person on the driving seat).

Suspension
- Vehicles without self-leveling suspension are rolled for few meters or rocked so that the suspension settles to a level position.
- Vehicles with self-leveling suspension are set and operated to the correct level according to the operating instructions.

Tire pressure
The tire pressure must be adjusted as per the vehicle manufacturer's instructions in accordance with the laden state.

Compulsory function checks on headlamp-leveling control systems
- Systems that operate automatically should be set or operated according to the manufacturer's instructions.
- On vehicles registered before 1/1/1990, a positively locating adjuster position is not required.
- Manually operated systems with two positively locating adjuster positions:
  On vehicles on which the headlamp beam is raised as the vehicle payload is increased, the adjuster must be set to the position at which the beam is at its highest (smallest degree of dip).
  On vehicles on which the headlamp beam is lowered as the vehicle payload is increased, the adjuster must be set to the position at which the beam is at its lowest (smallest degree of dip).

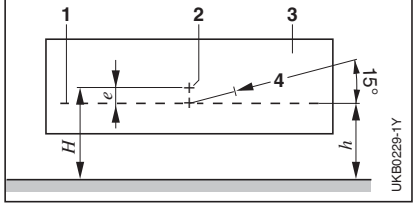
Surface and testing environment
- The vehicle and headlamp tester must be standing on a flat surface (based on ISO 10604 [26]).
- Adjustments and tests should be carried out in an enclosed space where the lighting conditions are not too bright.

Adjusting and testing with a headlamp aiming device
- The headlamp aiming device should be aligned at the specified distance in front of the headlamp under test (except in the case of automatic equipment).
- In the case of headlamp aiming devices which do not run on tracks, vertical alignment relative to the vehicle's longitudinal center axis should be carried out separately for each headlamp. The test should then be carried out without moving the unit sideways again.
- In the case of headlamp aiming devices which run on tracks (or the like), alignment with the vehicle's longitudinal center axis need only be carried out once at the most favorable position (e.g., in a central position in front of the vehicle).
- The specified adjustment dimension for the headlamp concerned should then be set on the headlamp aiming device, and the headlamp adjustment checked and the headlamp adjusted to the correct setting.

Adjusting and testing with a test surface
- The test surface must be vertical to the surface on which the vehicle is standing and at right angles to the vehicle's longitudinal center axis.
- The test surface should be finished in a light color, adjustable vertically and horizontally, and marked with the markings shown in Figure 45.
- The test surface should be positioned at a distance of 10 m in front of the vehicle so that the center mark is aligned with the center of the headlamp under test or adjustment (Figure 46). In the case of lamps with very low beams (e.g.,

fog lamps), a shorter distance can be chosen by calculating the adjustment dimension accordingly.
- Each headlamp must be set individually. Therefore, the other headlamp(s) must be covered over.
- The vertical position of the test surface must be set so that the top cutoff (parallel to the ground) is at the height $h = H - e$. If the surface is not 10 m from the vehicle, the setting e must be converted accordingly.

Figure 45: Test surface for headlamp beam
1 Top cutoff, 2 Center mark, 3 Test surface, 4 Break point.
H Height of headlamp center above standing surface in cm,
h Height of test-surface top cutoff above standing surface in cm,
$e = H - h$ Adjustment dimension.



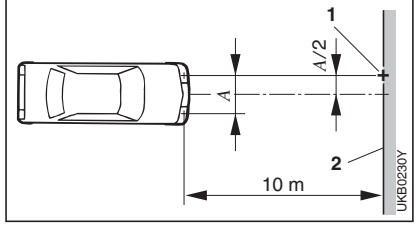


Figure 46: Relative positions of test surface and vehicle longitudinal axis
1 Center mark,
2 Test surface.
A Distance between headlamp centers.

Notes on adjustment
In the case of headlamps with asymmetrical lower beams and fog lamps, the highest position of the light-dark boundary must be on the top cutoff and run as horizontally as possible across the minimum width of the test surface. The lateral adjustment of the headlamps must be such that the light pattern is positioned as symmetrically as possible about the perpendicular line running through the center mark.

In the case of headlamps for asymmetrical lower beam, the light-dark boundary must touch the top cutoff to the left of the center. The intersection between the left section (which should be as horizontal as possible) and the sloping section on the right of the light-dark boundary must be located at the perpendicular line passing through the center mark.

The center of the high beam must be on the center mark.

For headlamps which feature a common adjustment facility for low beam and fog lamps or for high beam, low beam and fog lamps, it is always necessary to use the low-beam headlamp as the basis for adjustment (adjustment dimension e, see Table 5).

Table 5: Headlamp adjustment (excerpt from StVZO (Road Traffic Licensing Regulations))

Vehicle type: Motor veh., > 2 whs. Headlamp position: height above road surface	Adj. dimension "e" Low lamp	Fog beam
Approved to 76/756/EEC or ECE R48 and StVZO, first registered on 1 Jan 1990 or later, < 1200 mm	Adj. dimension on vehicle e.g. ≡D 1.0%	–2.0%
First registered 31 Dec 1989 or earlier, ≤ 1400 mm, and first registered after 31 Dec 1989, > 1200 mm, but ≤ 1400 mm	–1.2%	–2.0%

Headlamp aiming devices
Function
Correct adjustment of motor-vehicle headlamps should ensure the best possible illumination of the roadway by the low beam while minimizing glare for oncoming traffic at the same time. For this purpose, the inclination of the headlamp beams with respect to a level base surface, and their direction to the vertical longitudinal center plane of the vehicle, must satisfy official directives.

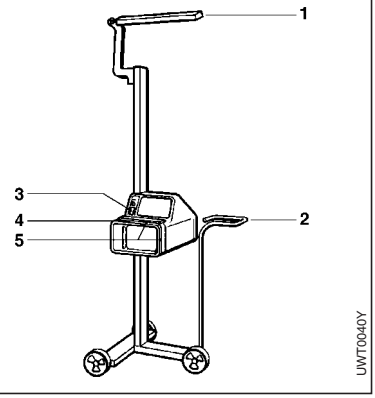
5 Markings for center of lens.



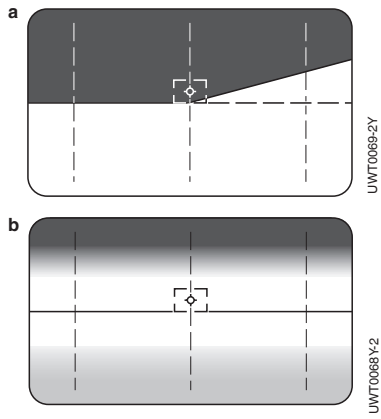


Figure 48: Viewing window in aiming device
a) Top cutoff for light-dark boundary for asymmetrical lower beam,
b) Center mark for middle of upper-beam pattern.

Equipment design
Headlamp aiming devices are portable imaging chambers (Figure 47). They comprise a single lens and an aiming screen located in the focal plane of the lens, and are rigidly connected to it. The aiming screen has markings to facilitate correct headlamp adjustment, and can be viewed by the equipment operator using suitable devices such as windows and adjustable refraction mirrors. The prescribed headlamp adjustment dimension e, i.e., the inclination relative to the centerline of the headlamp in cm at a fixed distance of 10 m, is set by turning a knob to move the aiming screen (Tables 4 and 5).

The aiming device is aligned with the vehicle axis using a sighting device, such as a mirror with an orientation line. It is turned and aligned so that the orientation line uniformly touches two external vehicle-reference marks. The imaging chamber can be moved vertically and clamped at the level of the vehicle headlamp.

Headlamp testing
The headlamp can be tested after the equipment has been correctly positioned at the front of the lens. An image of the light pattern emitted by the headlamp appears on the aiming screen. Some test devices are also equipped with photodiodes and a display to measure the luminous intensity.

On headlamps with asymmetrical lower-beam patterns, the light-dark boundary should touch the horizontal top cutoff; the intersection between the horizontal and sloping sections must be located on the perpendicular line running through the center mark (Figure 48). After adjusting the lower-beam light-dark boundary in accordance with the regulations, the center of the upper beam (assuming that high and low beam are adjusted together) should be located within the rectangular border about the center mark.

Headlamp adjustment, USA

For headlamps compliant with US Federal legislation, visual (vertical only) adjustment as permitted since 5/1/1997 has become increasingly widespread in the US since mid-1997. There is no horizontal aiming here.

Before then, the use of mechanical aiming devices was the most common method of headlamp adjustment in the USA. The headlamp units were equipped with three pads on the lenses – one for each of the three adjustment planes. A calibrating unit is placed against these pads. Aiming is checked using spirit levels. With the VHAD (Vehicle Headlamp Aiming Device) method permitted since 1993, the headlamps are adjusted relative to a fixed vehicle reference axis. This procedure is carried out using a spirit level firmly attached to the headlamp. As a result, the three lens pads were no longer required.

Automotive glazing

The material properties of glass

Basic components

Window panes for automotive use are made of silica glass. The basic chemical constituents and their proportions are as follows:

- 70 to 72 % silicic acid (SiO_2) as the basic component of glass,
- Approx. 14 % sodium oxide (Na_2O) as flux,
- Approx. 10 % calcium oxide (CaO) as stabilizer.

These substances are mixed in the form of quartz sand, soda ash, and limestone. Other oxides such as magnesium and aluminum oxide are added to the mixture in proportions of up to 5 %. These additives improve the physical and chemical properties of glass.

Manufacturing flat glass

The glass panes are made out of the basic product, flat glass. Flat glass that is cast using the float-glass process is used. This process involves melting the mixture at a temperature of 1,560 °C. The melt then passes through a refining zone at 1,500 to 1,100 °C, and is then floated on a float bath of molten tin. The molten glass is heated from above (smoothing of the surface by fire-finishing). The flat surface of the molten tin creates flat glass with flat parallel surfaces of a very high quality (tin bath underneath, fire-finishing on top). The glass is cooled to 600 °C before it is lifted out of the float bath into the cooling section. After a further period of slow, non-stress cooling, the glass is cut into sheets measuring 6.10 × 3.20 m^2.

Tin is suitable for the float-glass process because it is the only metal that does not produce any vapor pressure at 1,000 °C and is liquid at 600 °C.

Table 1: Material properties and physical data of glass and finished windshields and windows

Property	Dimension	TSG	LSG
Density	kg/m^3	2,500	2,500

[1] Properties of finished laminated safety glass (LSG). In calculating the permissible bending stress, the coupling effect of PVB film is to be disregarded.
[2] Calculated values; these values already contain the necessary safety margins.
[3] Figures for optical properties depend very much on the type of window.

Automotive windshield and window glass

Glass used for automotive glazing is of two types:
– Single-pane toughened safety glass (TSG), which is chiefly used for side-window, rear-window and sunroof glazing.
– Laminated safety glass (LSG), which is used primarily for windshields and rear windows, but also for sunroofs. LSG is also increasingly being fitted in vehicle side and rear windows.

The materials from which TSG and LSG panes are made are the basic glass types:
– Transparent float glass: This glass offers the best possible light transmittance.
– Tinted float glass: This glass has a homogeneous green or gray tint within the material; the tint blocks heat from the sun.
– Coated float glass: The glass is coated on one side with noble-metal and metal oxides; the coating reduces heat and UV radiation entering the vehicle, thus providing thermal insulation.

TSG panes
TSG panes differ from LSG panes as they have greater mechanical and thermal strength, and their breaking and shattering behavior is different. They pass through a toughening process which greatly prestresses the surface of the glass. In case of breakage, these panes shatter into many small blunt-edged pieces (to eliminate the risk of injury).

Post-processing (by grinding or drilling) of TSG panes is not possible. The standard thicknesses are 3, 4 and 5 mm.

LSG panes
An LSG pane is made of a crack-proof, flexible plastic intermediate layer of polyvinyl butyral (PVB) bonded between two sheets of glass. When subjected to impact or shock, the glass splits into web-like crack patterns. The plastic intermediate layer holds the broken pieces of glass together (to eliminate the risk of injury). The laminate retains its integrity and transparency when the glass is shattered.

The standard thicknesses for LSG panes are 4 to 5 mm.

Optical properties
The requirements for the optical quality of automotive glazing are as follows:
– unimpeded vision,
– flawless vision,
– undistorted vision.

Achievement of optimum optical quality has to be balanced against structural requirements and the vehicle-body design, taking account of such factors as
– glazing with large surface areas,
– glazing that is fitted laying flat,
– cylindrical or spherical panes,
– panes with a high degree of curvature.

Possible quality impairments arise from:
– optical deflection,
– optical distortion,
– double imaging.

Optical deflection increases with:
– increasing obliqueness of the angle of incidence, i.e., increasing slope of the window,
– increasing pane thickness,
– reducing radius of curvature (increasing degree of bend),
– increasing divergence from perfect surface parallelism of the original glass sheet.

Green- or gray-tinted glass is used as heat absorption glass because it blocks the transmission of infrared rays (heat radiation) more strongly than shorter wavelengths. On the other hand, it also reduces transmittance within the visual spectrum. The PVB film in LSG absorbs light in the ultraviolet range.

The optical properties of TSG and LSG panes are roughly the same because the optical properties of the intermediate plastic layer in LSG are very similar to those of glass in the visible spectrum.

Functional design glazing

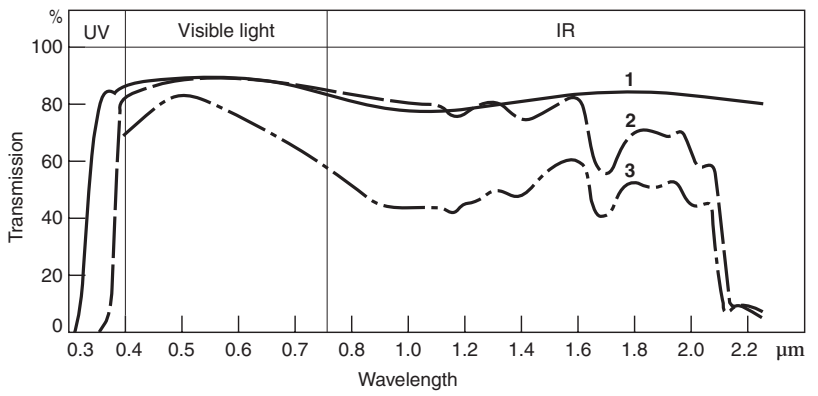
The demands placed on glazing are continually increasing. The flat panes used in the past simply served to protect occupants from wind and weather. Now, automotive glazing performs a wide variety of functions.

Tinted glazing
This is made from glass which is tinted within the material, and reduces the direct penetration of solar radiation into the vehicle interior.

The reduction in the transmittance of solar energy occurs chiefly in the long-wavelength spectrum (infrared, Figure 1), and this mainly lowers the transmittance of energy, thus reducing the heat transmitted to the vehicle interior. The degree to which light transmittance within the visible spectrum is affected depends on the degree of color tinting and the thickness of the glass.

For windshields, light transmittance must be at least 70%. Strongly tinted glass with a light transmittance of less than 70% can be used in windows from the B-pillar to the rear, if the vehicle has two exterior mirrors. For sunroof glazing, tinted glass with a significantly lower light transmittance is used.

Coated glazing
This type of glazing uses glass with a metal or metal-oxide coating. Depending on the production process, the coating may be carried out before or after the sheet of glass is bent and prestressed. The coating is applied to the inner glass surface of an LSG pane.



This type of coated glazing has a light transmittance of less than 70%. Consequently, it can be fitted from the B-pillar to the rear, if the vehicle has two exterior mirrors.

Coated glass can also be used for sunroof glazing. Another type of sunroof glazing uses pyrolytically coated windows which are post-processed after the coating has been applied.

Coated glazing reduces direct solar radiation into the vehicle interior and absorbs solar energy in the infrared and ultraviolet ranges.

Windshields with sunshield coating
A coating is applied to the inner surface of the outer or inner layer of glass in a laminated glass pane. The coating is a multilayer interference system with silver as its base layer. As the coating is on the inside of the laminate, it is permanently protected against corrosion and scratching.

Figure 1: Light transmittance of automotive windshield and glass
1 Float glass and TSG windows, thickness 4 mm, non-tinted,
2 LSG windows, overall thickness 5.5 mm, non-tinted,
3 LSG windows, overall thickness 5.5 mm, green.
UV Ultraviolet,
IR Infrared.

The purpose of the coating is to reduce the transmittance of solar energy by more than 50 %. thus reducing the heat transmitted to the vehicle interior. Transmittance is reduced primarily in the infrared range so that visible light transmittance is altered negligibly. The reduction is achieved largely by reflection, so that secondary reflection into the interior is low. The light transmittance of this glass in the UV range is very low, i.e., less than 1 %.

Sunroof glazing made from laminated safety glass

The bent laminated safety glass consists of two tinted-glass layers which are thermally partially prestressed in order to increase mechanical strength. They are bonded to either side of a highly crack-resistant and specially tinted film. The overall thickness depends on the surface area of the glass, and the overall design of the sunroof.

Absorption that takes place mainly in the infrared range guarantees minimum heat penetration. The coating also provides low light transmittance and complete filtering of UV light.

Automotive insulation glass

Automotive insulation glass is made of two flat or curved sheets of single-pane toughened safety glass (3 mm) separated by an air gap (3 mm). This type of insulation glass reduces heating of the vehicle interior, particularly in combination with a tinted coating. Transmittance is reduced primarily in the infrared range so that visible light transmittance is altered negligibly.

Insulation glass also provides better thermal insulation in the winter and improves sound insulation.

Insulation glass is now only used on commercial vehicles such as buses, trains and airplanes.

Heated laminated safety glass

Heated laminated safety glass can be used for windshields or rear windows. They prevent icing and misting of the glass pane, even in extreme winter temperatures, and ensure clear visibility.

Heated laminated safety glass is made up of two more sheets of glass with a PVB film bonded between them. Inside the PVB film, there are heater filaments which may be less than 20 µm thick, depending on the heat output required. The heater filaments may be laid in a waveform pattern or in straight lines. They may also run vertically or horizontally. The heated area may cover the whole of the pane or may be divided into separate zones with varying heat outputs. In this way, the windshield wipers can be prevented from freezing to the windshield in subzero temperatures.

Heated windows can also be created by layering. In contrast to filament heating, these layers have the advantage of being invisible and reflecting infrared radiation.

Automotive antenna glass
This type of glass has antenna wire embedded in it. In the case of windows made of single-pane toughened safety glass (roof and side windows), the antenna is printed on the glass and is located – almost invisibly – on the inner surface of the window. With laminated safety glass windows (windshields), the antenna wiring system is embedded or printed onto the inner film.

Acoustic glazing
An acoustic windshield is composed, like every windshield, of two individual sheets of glass – an outer and an inner sheet which are firmly connected to each other by way of a sturdy plastic film of polyvinyl butyral (PVB). In the case of acoustic glazing, however, the conventional PVB film is replaced by acoustic PVB which has a highly damping acoustic core located in the middle between two layers of standard PVB. The two outer layers of film of conventional plastic thus safeguard the mechanical properties, while the core layer of damping material absorbs vibrations.

Acoustic windshields reduce the transmission of low-frequency engine vibrations into the vehicle interior. Engine-vibration noises are absorbed by the windshield, these booming noises thus being reduced at low frequencies by up to 5 dB. Side windows can also be fitted with acoustic glazing in the meantime.

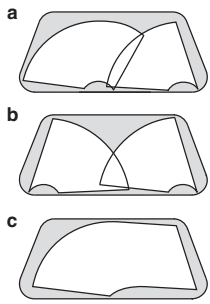
Water-repellent glazing
A coating on the glass causes tiny pearls of water to form on the glass surface when it rains. These are blown off the glass by the air stream.

All glass surfaces can be fitted with this function. After several years of use, the effectiveness of water-repellent glazing can be fully restored with a regenerating kit.

Panorama roofs
There is a wide selection of panorama roofs available, ranging from the closed, large-surface glass roof, through the twin- or multi-panel roof, to the lamellar sunroof.

The following glass technologies can be used for panorama roofs:
– conventional laminated safety glass, 5 mm thick,
– partially prestressed laminated safety glass, 5 mm thick.

Switchable glazing
There are various technologies for influencing the transparency of a pane “at the touch of a button”. One of the common methods is based on liquid crystal which are embedded in plastic foil. When a voltage is applied, all the crystals are orientated in one direction with the result that the pane is switched from opaque to transparent. The switching duration is under one second.



HUD glazing
A head-up display projects a variety of information onto the windshield (e.g., driving speed, navigation, road-sign detection) while the vehicle is in motion. Unlike a conventional windshield, an HUD windshield uses PVB film which increases minimally in thickness from the engine edge to the roof edge. This produces a sharp HUD image of high optical quality. The optimum configuration between projector and windshield is being established as part of elaborate simulation and development work.

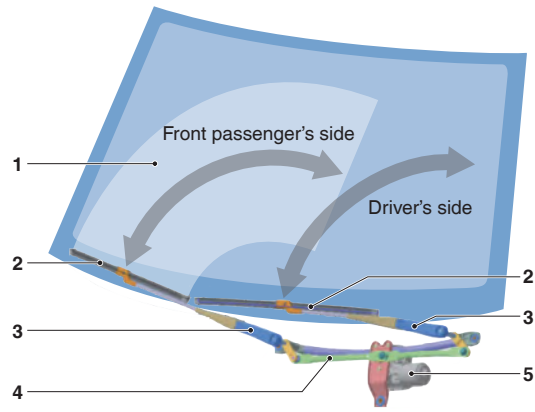
Windshield, rear-window and headlamp cleaning systems

The windshield and rear-window cleaning systems is to provide the driver with sufficient visibility in the motor vehicle at all times. The following different types of system are used:
– front wiper systems,
– rear wiper systems,
– windshield and rear-window washer systems in combination with wiper systems,
– headlamp cleaning systems.

Figure 1: Front wiper systems for fulfilling required passenger-car areas of vision
a) Tandem system,
b) Opposed-pattern system,
c) Wiper-blade-controlled single-arm system.



Front wiper systems

Functions and requirements
The function of front wiper systems is to remove water, snow and dirt (mineral, organic or biological) from the windshield. Boundary conditions are among others:
– operational at high temperature (+80 °C) and low temperature (–40 °C),
– corrosion resistance against acids, bases, salts, ozone,
– endurance strength under load (e.g., due to high snow load),
– pedestrian impact protection,
– cleaning effect at high driving speeds,
– low operating noise.

Legislators have translated the demand for adequate visibility into standardized areas of vision on the windshield (e.g., for Europe [1]). These are subdivided into several areas and must be cleaned by the wiper system to fixed percentage levels. The most important wiper systems for passenger-car windshields which satisfy these requirements are shown in Figure 1.

Wiper systems for commercial vehicles are similar to those for passenger cars, but are subject to different requirements especially with regard to driving speed and windshield shape.

Figure 2: Front wiper system
1 Windshield,
2 Wiper blade,
3 Wiper arm,
4 Wiper linkage,
5 Wiper drive.

Operating principle

Essentially a front wiper system consists of a wiper drive with or without linkage, the wiper arms, and the wiper blades (Figure 2).

The wiper drive moves the wiper arms at a specific angle over the windshield so that the driver and front passenger have a clear view. A specially shaped rubber wiper lip provides for an optimal wiper result.

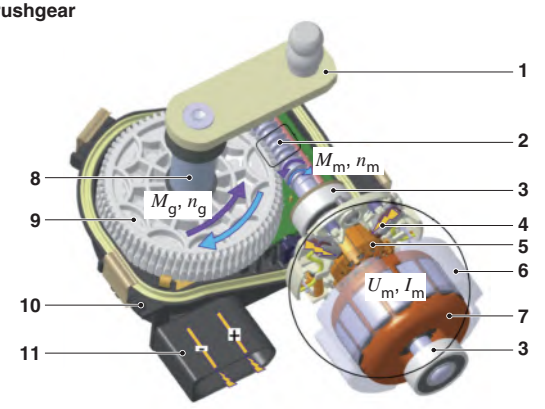
Front wiper drive

Motor-gear unit

Front wiper drives essentially consist of an electric motor with a reduction gear. Mainly permanent-field DC motors with brushgear (mechanical commutation) are used as electric motors and helical-gear mechanisms are used as gears (Figure 3).

Brushless permanent-field DC motors with electronic commutation are for cost reasons still in the minority and only appear occasionally on the market.

Motor design



The motors are for cost, weight and space reasons high-speed in design. Adaptation to the speed and torque requirements of the wiper system is performed via the helical-gear mechanism.

The primary function of wiper drives is to guarantee visibility under anticipated conditions, i.e., among others sufficiently frequent windshield wiping. For front wiper systems this usually means around 40 timers per minute (setting 1) and under more extreme conditions around 60 times (setting 2). This is stipulated in Europe [1] with the demand for a wiping frequency of at least 10 and at most 55 wiping cycles per minute and a second wiping frequency of at least 45 complete wiping cycles per minute. The difference between the highest and lower wiping frequency must be at least 15 wiping cycles per minute.

The classification by power output often used for electrical machines is not suitable for drives for wiper systems. Wiper systems are normally operated on a wet windshield; in this case, minimal torque is demanded of the motor at high rotational speeds. On the other hand, in the case of high-load states such as when the wiper blade is frozen, a high torque is required at low rotational speed. In both cases, the power output (product of torque and rotational speed) is low. Because the drive variable is dependent on the required torque at the high load point, this torque is used as the classification feature.

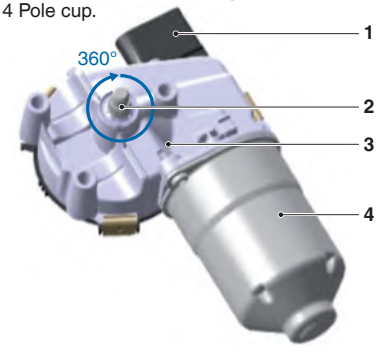
Rotary drives
Rotary drives (Figure 4) are characterized by the fact that the output shaft of the wiper drive rotates permanently in the same direction (360°). The actual wiping motion on the windshield is determined by the wiper linkage and its kinematic configuration.

The speed/torque equation and the starting torque derived from it are governed by the following relationships:



$$n = -2\pi \frac{R_A}{c^2 \Phi^2} M + \frac{U_{KL}}{c\Phi}\ , \qquad (1)$$

$$M_A = \frac{1}{2\pi} \frac{U_{KL}}{R_A} c\Phi\ . \qquad (2)$$

$c = zp/a$ Motor constant,
U_{Kl} Terminal voltage,
Φ Interlinked winding flux,
R_A Armature resistance,
M Torque,
M_A Starting torque for $n = 0$,
z Effective total number of conductors,
$2a$ Number of parallel armature-winding paths,
p Number of pole pairs.

The two speed settings are obtained in such systems by having carbon brushes to ground (–) and to battery voltage (+) for setting 1 and switching to a third carbon brush (Figure 5), which is also connected to battery voltage (+) and delivers setting 2.

Figure 4: Rotary wiper drive
1 Gear-mechanism cover with electrical connection, 2 Output shaft,
3 Gear-mechanism housing,
4 Pole cup.

In response to the effect of the third brush there are situated under a magnet conductors which bring about a braking torque. When this braking torque is subtracted

Figure 5: Position of third carbon brush

M_A Starting torque.

from the useful torque of the conductors under the other magnet, the third brush, which concerns the number of conductors, acts is if to reduce the number of conductors for a constant wire cross-section, i.e., the speed/torque curve should rotate about the starting point M_A (Figure 6a). When the armature resistance is being determined, however, these conductors cannot be ignored, producing an armature resistance that is greater that the torque effect from the perspective of the number of conductors. According to equation (2), therefore, the starting torque will decrease and a center of rotation of the curve will appear which is in the rear part of speed/torque curve for M_A^* (Figure 6a).

The wiper drives have a mechanical sensor system to ensure that the wiper blades adopt the correct parking position. Because the position of the output shaft of the rotary drive has a 1:1 correlation with the wiping angle, this function can be guaranteed with a reference position at the output. Mainly sliders in the gear-mechanism cover with a contact disk in the helical gear are used as the parking-position system (Figure 7).

High-load and locking protection is provided in rotary drives conventionally by means of a thermoswitch.

Reversing drives

In the case of reversing drives the output shaft oscillates at a defined angle, usually less than 180° (Figure 8). Output to the wiper shafts is provided, as is also the case with rotary wiper drives, via a wiper linkage or in direct drives directly to the wiper shaft.

The gear-mechanism cover incorporates electronics with software. These induce, by reversing the polarity of the terminal voltage, a reversal of the electric-motor direction and with it a reversal of direction of the wiper blades at the corresponding turning points. Furthermore, pulse-width modulation of the applied terminal voltage is used to generate different motor speeds and thus controllable wiper speeds or wiper frequencies (Figure 6b). Therefore, reversing drives with a DC motor with brushgear and mechanical commutation, unlike conventional rotary drives, have only two carbon brushes.

The position and speed of the output is relevant to controlling the drive. For example, these variables are detected via Hall sensors integrated in the electronics and sensor magnets in the helical gear and processed with corresponding software. The signals from this sensor system are also used to detect the parking position (Figure 9) and spare the mechanical parking-position system of conventional rotary drives.

Figure 7: Mechanical parking-position system

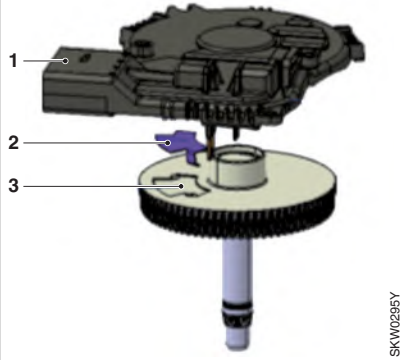

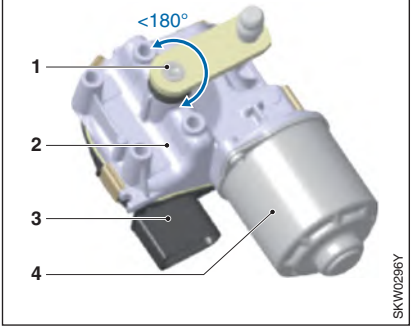

Figure 8: Reversing wiper drive

1 Output shaft,
2 Gear-mechanism housing,
1 Gear-mechanism cover with electrical connection,
4 Pole cup.

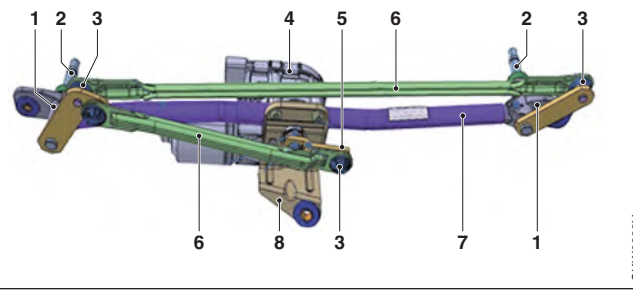
High-load and blocking protection is likewise guaranteed here by the integrated electronics.

Wiper linkage
The wiper linkage is the connection between the drive and one or more wiper arms. It transfers the movement of the wiper drive via the motor crank with ball pivot to the articulated rods and via these to the ball pivot of the wiper bearing (Figure 10).

The wiper arm is connected by means of a collar nut for example to the wiper-bearing shaft and the wiper drive is connected by means of a plate and corresponding screws in the gear-mechanism housing to a shaped tube. The shaped tube simplifies installation in the vehicle and limits the wiping-angle tolerances.

The following different design variations are available.

Rotary drive
The drive runs in a circle (360°) and the linkage transfers the circular motion into the oscillating motion of the wiper arms (Figure 11a). The requested wiping angle determines the kinematic configuration of the linkage, i.e., the angle between the upper stop of the wiper blade near the A-pillar (upper turning point) and the lower stop near the bottom edge of the windshield (lower turning point).

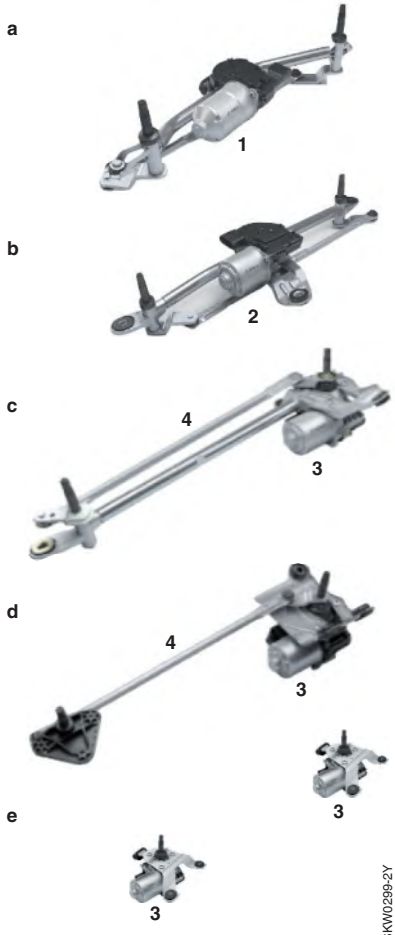


Reversing technology
The electronically controlled drive rotates less than a half rotation (<180°). The linkage transfers the force from the drive to the wiper arms (Figure 11b). The advantage of such systems over the rotary drive lies in the fact that the space required for the linkage kinematics is roughly halved.

In direct drives the wiper arm is directly connected to the output shaft. Here there are systems with reduced linkage complexity (Figure 11c), omitted shaped tube (Figure 11d), and systems entirely without linkage (Figure 11e).

Figure 9: Electronic parking-position system
1 Gear-mechanism cover with electronics and sensor,
2 Sensor magnet,
3 Helical gear.

Figure 10: Basic wiper linkage
1 Wiper bearing,
2 Wiper-bearing shaft,
3 Ball pivot,
4 Wiper drive,
5 Motor crank,
6 Articulated rod,
7 Shaped tube,
8 Plate.



Omitting the shaped tube cuts down on the number of wiper-linkage parts, but increases the amount of fitting work by the vehicle manufacturer in that more parts must be connected to the vehicle. Furthermore, this increases the demands placed on the rigidity of the vehicle body and necessitates increased precision when installing the components in order to ensure wiping-angle precision.

When the wiper linkage is omitted, the drive is directly screwed to the body by means of a plate.

Additional functions, such as, for example, an extended parking position, an overload-protection function (e.g., for snow), an infinitely variable wiping speed, and a consistently large wipe pattern over varying operating conditions (e.g., driving speed), can be implemented with electronically controlled wiper systems.

4 Wiper linkage.

Wiper arms

The wiper arm is the connecting element between the wiper linkage and the wiper blade. It is screwed to the tapered wiper-bearing shaft by its mounting end, which is usually made of diecast aluminum or steel sheet (Figure 12). The other end is generally a steel strip and holds the wiper blade. A distinction is made here

Figure 12: Wiper arm (side and top views)
1 Steel strip with hook-type fastening,
2 Joint section,
3 Tension spring,
4 Attachment part with taper for mounting on wiper-bearing shaft.

between hook-type, side and front fastenings (Figure 13).

To further improve the visibility conditions the washer fluid of the windshield washer system is specifically directed to where it is needed, i.e., directly in front of the wiper blade. Nozzle bodies (spray nozzles) are integrated in the wiper arm (Figure 14) and spray holes integrated in the wiper blade (Figure 15) for this purpose. This improves the cleaning effect, widens the field of vision, and facilitates a clear view. Unlike conventional systems, there is no wide-area spray mist. This additionally improves the view event at higher driving speeds. Depending on the available equipment specification in the vehicle, these systems come heated or unheated.

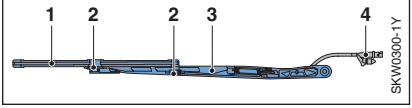
2 Nozzle body,
3 Wiper arm,
4 Electrohydraulic connection.



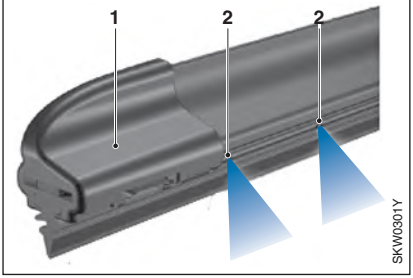


Figure 15: Wiper blade with spray holes
1 Wiper blade,
2 Spray holes.

The wiper bearing is screwed to the body. The position of the wiper arm in relation to the windshield is established by way of the position of the wiper bearing relative to the windshield. The field of vision is established in combination with the wiper-blade length and the wiping angle.

The position of the wiper blades is defined by the angular position of the wiper bearings to the windshield and by applying additional torsion to the wiper arms. The aim is to incline the wiper arms laterally at their reversal points towards the wipe-angle bisector. This helps the wiper-blade elements to swivel into their new working position. This, in turn, reduces wiper-blade wear and the reversing noise.

Wiper blades

The wiper blade holds the wiper-blade element and guides it over the windshield. Essentially there are two different types: conventional wiper blades (Figure 16) and jointless wiper blades (Figure 17). Wiper blades are used in lengths of 260 to 800 mm. Their dimensions for mounting (e.g., hook-type or snap-in fastening) are standardized.

Conventional wiper blade

In conventional wiper blades the contact pressure is distributed by claw brackets (Figure 16). Low-wear operation is achieved by compensating the play in the mountings and linkages. The tops of the center brackets are perforated to prevent blade liftoff at high speeds. In special cases, wind deflectors are integrated into the wiper arms or blades to press the blades against the windshield.

Jointless wiper blade
The flat, jointless wiper blade (aero-wiper blade) represents the current development status in wiper-blade design (Figure 17).

The contact pressure over the wiper-blade element is no longer distributed by the claws of the wiper bracket, but by two preshaped spring strips (sprung rails) specially adapted to the shape of the windshield. They press the wiper-element lip more evenly against the windshield. This reduces wear on the wiper-element lip and increases wipe quality. In addition, the elimination of the bracket system means that there is no linkage wear, the overall height of the wiper system is substantially reduced, the weight is lower, and the wiper is quieter (there is also less wind noise).

The top edge of the wiper blade is in the shape of a spoiler (air deflector) and allows the blade to be used even at very high speeds without any modification. The flexible material of the spoiler is also much less likely to cause injury to pedestrians in the event of an accident (pedestrian impact protection).

An adapted, simplified connection to the wiper arm ensures a reliable attachment of the wiper blade when the wipers are in operation, and also allow easy replacement when required.

Wiper-blade element
A crucial element of the wiper system is the wiper-blade element. It is retained by the claws of the bracket system (Figure 16) or supported by spring strips (Figure 17). The edge of the rubber lip touches the windshield over a width of 0.01 to 0.015 mm. When moving across the windshield, the wiper-blade element must overcome coefficients of dry friction of 0.7 to 1.7 (depending on air humidity), and coefficients of wet friction of 0.1 to 0.5

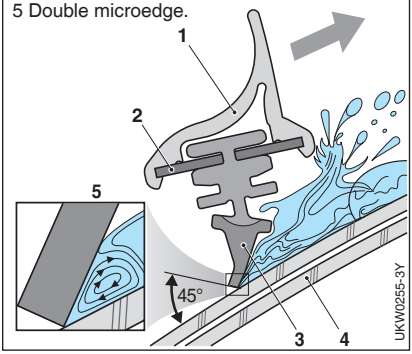
(depending on frictional velocity). The correct combination of wiper-element profile and rubber properties must be chosen so that the wiper lip can cover the complete wipe pattern on the windshield surface at an angle of approx. 45° (Figure 18).

The two-component element (twin wiper), made of synthetic rubber, consists of a specially hardened, abrasion-resistant lip which merges into an extra-soft spine. The soft spine ensures that the wiper element has optimum reversing characteristics and wipes smoothly.



Rain sensor

The rain sensor (see Sensors) detects how heavy the rain is, and converts this data into an appropriate signal that is sent to the wiper drive. This is automatically switched on and, depending on the requirement, operated in the intermittent setting or in setting 1 or setting 2.

The full potential of the rain sensor is fully realized with an electronically controlled wiper system, whose wiping speed can be infinitely re-adjusted to the rain intensity.

Rear wiper systems

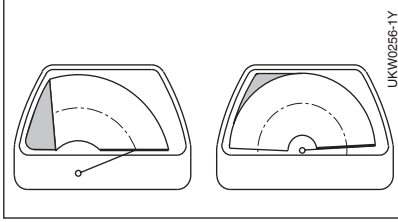
Function and requirements

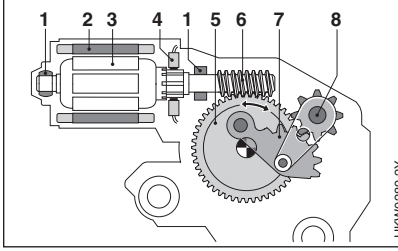
Rear wiper systems are used when the rear window, on account of its sloping angle or the body shape, is prone to getting very dirty and rear visibility is compromised. The principle of rear-window cleaning is generally the same as that for windshield cleaning systems.

A rear-window cleaning system is subject to much lower demands than those of a front wiper system. The rear wiper system is therefore frequently operated in intermittent mode and its field of vision is not subject to any statutory requirements. The wiping angle typically ranges between 60° and 180° (Figure 19).

Figure 19: Rear-window wipe patterns.

The gray areas represent impaired visibility when vehicles are overtaking.





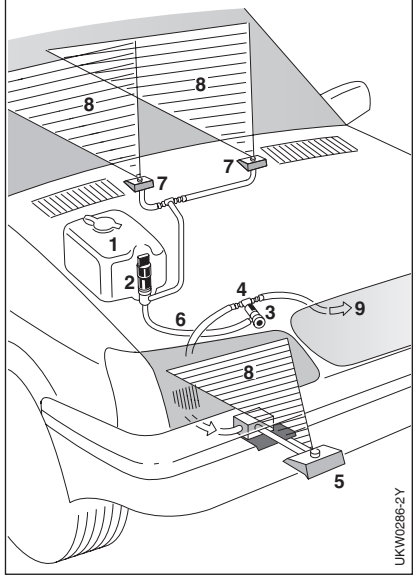


Figure 20: Rear wiper drive with oscillating mechanism.

1 Bearing, 2 Magnet, 3 Armature,
4 Commutator with carbon brushes,
5 Helical gear, 6 Worm, 7 Oscillating mechanism, 8 Output shaft.

Rear wiper drives
Rear wiper drives are essentially no different from front wiper drives. A rear-window wiper system is usually driven by an electric motor with integrated oscillating mechanism, which assumes the function of the linkage in front wiper systems and performs the oscillating movement of the output shaft (Figure 20). The wiper arm is directly attached to the output shaft of the wiper drive.

Figure 21: Windshield washer system and high-pressure washer system for headlamps.

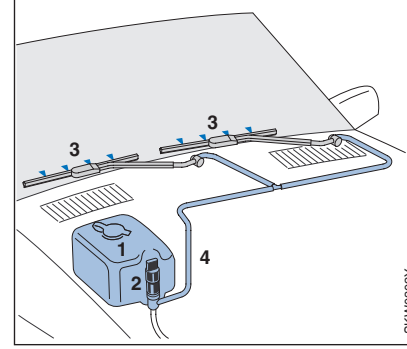
5 Nozzle holder for headlamp cleaning,
6 Tube,
7 Nozzles of windshield washer system,
8 Spray area,
9 Tube to left headlamp.



Windshield and rear-window washer systems

Design
To ensure good cleaning, it is imperative that the wiper system is backed by a washer system. Electrically driven centrifugal pumps are used to direct water mixed with detergent additive from the washer-fluid reservoir through nozzles in a pointed spray or through sprinkler nozzles as water mist onto the windshield (Figure 21).

To spray the windshield with water, the nozzles are positioned on the engine hood or in line with current development trends directly on the wiper arm, or the spray holes are integrated in the wiper blade (Figure 22). The capacity of the washer-fluid reservoir is usually 1.5 to 2 *l*. If the same washer-fluid reservoir is also used to supply the headlamp washers, a capacity of up to 7 *l* may be required. A separate reservoir may be provided for the rear-window cleaning system.

Electronic control
The washer system is often linked to the cleaning system by means of an electronic control system so that water is sprayed onto the rear window or windshield for as long as a pushbutton remains pressed. The wiper system then continues to operate for several additional cycles after the pushbutton is released.

Figure 22: Windshield washer system with nozzles integrated in the wiper arm.
1 Washer-fluid reservoir, 2 Pump,
3 Wiper blade with spray holes integrated in the wiper blade,
4 Tube.

Headlamp cleaning systems

Pure washer systems have become established for cleaning headlamps. The advantages of the headlamp washer system over the previously used wiper systems lie in its simple design and in the fact that it is easier to adapt to the vehicle styling concept.

A headlamp washer system is prescribed by law in Germany for xenon headlamps to prevent oncoming traffic from being dazzled by light diffusion.

Design

High-pressure washer systems (Figure 21) consist of the washer-fluid reservoir (the washer fluid required is taken from the reservoir for the windshield washer system), the pump, tubes with a non-return valve, and the nozzle holders (horn) with one or more nozzles. As well as fixed nozzle holders on the bumpers, there are also telescopically extending nozzle holders. The telescope improves the cleaning effect because it can assume an optimum spray position. In addition, when not in use, the nozzle holder can be concealed, e.g., inside the bumper.

Cleaning effect

The cleaning effect is chiefly determined by the cleaning pulse of the water jet. The decisive factors here are the distance between the nozzles and the headlamp lens, the size, the contact angle, the contact velocity of the washer-fluid droplets, and the amount of washer fluid. It is important that the nozzles be positioned correctly so that water jets properly cover the headlamps at all driving speeds.

Passenger-compartment climate control

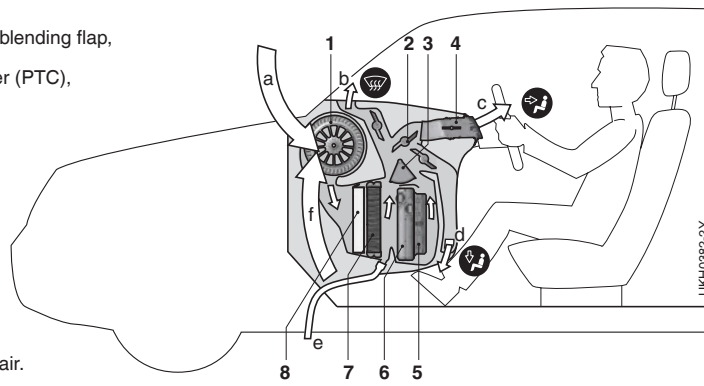
Climate-control requirements

The system for controlling the climate in the passenger compartment of automobiles and commercial vehicles must fulfill many functions. Firstly, it must create a comfortable climate for all the occupants. To this end, cooled or heated air (depending on the outside temperature) is fed into the passenger compartment so as to meet the physiological needs of the occupants. A further function of climate control is to keep the passenger compartment free of unpleasant odors and pollutants.

Climate control also has the safety-related function of demisting and de-icing the windshield and side windows. Statutory requirements that vary from country to country must be met.

The comfort requirements and thus the functions of the A/C unit normally increase with the vehicle category. Regionally different climate-control requirements must also be taken into consideration. In Europe, for instance, vehicles with a system of climate control which is as unobtrusive as possible are preferred, whereas in the USA a cool, noticeable air current is desired.

Design and operating principle of the A/C unit



Air intake

The A/C unit is installed out of sight of the occupants under the vehicle's instrument panel. Fresh air is usually drawn in at the base of the windshield (Figure 1). Rainwater and snow are removed en route to the A/C unit. The outside air is drawn in by a radial fan and delivered through an opening in the bulkhead (partition between engine and passenger compartments). There is a further possibility of drawing in passenger-compartment air (recirculated air) through a second air inlet. The proportions of fresh air and recirculated air from the drawn-in air are controlled by flaps.

Fresh air is needed to supply oxygen to the passenger compartment. In recirculated-air mode, unpleasant odors and pollutants are prevented from entering the passenger compartment. In addition, power consumption is significantly reduced in recirculated-air mode, since the air to be temperature-regulated does not have to be heated and cooled so much in heating and cooling modes respectively. However,

Figure 1: Passenger-compartment climate control

d Air vent, footwell,
e Condensate drain,
f Recirculated air.

cold and thus dry fresh air must sometimes be used to prevent the windows from misting over due to condensation of damp passenger-compartment air.

Air cleaning
To clean the air, a sheet of filter fleece is pleated, i. e. folded, and preferably installed in the shape of a rectangular filter element before and after the fan in the A/C unit. The filter element is mainly positioned in such a way as to filter not only the fresh air, but also the recirculated air. The filter element has a limited retention capacity and must therefore be replaced. An activated-carbon layer can also be applied to the filter fleece (hybrid filter) in order to filter out particulates and pollutants.

Air cooling
The cleaned air is then cooled on the surface of an evaporator, which is now usually made entirely of aluminum. The air dissipates its energy proportionally to the evaporating refrigerant which is routed through the evaporator.

Because cold air can absorb less moisture than warm air, water is separated out as it cools and routed downwards along the evaporator. The water collects in the housing section under the evaporator, the condensate drip pan, and is discharged via the condensate outlet from the A/C unit to the atmosphere.

Air temperature regulation and distribution
After the evaporator the desired air temperature is set by a blending-flap system. To this end, the air is directed entirely or in part through a radiator (through which engine coolant flows) or – in pure cooling mode – past the radiator directly to the air vents. The air is continuously distributed to the two channels in any proportion by one or more temperature blending flaps. The cold and warm air currents are blended to suit demand in the downstream blending chamber. The air currents are blended in such a way as to cater for the comfort sensation of "cool head and warm feet". For this purpose air is blown out at different temperatures at the three main "Footwell", "Ventilation" (air vents in the instrument panel) and "Windows" vent levels, generating temperature stratification of up to 15 K.

The volume of air blowing out of the individual vents is continuously adjustable to any proportion by hand or by motor-driven vent flaps.

In further expansion stages of the A/C unit additional vents can be provided for the rear passengers or temperature regulation of the passenger compartment can be set differently for different seats. The first expansion stage is two-zone temperature regulation. The interior temperatures on the driver and front-passenger sides can be set independently of one another. Three-zone climate control caters for the rear-seat area as an additional climate zone, while four-zone climate control provides for individual climate control for driver, front passenger and two passengers in the back.

A new feature is individual adaptation of the footwell temperature, or "variable stratification". In this case, the outlet temperature in the footwell can be increased while the basic setting remains unaltered (for example for people with feet which are sensitive to cold).

Booster heater
In modern optimized-consumption internal-combustion engines the waste heat available in the engine coolant is reduced, and thus with it the heat supply in the heating circuit. In this case, an electric PTC booster heater is installed in the air passage after the radiator. By using PTC ceramic heating elements (PTC, Positive Temperature Coefficient), the booster heater automatically reduces its heat output at a defined limit temperature, since the resistance of the PTC elements increases abruptly. The PTC booster heater is therefore intrinsically safe.

The utilization of further heat sources, such as heat recovery from exhaust gas for example, is currently being developed.

Air routing
The temperature-regulated air is directed through plastic blow-channels to the relevant vents. Window and footwell outlets are not adjustable. The blow direction (nozzles) and the air volume can be individually adjusted at the air vents.

Supplementary A/C units
In luxury-class vehicles supplementary A/C units are sometimes use for the rear passengers. These are designed either, like the main A/C units, as heater-coolers or as pure coolers, and are usually supplied with recirculated air. Supplementary A/C units are installed, for example, in the center console, above the rear wheel arch, in the spare-wheel recess, or behind the rear seat bench.

Alternative A/C-unit concepts
The A/C unit described above sets the desired temperature by blending cold and warm air and represents the standard design used today. Alternative A/C-unit concepts may be used in which the air after the evaporator is routed directly through the radiator. A valve can be used to steplessly adjust the water flow rate through the radiator and thus the desired level to which the air flowing through is heated. The blending-flap system for blending cold and warm air is omitted.

Because of the thermal inertia of the water-filled aluminum radiator, desired changes to the air outlet temperature can only be completed slowly. To ensure that the passenger compartment is quickly cooled with the maximum air mass, these concepts normally utilize an additional air-side bypass past the radiator.

The advantage of this concept is the slightly more compact design of the A/C unit and the possibility of shutting off the radiator on the water side and thus avoid the unwanted situation of the air being heated in cooling mode by hot components in the A/C unit. The disadvantage is the expense of integrating a water valve.

Regulation of climate control
The climate of the passenger compartment is controlled by making inputs at the A/C operating unit, by adjusting the air vents and – in more luxurious vehicles – by means of various sensors. The variations range from direct mechanical activation of the A/C unit via Bowden cables and flexible shafts to fully automatic, processor-controlled air conditioning, where only the desired temperature is set.

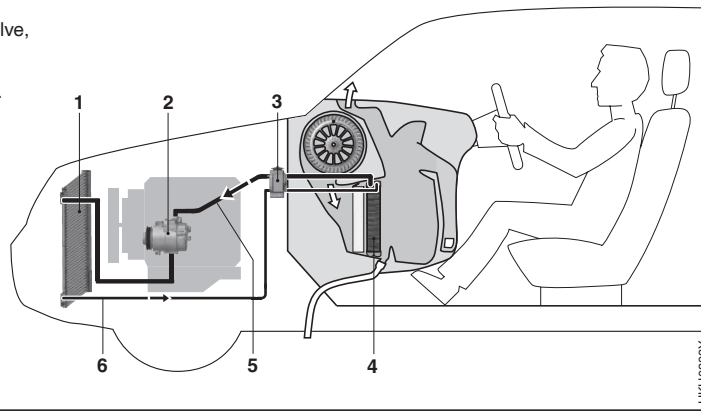
The variables that can be influenced are blow-out temperature, air flow rate, air moisture, and air distribution to the different vents. The secondary variables are interior temperature including temperature stratification, air flow, acoustics at each seat, and misting status of the windows.

Most people find the following configurations pleasant: in summer mode cold air from the vents in the instrument panel, in winter mode warm air from the footwell and defrost vents (for keeping the windows clear), and in transition mode, heated air in variable proportions from the defrost, footwell and ventilation vents in the passenger compartment. Additional influencing factors can play a part in automatic air conditioning. The status and intensity of the Sun can be determined by solar sensors and included in the control operation. Air-quality sensors detect pollutants and odors in the ambient air and prevent them from entering the passenger compartment by closing the fresh-air inlets. Moisture sensors for the windshield enable action to be taken to prevent imminent window misting. The desired and actual passenger-compartment temperatures are compared by of temperature sensors.

Climate-control systems

Heating circuit
The waste heat from the engine is a source of energy which can be utilized without great expenditure to heat the passenger compartment. The hot coolant flows through the radiator in the A/C unit. The air passing through the radiator is heated.

In order to maintain the interior temperature in winter after a journey when the engine is switched off, it is possible to use an electric water pump, which forwards the coolant and makes the heat stored in the cooling system usable.



Refrigerant circuit
The function of the refrigerant circuit is to absorb the thermal energy of the air to be cooled in the evaporator and dissipate it at another point, outside the passenger compartment, to atmosphere. This is effected by using the cold-loss process in a closed refrigerant circuit (Figure 2). The main components of this circuit are the evaporator with expansion valve in the A/C unit, the condenser at the front of the vehicle, usually mounted directly in front of the coolant radiator, and the compressor secured to the engine block and driven by the engine.

The components are connected by metallic pipes which can contain flexible sections for decoupling. The compressor draws the gaseous refrigerant from the evaporator and compresses it, i.e. the pressure and temperature levels are greatly increased. In the condenser the hot refrigerant dissipates heat to the ambient air flowing through the condenser. This cooling condenses the vapor-state refrigerant. If the air stream is not enough to cool the refrigerant sufficiently, the radiator fan increases the air flow rate through the condenser. The refrigerant – now in liquid form and under high pressure – is atomized in the expansion valve and directed to the evaporator. The pressure level drops suddenly, as a result of which the refrigerant is highly cooled as it evaporates, and absorbs the heat of the air to be cooled in the A/C unit.

The evaporated refrigerant exits the evaporator in gaseous form and passes the expansion valve again, which, on the basis of the pressure and the temperature of the exiting refrigerant, alters the throttling cross-section on the inlet side so as to inject into the evaporator just that amount of refrigerant that can evaporate in the current operating state.

The cold gaseous refrigerant is drawn in again by the compressor and the circuit begins afresh.

Figure 2: Climate-control refrigerant circuit
1 Condenser with integrated refrigerant collector and dryer,
2 Compressor,
3 Expansion valve,
4 Evaporator,
5 Intake line,
6 Pressure line.

In order to prevent ice from forming on the air side of the evaporator, which would reduce the evaporator air cross-section, the minimum air temperature must not drop below 0 °C. To measure the air temperature after the evaporator, either an air-temperature sensor is used which regulates the compressor accordingly if the temperature drops below a fixed level, or the minimum intake pressure and thus the evaporator temperature are limited in the compressor. The refrigerant output can be adjusted between zero kilowatts (refrigerant does not flow through the evaporator) and a maximum output of approx. 8 kilowatts (for maximum refrigerant quantity and air flow rate).

Refrigerant
The fluorocarbon 1,1,1,2-Tetrafluorethane, which goes by the trade name R134a, is used as the refrigerant for vehicles with homologation before 2011-01-01 or vehicles where an existing type approval has been expanded (see Refrigerants, Operating fluids).

Because of this refrigerant's GWP (Global Warming Potential) of approx. 1,400 and the statutory provision which will come into force in Europe in 2011, which prescribes a refrigerant with a GWP of less than 150 for new vehicle models, an alternative refrigerant must be used here. There is currently still a lively debate regarding applicability of the alternative refrigerants. 2,3,3,3-Tetrafluoropropene with the trade name R-1234yf and carbon dioxide with the trade name R-744 are being pursued as alternatives. Starting at 2017-01-01 in Europe, all newly approved passenger cars must use a refrigerant with a GWP of less than 150.

Climate control for hybrid and electric vehicles

In vehicles with an engine start/stop function, it is necessary to keep the interior climate constant when the engine is switched off. For heating, an electric water pump can be used to utilize the residual heat from the engine circuit. For cooling, evaporators have been developed with a cold accumulator on the basis of a material which can store cold by means of a phase change and dissipate it again when stopped at traffic lights with the engine switched off. The interior climate can thus be kept at a pleasant level for up to two minutes.

In vehicles which run partly or entirely on electricity, a compressor is used which is electrically powered. Two solutions are available for heating. Either the water required for the radiator is electrically heated and supplied to the circuit by an electric pump, or the radiator is replaced by an electric heating element, the high-voltage PTC. Electric heater and electric compressor also open up the possibility of independent climate control. When the battery is sufficiently charged or connected to a charging station, the vehicle can be both preheated and precooled.

Because the power required for climate control can amount to several kilowatts and thus the range of an electric vehicle is reduced significantly, current developments are focused on increasing the efficiency of climate control.

Cabin filters

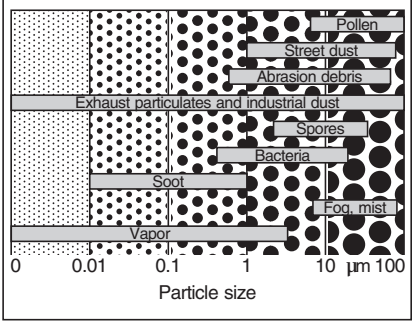
Function

Heating and air-conditioning systems in motor vehicles draw in air from the outside. After conditioning, the air passes into the passenger compartment together with any particles or gaseous pollutants it may contain. These air pollutants (Figure 3) can cause allergic reactions. Therefore, it makes sense to filter out particles and gases. A filter also reduces the amount of dirt that builds up on the fan, in the heating system, on the instrument panel, and on the inside of the windshield.

Depending on the requirement, either particle filters, charcoal filters, or biofunctional filters are used. Charcoal filters have the advantage that, besides filtering out particles, they can also prevent unpleasant odors from entering the passenger compartment. This is achieved by carefully embedding activated charcoal granules (up to 300 g/cm^2) on the particle-filter medium to eliminate aromatic substances. The activated charcoal also adsorbs ozone, benzene, and toluene, for instance. Biofunctional filters are furthermore used to prevent the growth of bacteria and to retain allergenic proteins.

Filter media

Whereas in the past filter media were primarily paper-based, the situation has now changed as a result of the greater demands placed on the filter system (removal of particles smaller than 0.001 mm). Present-day filter media generally consist of polyester or polypropylene-based nonwoven materials. The particle filter consists of three graduated fiber layers: the preliminary filter, the microfiber nonwoven layer with electrostatically spun microfibers, and the base nonwoven material. An activated charcoal filter also has an activated charcoal layer in addition to the three fiber layers. In a biofunctional filter a special coating on the filter medium provides the biofunctional effect.



When the filter material is made into a filter, a number of specific parameters must be considered. There is a complex interrelationship between the filter material used, the depth of the filter-element folds, and the distance between the folds. The interaction between these parameters is important in determining the filter performance in service.

Design

Cabin filters must be optimized in three areas: filtration efficiency, pressure loss, and dust-storage capacity. The specifics of the application determine which of these three considerations is given precedence. The best filter may, for example, be a filter that achieves the highest possible filtration efficiency at the expense of a tradeoff in the filter service life. Another filter design may be one where a long service life is achieved by a high dust-storage capacity at a defined level of filtration.

The service life of filters used in passenger cars is around 20,000 km, i.e. with today's servicing intervals, they are replaced each time the car is taken for a scheduled service.

Figure 3: Prevailing particle sizes in road traffic

Auxiliary heater systems

Function and designs
Auxiliary heater systems use the fuel carried in the vehicle's tank to generate heat. Air heaters (Figure 4) are used to heat the passenger compartment directly. They transfer the heat generated during combustion to the cabin air. Coolant heaters (Figures 5, 6, 7) introduce heat into the cooling water and are thus suitable both for preheating engines and for heating the passenger compartment via the vehicle's heat exchanger with blower.

Air heaters are particularly efficient due to the direct transfer of heat to the air and are suitable for long periods of heating. Coolant heaters use the cooling circuit and the vehicle's existing air ducts and are therefore particularly suitable for covering the heat deficit of low-consumption drives and for preheating the passenger compartments and engines of passenger cars.

Further advantages of auxiliary heater systems are:
– Ice-free windows thanks to preheating,
– Optimized heating comfort,
– Use of a truck sleeping cabin even in winter,
– Less wear and lower emissions when starting with a preheated engine (with coolant heater only),
– Operating temperature of the catalytic converter reached more quickly (with coolant heater only).

Of increasing importance is their use in passenger cars with deficient heat output from waste heat caused by increased drivetrain efficiency by means of electrification. Particularly in plug-in hybrid vehicles – but also in purely battery-powered vehicles – fuel-powered heaters, on account of their great efficiency in converting chemically bound energy into heat, ensures that the range in electric driving mode is not limited in the case of the storage capacity of the traction batteries being specified.

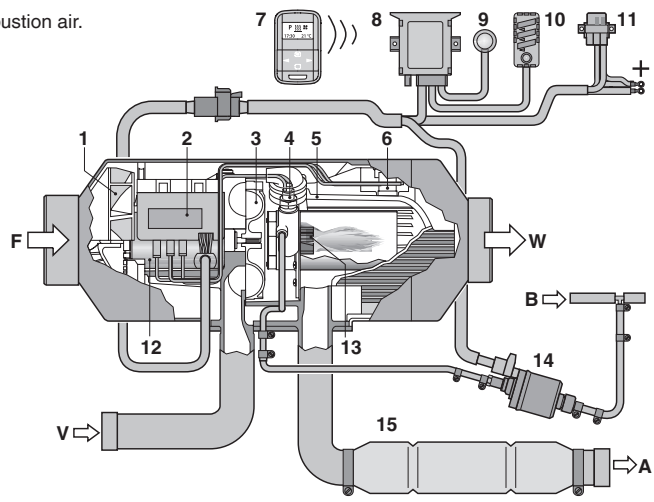
Air heaters
Application
Air heaters are primarily used in trucks and commercial vehicles. Their main advantages are low costs, faster installation, and lower power and fuel consumption. A dramatic increase in their use was witnessed in the USA with the introduction of legislation prohibiting the running of the engine to provide heat during breaks in driving since heaters can heat the cabs with clearly lower fuel consumption.

Operating principle
Air heaters (Figure 4) operate independently of the vehicle's own heat balance. A combustion-air blower draws the air required for combustion from the surrounding atmosphere, and blows it into the burner. An electric metering pump delivers diesel or gasoline as fuel via an evaporator (component not visible in Figure 4) to the burner, where it mixes with combustion air, is ignited by a sheathed-element glow plug, and burns. The heating-air blower draws in the fresh air to be heated, blows it through a heat exchanger, and into the vehicle cabin.

In cold countries a heat output of approx. 4 kW is required. In temperate climates units with approx. 2 kW are sufficient.

An important safety aspect is that combustion air and exhaust gas from the cabin air must be kept entirely separate. This prevents exhaust gas from entering the cabin.

The heat output is regulated by varying the quantity of fuel, combustion air and fresh air. If the temperature measured by the room-temperature sensor deviates from what is set at the operating element (e.g. radio remote control), the output of the heater is adapted until the desired temperature is reached once again. An overheating sensor registers unacceptable temperatures through defects or malfunctions that occur (e.g. overheating due to blocked heating vents) and switches off in good time if necessary. A flame sensor determines by means of the heat-exchanger temperature whether the burner has ignited and detects when the flame goes out.



Installation
Air heaters for commercial vehicles can usually be fitted directly inside the cab. In trucks, for instance, the preferred locations are in the co-driver's footwell, on the rear cab wall, under the bunk bed, on the outside of the cab wall, or in a stowage compartment. The exhaust pipe always runs under the floor (either into the wheel arch, or out of the rear cab wall).

Most sensor units in the fuel tanks of passenger cars and trucks already have a connection available for supplying fuel to the air heater. If necessary, an extra tank sensor unit is fitted. A fuel reserve for driving is guaranteed by the immersion depth of the fuel-tank extraction fittings or the vehicle electronics, which switches off the heater from a minimum fill level.

Coolant heaters
Application
Coolant heaters up to approx. 5 kW heating capacity are used both in passenger cars and in trucks. They use the cooling circuit and already existing heat exchangers to heat the engine and cabin, as well as the available fans, air ducts, flaps, and vents. They are thus easy to retrofit. Heaters up to approx. 12 kW are used in trucks to preheat the engine. The large body surface area and high interior volume of city and tour buses mean that they require heating capacities of up to 35 kW.

The main types are auxiliary and booster heaters for passenger cars. These heaters are integrated directly in the cooling-circuit feed line between the engine and the heat exchanger of the passenger

cell (Figure 5). They utilize the existing devices: vehicle heat exchanger with blower, air flaps and vents.

Quick-starting heaters are used to meet high demands with regard to heating-up speed; these reach their full heat output level after approx. 30 s. The required acceleration of fuel vaporization is achieved by heating the vaporizing apparatus electrically during the starting sequence.

Auxiliary heaters for preheating engine and passenger compartment before starting driving

Heat is generated through combustion of fuel along similar lines to air heaters. The generated heat is transferred to the cooling water flowing between the water jacket and heat exchanger (Figure 7) of the heater.

The simplest method of integrating them in the vehicle's cooling system is to

Figure 5: Coolant heater, integrated in cooling circuit
(Standard type)

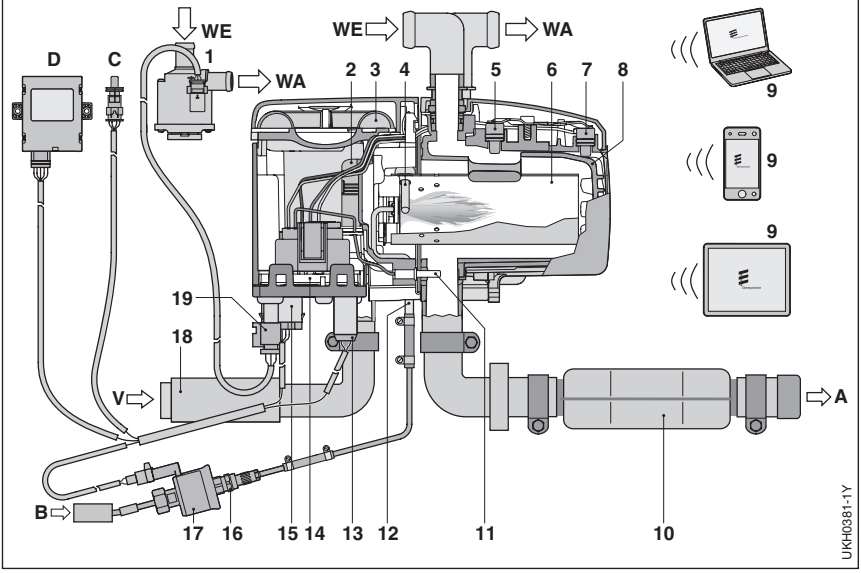
Separation by thermostat and non-return valve into small water circuit (priority for interior heating) and large water circuit (with motor).



connect them in series between the engine and the heat exchanger in the primary circuit (Figure 5). A disadvantage with engines over approx. 2.5 l is that engine heating makes heating the passenger compartment much slower. In this case, the passenger cell can be heated as a matter of priority via an additional small circuit (Figure 6). This offers, irrespective of the engine, the advantage of being able to use the heating also for short-distance service without discharging too much the starter battery, which during the starting phase powers the glow element, the burner fan, the water pump, and the metering pump. Flow passes through the engine only after the thermostat opens when a high water temperature is reached. The non-return valve prevents the circuit from being bypassed via the thermostat.

The water pump (Figure 7) in auxiliary heaters pumps cooling water to the heating-system heat exchanger, where it is heated by heat transfer by the burner exhaust gas. On the one hand, the heated water preheats the vehicle engine; on the other hand, the vehicle's own heat exchanger (Figures 5 and 6) dissipates the heat. The heated air is blown controllably through the existing ventilation system into the vehicle cabin.

Control for manual immediate operation and for preprogramming switch-on times and heating duration is performed via radio remote control, via the Internet for example by means of a smart-phone app, or via a menu in the vehicle's own A/C operator unit.

Booster heaters for covering heat deficits while driving
Efficiency-optimized drivetrains, such as highly turbocharged diesel and gasoline engines with small displacements and hybrid drives, generate on account of their efficiency insufficient waste heat to heat the passenger compartment. Booster heaters are used to make up this heat deficit. They operate only at outside temperatures below +5 °C and when the engine is running. They therefore do not require their own water pump.

Booster heaters can be upgraded to an auxiliary heater by retrofitting a water pump and a control element with ECU.

When used in an electric vehicle or in a plug-in hybrid vehicle, the fuel-powered heater can cover the entire heat demand.

Installation
To avoid heat losses through long cooling-water hoses, coolant heaters are usually installed in the engine compartment. The confined installation conditions necessitate a very compact construction. Installation is simplified by integrating all the components required to generate and deliver heat in the heater unit (Figure 7).

Regulations
All auxiliary heaters and booster heaters run on fuel have type approval in accordance with ECE Regulations No. 10 [1] and No. 122 [2].

If a heater with this type approval is retrofitted in line with the manufacturer's installation instructions, no inspection/approval by an expert or inspection body is prescribed. The installation of auxiliary heaters in vehicles used for international transport of hazardous goods is governed by the European ADR agreement (Accord européen relatif au transport international des marchandises Dangereuses par Route). The heater must be switched off for safety reasons before the vehicle enters a hazardous area (e.g. refinery or filling station). The heating also switches off automatically as soon as the vehicle engine is shut down or an ancillary (e.g. auxiliary drive for discharge pump) is switched on.

Regulations in the USA
The heater requires CARB approval (emissions certificate) for installation and operation in medium and heavy commercial vehicles.

Comfort and convenience systems in the door and roof areas

Power-window systems

Power windows have mechanisms that are driven by electric motors. There are two types of design in use (Figure 1):

– Arm window lift: The window-lift-drive pinion engages with a quadrant gear, which is connected to a rod linkage. This system is highly efficient. On the down side, the system requires a large amount of space for fitting and is heavy.
– Flexible cable window lift: The window-lift drive turns a cable reel, which operates a flexible cable mechanism. Systems with two guide rails are used for the most part in front doors. Systems with one guide rail are preferred in rear doors. A crucial advantage of these designs is their excellent ability to guide the window glass.

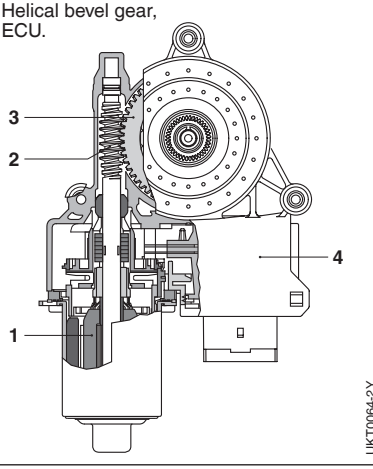
a) Arm window lift, b) Flexible cable window lift.
1 Power-window drive,
2 Guide rail,
3 Driver,
4 Rod linkage,
5 Drive cable (Bowden cable),
6 Quadrant gear.



Power-window drive

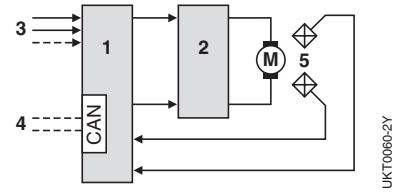
The power-window drive consists of a DC motor with downstream reduction gearing (Figure 2). For comfort and safety reasons, many power-window drives are equipped with an ECU. The gearing is designed as a helical bevel gear to create the necessary self-inhibiting effect which prevents the window from opening inadvertently of its own accord or being opened by force. Special tribological measures and the magnetic-circuit configuration of the DC motor further improve the drive's self-inhibiting properties. Space limitations inside the door make narrow (flat) drive units imperative.

Dampers integrated in the gearing mechanism provide good damping characteristics at the window-glass end positions.

Figure 2: Power-window drive with integrated ECU
1 Power-window drive motor,
2 Worm,
3 Helical bevel gear,
4 ECU.

Electronic control unit (ECU)

Two different operating modes are used. In manual mode the power-window drive is operated using a switch which is pressed over the full extent of window travel. In automatic mode the window glass is opened or closed by a short pressing of the switch.



A force-limitation device is required by law to avoid injuries in the course of au-

tomating closing. In Germany, paragraph 30 of the StVZO [1] (Road Traffic Licensing Regulations) stipulates that the force-limitation device must be effective when the window is moving upwards within a range of 200 to 4 mm from the upper edge of the window aperture. The power-window drive includes integral Hall sensors to monitor motor speed during operation (Figure 3). If a drop in speed is detected, the DC motor's direction of rotation is immediately reversed. The window closing force, measured for a spring rate of 10 N/mm, must not exceed 100 N. To be able to close the window safely, the force-limitation device is automatically deactivated before the window glass enters the door seal. The window position is monitored over its entire range of movement.

Depending on the vehicle topology, the electronic control may be accommodated in a central ECU or decentrally in the door, preferably directly in the power-window drive. Decentralized electronics can be networked via a LIN-bus interface. The advantages of such a solution are fault diagnosis of the electronics and reduction of the amount of wiring.

Sunroof systems

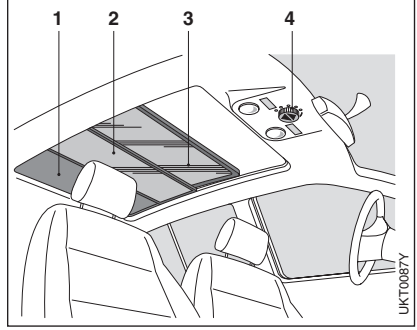
Design variations
Power-sunroof drives can combine tilting- and sliding-sunroof functions. Three different types of sunroof systems may be used:
– The simple sliding/tilting sunroof: A panel (frequently made of glass) can be tilted or slid to the rear underneath the roof skin.
– The large sunroof or panoramic sunroof: This system utilizes up to three sliding-sunroof drives with different adjustment options (Figure 1, e.g. adjusting a glass panel in the front and rear areas, or with a fixed glass panel and an electrically adjustable roller sun blind).
– The spoiler sunroof: Here the glass panel is tilted and then moved to the rear over the roof skin (hence the term “spoiler”).

Power-sunroof drives
Sunroofs and roller sun blinds are primarily adjusted by means of torsion- and pressure-resistant control cables or plastic toothed straps with mechatronic drives. These are located in the roof between the windshield and the sliding sunroof or at the rear of the vehicle.

In the event of an electric-adjustment failure, the sunroofs can be closed by means of a hand crank provided on the drive.

The drive consists of a permanent-field DC motor with helical gear drive, a power output of approximately 30 W and an ECU. The motor is protected against thermal overload by software thermal protection.

Electronic control
The electronic control system operates with a microcomputer responsible for evaluating incoming signals and monitoring sliding-sunroof position.



Control is provided by means of exact position pulses. The pulses come from the ring magnet (up to 12-pole), which is mounted on the motor armature. They are sensed and evaluated by two Hall-effect switches. As well as exact positioning, it is also possible to effect closing-force limitation in order to avoid injuries during automatic operation when both opening and closing.

The drive is actuated via external signal inputs using pushbuttons, switches, and analog or digital preselector switches (e.g. potentiometers, digital sensing via Gray code).

Control can be integrated in the vehicle’s bus system (CAN, LIN) and diagnostic information can be output. Electronic control offers the opportunity to easily implement a wide range of functionalities and comfort and convenience functions (e.g. preselectable position control, closing via remote control, automatic closing in the event of rain, combination with the central locking system).

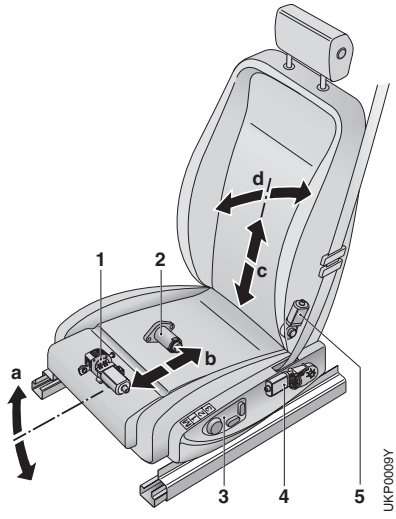
Comfort and convenience functions in the passenger compartment



Electrical seat adjustment

On the one hand, the electrical seat adjustment ensures greater operating convenience than mechanical operation, and, on the other hand, it is also preferred on account of its lower space requirement or in the case of poor accessibility of the various adjustment planes.

The four main adjustment planes feature longitudinal adjustment of the full seat, tilt adjustment of the seat backrest, and height and tilt adjustment of the seat cushion.

Figure 1: Electromechanical seat adjustment

5 Electric drive for tilt adjustment of the seat backrest,
a Tilt adjustment of the seat cushion,
b Longitudinal adjustment of the full seat,
c Height adjustment of the seat,
d Tilt adjustment of the seat backrest.

Drives

Electric motors with different gear variants are used (e.g. lifting and rotating spindles, planetary gears, and two-stage spur gears) are used as drives for electrical adjustment.

To simplify entry and exit, the drives can be designed in such a way that adjustment is completed particularly quickly (easy entry). This function is particularly useful for gaining access to the second row in a two-door vehicle.

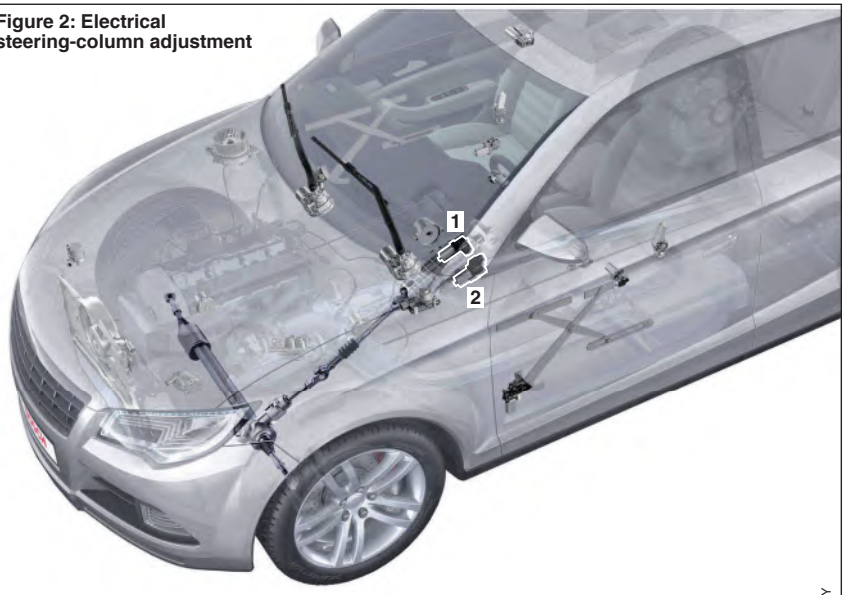
Position detection

Drives with position detection are increasingly being used to enable the seat position to be stored individually for different drivers and to retrieve and adjust this position (memory function). Position detection is effected either via Hall generators or via sensorless evaluation of the current signals from the electric motor (also called Sensor Less Control, SLC).

The memory function simplifies and speeds up adjustment of the seat position for an individual driver after a change of driver.

Further adjustment options

Aside from the four main adjustment planes for the driver and the front passenger, a wide range of additional adjustments can be performed electrically such as seat-cushion depth, head restraint, and lumbar support.



Electrical adjustments are increasingly also being performed for the second and third seat rows in larger vehicles (e.g. off-road vehicles). A significant motivation for this is to make it much easier and more convenient to load larger objects.

Electrical steering-wheel adjustment

A further comfort and convenience function which is often combined with electrical seat adjustment is electrical steering-wheel adjustment. Here both the longitudinal clearance and the height of the steering wheel can be infinitely adjusted via a drive similar to the spindle drives for seat adjustment.

This function is particularly useful in combination with the memory function. In this way, for example, entry and exit are made easier by extending the clearance between the driver's seat and the steering wheel prior to entry and exit. During driving the positions of the seat and steering-wheel adjustments individually preprogrammed for the driver are set.

Figure 2: Electrical steering-column adjustment

Safety systems in the motor vehicle

Phases of vehicle safety

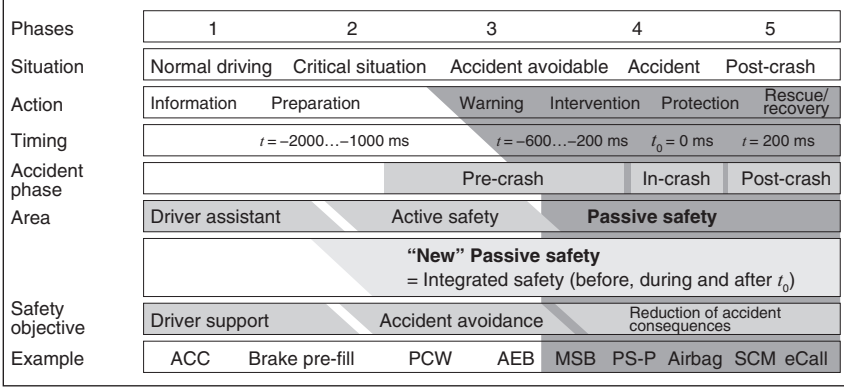
Vehicle safety can be broken down into the categories of active safety and passive safety. Active safety systems help to prevent an accident. Passive safety systems are used when an actual accident occurs.

Vehicle safety is divided into five phases (Figure 1). Active safety includes normal driving, in which safety systems issue warnings, provide recommendations, or make corrections (phase 1 and phase 2). In the event of a collision passive vehicle safety intervenes in a protecting (phase 3 and phase 4) and in the post-crash phase in a life-saving capacity (phase 5).

Different safety systems are available, depending on the vehicle equipment. Owing to its effectiveness in accident avoidance, driving-dynamics control (Electronic Stability Program, Electronic Stability Control, ESC) for example has established itself in all vehicle classes and has been required by law in Europe since 2012 for newly registered vehicles.

Normal driving operation

Belt-reminder system



If the driver or front passenger does not have their seat belt fastened, there is a visual and acoustic warning signal (SBR, Seat Belt Reminder, belt-reminder system, Figure 2a). Sensing is performed for example by means of a seat-occupancy mat (see Occupant sensing). The presence of further occupants in the rear passenger compartment is optionally detected via sensors. In this case, the term used is Enhanced Seat Belt Reminder (ESR).

Child seats

The use of child seats is required by law. Provisions also stipulate that the front-passenger airbag must be deactivated if a rear-facing child seat is placed on the front passenger seat (COP, Child Occupant Protection). The airbag can be manually or automatically switched depending on regional variation. The corresponding function lamp lights up when the airbag is deactivated (Figure 2b).

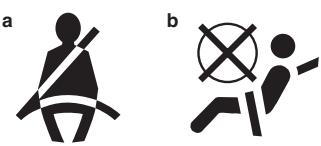
PS-P: Presafe-Pulse, triggering before t_0
Brake pre-fill: Application of brake pads
AEB: Automatic Emergency Braking
SCM: Secondary Collision Mitigation
eCall: emergency Call



Critical situation
If a critical situation ensues for example in response to full braking or in the event of braking on a different surface, targeted brake interventions on individual wheels and interventions in the engine management bring about a stabilization of the vehicle (driving-dynamics control). Another example of how the vehicle is prepared for a potential accident is the pre-filling of the brake system (brake pre-fill). The braking effect starts earlier once the brake pedal is pressed, resulting in a shorter braking distance.

However, physical limits are placed on the effectiveness of these safety systems. An accident is unavoidable if these limits are exceeded.

Before the crash
For improvement of the deployment function of the occupant-protection systems and advance detection of the type of impact (pre-crash detection), microwave radar, ultrasound or lidar sensors are used to measure relative speed, distance, and angle of impact for frontal impacts. If distances are too short at a corresponding speed, optical and acoustic warnings can be issued or the brake can be activated (AEB, Automatic Emergency Brake, see Emergency brake systems). Electromechanical reversible seat-belt pretensioners are used with pre-crash sensing. The fact that they are reversible means that in a dangerous situation they can already be tightened prior to a possible collision. In this way, belt slack is already eliminated before the crash, enabling the occupants already at an early stage to participate in the vehicle's deceleration during a braking operation.

Figure 2: Warning lamps in the instrument cluster
a) Symbol lights up if seat belt is not fastened.
b) Front-passenger airbag deactivated.

During the crash
The crash starts at t_0, the moment of first vehicle contact (in-crash) with the obstacle, and ends with the vehicle at a standstill. In this time window all the relevant retention systems are activated (see Occupant-protection systems) and if necessary emergency braking is initiated; this is intended to avoid a potential secondary accident or to mitigate the accident severity.

After the crash
Event Data Recorder
Vehicles with airbag systems store data relevant to the accident, e.g., impact accelerations, belt-buckle states or airbag deployment times, in a non-volatile memory of the airbag ECU (EDR, Event Data Recorder, crash recorder). The volume of data varies depending on the vehicle manufacturer and records a period of around 100 ms before and after the impact.

This enables the accident to be analyzed to a certain extent. For example, accidents with airbag deployment can be distinguished from near-accidents (near misses) and also accidents without airbag deployment. For another thing, the data permit a partial reconstruction of the vehicle situation before the accident for accident-research purposes. In addition, statutory requirements are thereby fulfilled. Thus, in the USA the use of an event data recorder in new vehicles has been required by law since 2012.

eCall
eCall (abbreviated form for emergency call) is an automatic emergency-call system for motor vehicles prescribed by the European Union which since April 2018 has been required to be installed in all new models of passenger cars and light commercial vehicles.

The airbag ECU activates, aside from hazard warning lights, door openers, deactivation of the fuel pump, and isolation of the battery, an emergency call via a carphone installed in the vehicle. The emergency-call center automatically receives information on the exact location of the vehicle and can if necessary talk to the occupants and initiate recovery and rescue operations.

Active safety

The aim of active safety is already in advance to prevent an accident from happening. The level of technical vehicle equipment helps to recognize dangers quickly in normal driving conditions and to avoid accidents. Active safety therefore already begins with a good view of the road traffic even at dusk/dawn and at night. The range of vision was virtually doubled when Bilux lights were replaced by halogen lamps in the 1970s. The introduction of xenon and LED headlights were further milestones.

Well-conceived operating concepts e.g. for the infotainment system via the multifunction steering wheel and the depiction of information in a head-up display enable the driver to keep their eyes on the road and the traffic. Even this is a contribution to active safety.

In the field of driver assistance the brake booster and power steering for example offer the potential to avoid accidents.

But active road safety also includes the driver's driving qualifications (e.g., driving-safety training), their traffic literacy and competence, their traffic-appropriate behavior, and their own responsible actions and initiative.

But, generally speaking, active safety refers to systems which actively intervene in the driving dynamics and thus actively support the driver. These systems are also called driver-assistance systems.

Examples of active safety systems

Active safety systems require information about the vehicle's driving and operating state (e.g., wheel speeds, yaw rate, steering-wheel angle) and also information about the vehicle's environment or surroundings (e.g., distance to the vehicle traveling in front). The advances in sensor technology led to the development of numerous active safety systems.

1978 saw the introduction of the first antilock braking system (ABS) ready for series production, a system which prevents the wheels from locking during heavy braking and thus keeps the vehicle steerable (see Wheel-slip control systems). Further development led to driving-dynamics control (Electronic Stability Control, ESC), in which the antilock braking system and the traction control system are integrated and which additionally detects the vehicle's swerving/skidding tendency and counteracts this tendency with targeted wheel-individual brake interventions and interventions in the engine management.

Adaptive Cruise Control (ACC), initially developed as a comfort and convenience system, has developed further in the direction of an active safety system. It relieves the strain on the driver by automatically adapting the speed to the vehicle traveling in front and where necessary brakes the vehicle to a standstill. In this way, the safety distance is constantly maintained.

Emergency Brake Assist performs an emergency-braking operation if it detects an object in front of the vehicle.

Lane Keeping Support warns the driver for example by vibrating the steering wheel if the vehicle leaves the lane without a turn signal having been activated. If the driver fails to react, the system can automatically steer the vehicle back to the original lane.

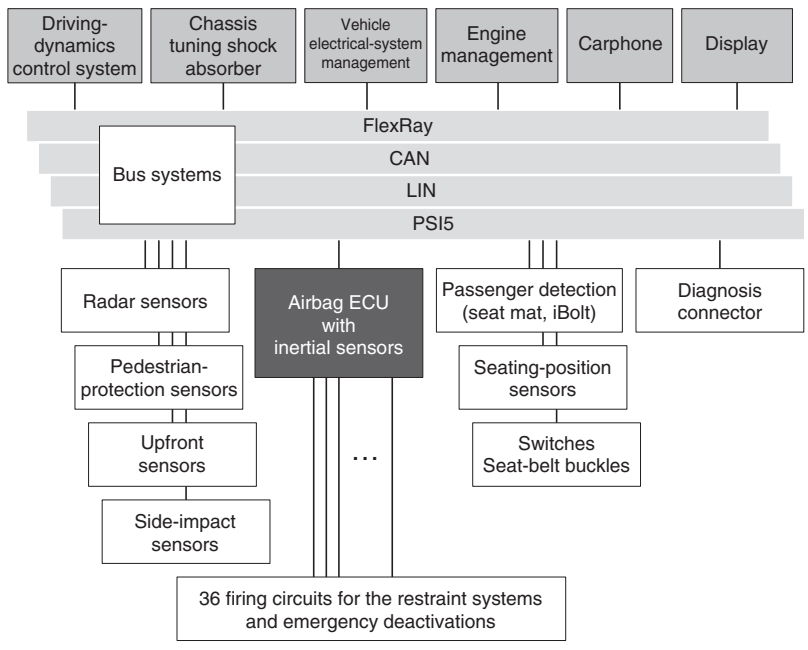
Blind-spot assistants and lane-change assistants monitor the areas to the sides of and behind the vehicle and warn the driver when a vehicle is approaching. These systems thus warn when a passing (overtaking) maneuver cannot be safely carried out.

Importance of active safety

Safety in motor vehicles was previously confined to passive safety. Occupant-protection systems have in the meantime become a matter of course; advances in these systems are more likely to occur in the background. Active safety systems are constantly subject to further development and new systems are always arriving. They are deployed initially in premium vehicles and then also appear in the lower vehicle classes. New active safety systems are vigorously promoted by the vehicle manufacturers.

Passive safety

Passive safety in a car increases occupant protection in the actual event of an accident. There are 150 milliseconds which decide in the event of a car accident whether the outcome remains confined to damage to property or escalates to serious injuries to the occupants. If an accident occurs, numerous vehicle components can be crucial to survival. From the passenger safety cell extending across a stable body, crumple zone, energy-absorbing steering column and headrests through to airbags and seat belts with belt pretensioners (see Occupant-protection systems), passive safety is aimed at mitigating the consequences of an accident. Many of these components are required by law and are therefore standard equipment in the vehicle.



Whereas active safety aims at avoiding an impending accident entirely, passive safety is intended to mitigate the consequences of an unavoidable accident. By linking with driver assistance and active safety, new enhanced passive-safety functions provide for more comprehensive occupant protection (see Figure 1).

System architecture, passive safety
The passive-safety functions are specific to the manufacturer, vehicle, and equipment specification. Figure 3 shows a possible architecture.

The airbag ECU collects information on the speed, temperature, belt-buckle states, the seating position of the occupants, and registers activation of the ignition. Diagnoses, driving states, and accidents are recorded in the vehicle and stored in an event recorder. Data can be read via the diagnosis connector and if necessary software updates can be performed.

Inertial-sensor signals, i.e., accelerations and yaw rates in all three directions, are also made available for other systems. In this way, spring-damping systems or

Figure 3: System architecture, passive safety

even brake and steering systems can be activated with these signals to optimize and stabilize the vehicle in terms of driving dynamics.

The information already in the lead-up to a crash – e.g., on the relative speed, moment of impact of potential collision objects – comes from a radar, lidar or video sensor system. This enables seats or reversible belt pretensioners for example to be preconditioned for the crash situation or warning signals to be issued.

The vehicle electrical-system management uses the signals from the airbag ECU to control the airbag warning lamps, the status of the seat belts and seat occupancy, the hazard-warning lights, and emergency door opening.

An emergency call is sent via the carphone in the event of a crash; there is also the possibility of communicating information on medical treatment to the emergency services in advance. The engine management switches off the fuel pump after a crash; if necessary, the battery is isolated.

Legal regulations and consumer tests

Legal regulations

Requirements with regard to passive safety in vehicles are laid down in legislation. These cover safety of drivers, passengers, and in particular children and pedestrians.

Safety requirements laid down in the EU are for example the provisions pertaining to head-on- and side-impact protection for the vehicle occupants and pedestrian protection. These are reflected in UN/ECE regulations, which apply to the EU but have in the meantime also be adopted by many non-European countries. Other countries follow these regulations to a large extent (exception: USA).

The USA has the Federal Motor Vehicle Safety Standards (FMVSS), which constitute the technical regulations pertaining to vehicle safety and are legislative in character.

Consumer tests

The country-specific NCAP (New Car Assessment Program) is intended to provide car buyers and car manufacturers with a realistic and independent assessment of the safety features of some of the biggest-selling vehicles. Standardized crash and rollover tests of vehicles are conducted for this purpose. The vehicles are occupied by dummies during the crash tests. The safety assessment is derived from the measured values recorded on the dummies. To assess the safety of child seats, child dummies are placed in the child seats recommended by the vehicle manufacturer.

Thus, Euro NCAP is a voluntary European program for assessing vehicle safety which is supported by the European Commission and a number of European governments, and by automobile clubs and consumer organizations. Euro NCAP publishes safety reports on new cars and awards a star rating, based on the performance of the vehicles in various crash tests, including head-on, side and pole impact and collisions with pedestrians [1]. The highest rating is five stars. The requirements imposed on the star rating increase in parallel with vehicle development so that a 5-star car ten years ago is not comparable with a 5-star car today.

The test conditions are constantly updated, the test program extended to include additional tests, and the assessment criteria tightened. More recent findings concerning accidents and their causes are reflected in new test-condition requirements. Where originally only the results from the crash tests were used for assessment, assessments of active safety (e.g., lane departure warning, emergency brake assist) are increasingly being included in the overall assessment.

Occupant-protection systems

In the event of an accident, occupant-protection systems are intended to keep the accelerations and forces that act on the passengers low and thereby lessen the consequences of the accident.

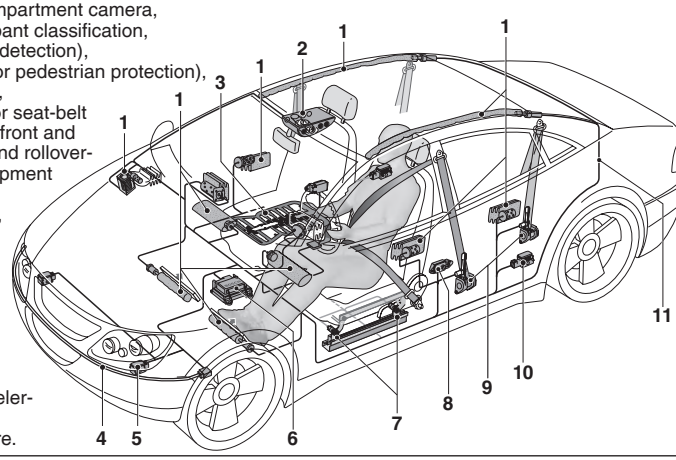
Seat belts with belt pretensioners provide a substantial proportion of the protective effect, absorbing the majority of the kinetic energy of the occupants. Together with a front airbag, the energy in the crash must be reduced in such a way that the occupant is not propelled up against the steering wheel or the dashboard.

In order to achieve optimum protection, the response of all components of the occupant-protection system must be adapted to one another. This is made possible by suitable sensors and high-speed signal processing. Optimum occupant protection against the effects of an impact is obtained through the precisely coordinate interaction of electronically fired, pyrotechnically inflated front airbags and seat-belt pretensioners. To maximize the effect of both protective devices, they are activated by the airbag ECU (triggering unit) installed in the passenger cell.

Figure 1 provides an overview of the occupant-protection systems in a passenger car.

Functions

Environment sensing



The ECU detects the different types of impact (e.g., head-on, oblique, offset, pole, rear-end, side impact) in the vehicle longitudinal direction (x-axis) and vehicle transverse direction (y-axis) with the aid of integrated acceleration sensors or structure-borne noise sensors. From their signals the crash severity and crash type to be expected is determined so that the appropriate retention systems can be activated at the right time.

Peripheral acceleration and pressure sensors installed on the vehicle body are connected via leads to the ECU. They facilitate earlier detection of vehicle contact and hence improved performance with regard to deployment of the retention systems. Especially in the case of side impacts with a small crumple zone, high-speed pressure sensors installed in the door have an advantage over acceleration sensors.

Rollover detection is performed by yaw and acceleration sensors. Aside from the yaw rate about the longitudinal axis, the vehicle lateral acceleration (y-axis) and the acceleration in the direction of the vertical axis (z-axis) are sensed.

Figure 1: Occupant-protection systems

8 Peripheral pressure sensor,
9 Seat-belt pretensioner with propellant charge,
10 Peripheral acceleration sensor,
11 Bus architecture.

The analysis algorithms in the ECU read in the data from the sensors permanently and compute whether an accident is occurring.

Activation of retention systems

The sensor signals are evaluated by intelligent algorithms, the parameters of which are optimized specifically for individual vehicles with the aid of simulations and crash tests. The airbag should not trigger from a hammer blow in the workshop, gentle impacts, bottoming out, or driving over curbstones or potholes.

The retentions systems connect to the ECU are activated when the trigger thresholds are exceeded. Current pulses activate pyrotechnic firing elements, which trigger the airbags or other retention systems.

In the event that the power supply to the ECU is interrupted by the vehicle battery as a result of the crash, a built-in power reserve provides the necessary availability.

The firing of retention systems for the relevant seat occurs only when the seat-belt buckle is connected; this is monitored by a seat-belt buckle switch.

Special functions

Advanced Rollover Sensing

The "Advanced Rollover Sensing" function uses signals from the driving-dynamics-control sensors to better detect soil-trip rollover processes. These data are used by the airbag ECU to calculate the speed vector and the lateral velocity. From these the deviation of the vehicle-motion vector from the vehicle's longitudinal axis and thereby lateral vehicle motion are determined.

Early Pole Crash Detection

The "Early Pole Crash Detection" function also uses the signals from the driving-dynamics-control sensors to better detect a side-on pole impact. In the event of a side-on pole impact the vehicle skids before the impact; this is detected with the yaw sensor. The information regarding the lateral movement of the vehicle is then used in the triggering algorithm to accelerate triggering of the side airbags.

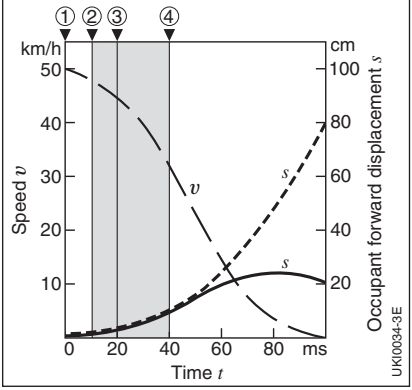
Secondary Collision Mitigation

In the event of accidents the initial collision may be followed by further collisions by the accident vehicle, for example as a result of the driver losing control of the vehicle. This phenomenon puts both the vehicle occupants and other road users at risk. The "Secondary Collision Mitigation" function provides assistance in the event of such accidents. If an impact occurs, the airbag ECU transmits this information to the driving-dynamics control ECU. The driving-dynamics control uses specifically targeted brake interventions to slow down the vehicle or where necessary to shut down the engine. Consequential accidents can thus be avoided or their severity reduced.

Further safety measures

By networking driving-dynamics control and airbag ECU, it is possible also to utilize the detection of unstable or critical states to initiate more specifically targeted safety measures. When an unstable driving state is detected, safety measures can be introduced in stages; these measures can include closing the windows and the sliding sunroof, and tightening a reusable (reversible) motor-driven seat-belt pretensioner.

Retention systems and actuators



Seat belts and belt pretensioners

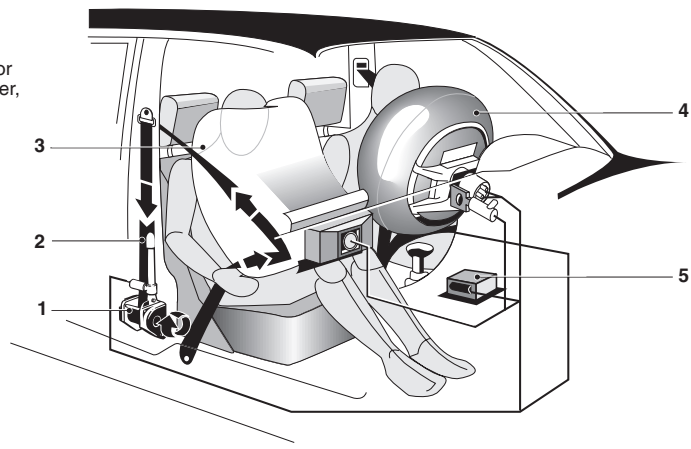
Seat belts

The function of seat belts is to restrain the occupants of a vehicle in their seats when the vehicle impacts against an obstacle. In this way, the occupants are already involved at an early stage in the deceleration of the vehicle during an impact (Figure 2).

Figure 2: Deceleration to standstill and forward displacement of an occupant at an impact speed of 50 km/h

① Impact,
② Firing of belt pretensioner and airbag,
③ Belt tensioned,
④ Airbag inflated.
– – – Forward displacement w/out restraint system.
—— Forward displacement w/ restraint system.

The standard type is the three-point belt with inertia-reel device. The belt buckle and the inertia-reel device are mounted on the seat or on the body (Figure 3). A loosely fitting belt (for example, when thick winter clothing is worn) results in belt slack. The softness of the clothing prevents the occupant from being involved at an early stage in the deceleration of the vehicle in the event of a collision. The occupant initially continues moving without being restrained, which reduces the protective effect of the belt. Furthermore, the slowed-down effect of the belt locking in an accident and the belt-webbing elongation contribute to belt slack.



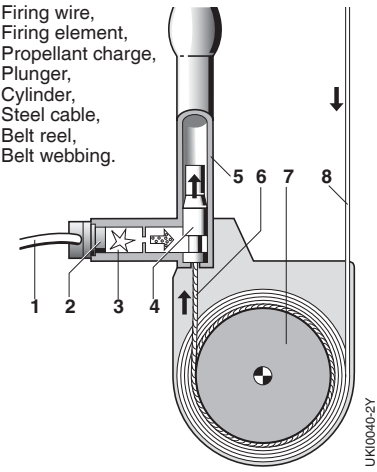
Because of belt slack three-point inertia-reel belts only afford limited protection in the event of a frontal impact at speeds in excess of 40 km/h against solid obstacles, because they cannot safely prevent the head and body from striking the steering wheel and the dashboard.

Shoulder-belt pretensioner

When activated, the shoulder-belt pretensioner eliminates the belt slack and the "film-reel effect" by rolling up and tight-

Figure 3: Occupant-protection systems with seat-belt pretensioner and front airbags

1 Inertia-reel device with seat-belt pretensioner,
2 Seat belt,
3 Front airbag for front passenger,
4 Front airbag for driver,
5 ECU.



ening the belt webbing. Here, the system electrically fires a pyrotechnic propellant charge (Figure 4). The gas charge released in this process acts on a plunger, which turns the belt reel via a steel cable in such a way that it is held tightly against the occupant's body. The belt webbing is therefore tightened already before the occupant starts their forward movement. With these belt pretensioners the belt webbing can be pulled back within a period of 10 ms by up to 12 cm.

Electromechanically actuated belt pretensioners are reversible and can therefore already be activated early in a hazardous situation without there being a collision.

Buckle tightener
When triggered by a propellant charge or by spring systems, the buckle tightener pulls the seat-belt buckle back and simultaneously tightens the shoulder and lap belts. It improves the restraining effect and the protection to prevent occupants from sliding forward under the lap belt ("submarining effect").

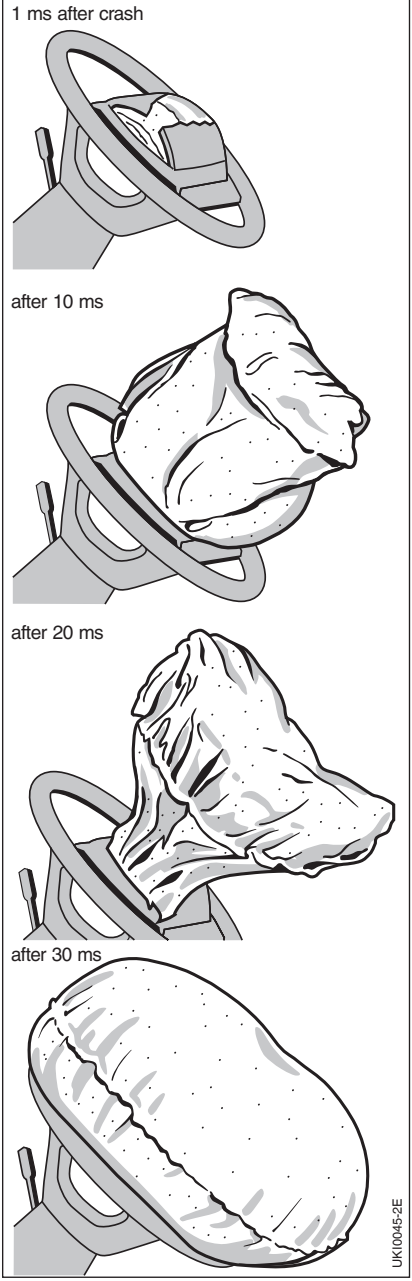
Combination of shoulder-belt and buckle tighteners
The combination of both systems offers greater tightener travel to obtain an improved restraining effect. The two tighteners are activated for the most part simultaneously or with a slight time lag.

Figure 4: Shoulder-belt pretensioner
1 Firing wire,
2 Firing element,
3 Propellant charge,
4 Plunger,
5 Cylinder,
6 Steel cable,
7 Belt reel,
8 Belt webbing.

Belt-force limiter
The maximum force of the belt is limited in order to limit the forces on the occupant's torso in the event of serious crashes. Otherwise the occupant may suffer broken collarbones and ribs with resulting internal injuries.

This can on the one hand be performed by a mechanical belt-force limiter, which limits the belt force to around 4 kN. This is effected for example by the deformation of a torsion bar in the belt-retractor shaft or a deployment control seam in the belt.

An additional protective effect is provided by an electronically controlled belt-force limiter, which after reaching a defined forward displacement reduces the belt force by activating a firing element to 1 to 2 kN.



Airbags and gas inflators
Front airbags
During an accident front airbags protect the driver and the front passenger against head and chest injuries (Figure 3) which can occur when the head strikes the steering wheel or the dashboard.

To perform this function, airbags have, depending on the installation location, type of vehicle, and structure-deformation behavior of the vehicle body, different filling capacities and shapes adapted to the vehicle conditions.

Pyrotechnic gas inflators inflate the driver and passenger airbags using dynamic pyrotechnics after a vehicle impact detected by the acceleration sensors (Figure 5). In order to achieve maximum protection, the airbag must be fully inflated before the occupant comes into contact with it. When the occupant comes into contact with the airbag, the airbag is partially deflated via deflation vents. The impact energy acting on the occupant is "softly" absorbed with noncritical (in terms of injury) surface pressures and deceleration forces.

The inflation speed and the hardness of the inflated airbag can be influenced in the case of two-stage gas inflators by a delayed firing of the second stage, which

Figure 5: Highly dynamic deployment of the driver airbag

injects and additional charge of air into the airbag in the event of high crash severity.

The maximum permitted forward motion of the driver until the airbag on the driver's side has inflated is approx. 12.5 cm. This corresponds to a time of approximately 40 ms in the case of an impact at 50 km/h on a hard obstacle. 10 ms after the impact the gas inflator is activated and after 30 ms the airbag is inflated. The airbag deflates after another 80 to 100 ms through the deflation vents.

Depowered airbags

So as not to put children and very light adults on the front passenger seat at risk from the inflation process, "depowered airbags" with a reduced inflation force are used above all in the USA.

To this end, in less serious accidents at reduced speed up to around 30 km/h the airbags are inflated with 20 to 30 % less gas-inflator output, reducing the inflation speed and the hardness of the inflated airbag. This reduces the risk of injury for occupants who are "out of position" (posture diverging from the normal seating position).

With the low-risk deployment method, depending on the severity of the impact, only the first front-airbag stage is fired or else both inflator stages to bring the full gas-inflator output to bear.

Airbags with active ventilation system

These airbags have a controllable deflation valve to maintain the internal pressure of the airbag constant even if an occupant falls against it and to minimize occupant trauma. A simpler version is an airbag with "intelligent vents". These vents remain closed (so that the airbag does not deflate) until the pressure increase resulting from the impact of the occupant causes them to open and allow the airbag to deflate. As a result, the airbag's energy absorption capacity is fully maintained until the point at which its motion-damping function comes into effect.

Knee airbag

In a few vehicle types, front airbags also operate in conjunction with inflatable knee pads, which safeguard the "ride down benefit", i.e., the speed decrease of the

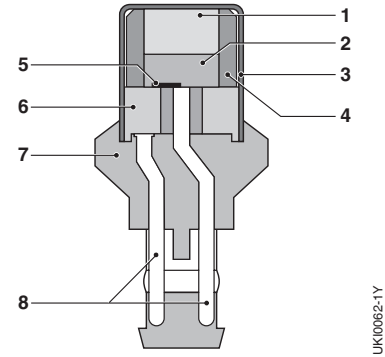
occupants together with the speed decrease of the passenger cell. This ensures that the upper body and head describe the rotational forward motion which is needed for the airbag to provide optimum protection. Furthermore, the knee airbag prevents contact with the dashboard support and thereby reduces the risk of injury in this area.

Side airbags
Side airbags which inflate along the length of the roof lining for head protection (e.g., inflatable tubular system, window bag, inflatable curtain) or for upper-body protection from the door or seat backrest (thorax bag) are designed in the event of a side impact to push the occupants away from the impact location and facilitate a cushioning of the impact and thereby protect them from injury.

The challenge for side airbags is the shorter time available for inflation compared with front airbags. Here there is no vehicle crumple zone and the spacing between the occupant and the vehicle body is very small. The time for crash sensing and activation of the side airbags must therefore be approximately 5 to 10 ms in the case of severe side impacts. The inflation duration for thorax bags may not exceed 10 ms.

Additional airbag equipment
A further improvement in the restraining effect is optionally provided in individual vehicles by airbags integrated in the thorax section of the seat belt (air belts, inflatable tubular torso restraints or bag-in-belt systems), which reduce the risk of broken ribs.

Inflatable headrests protect against whiplash and cervical-vertebrae injuries in the event of a rear-end impact (adaptive headrests), inflatable carpets on the other hand protect against foot and ankle injuries. Active seats, in which an airbag in the front section of the seat surface is inflated, impede the occupant's forward sliding movement (submarining effect).



Gas inflators
The gas inflator fills the airbag with gas and actuates the belt pretensioner. The pyrotechnic gas inflator contains a firing pellet, which when activated in turn ignites a solid propellant. The gas passes through a metal filter and the inflator's outlet ducts into the airbag.

The firing pellet (Figure 6) contains a reservoir holding the propellant charge and a priming wire. The firing pellet is connected to the airbag ECU via the connector pins and a two-wire circuit. To trigger the airbag, the ECU uses firing output stages to generate a current, which flows inside the firing pellet through the priming wire. This wire glows and activates the propellant charge.

The driver airbag fitted in the steering-wheel hub (volume approximately 60 liters) and the passenger airbag fitted in the glovebox space (approximately 120 liters) are inflated approximately 30 ms after firing.

Enhanced protective functions
Rollover protection
If a car turns over, there is the danger that non-belted occupants may be thrown through the side windows, or that parts of the bodies of belted occupants (e.g., arms) may protrude from the vehicle and

Figure 6: Firing pellet

7 Housing,
8 Connector pins.

incur serious injury. To provide protection in such cases, existing restraint systems such as seat-belt pretensioners and side and head airbags are activated. In convertibles, the extendable rollover bars or the extendable head restraints are triggered.

A rollover is sensed in the vehicle transverse and vertical directions (y- and z-axes) with micromechanical yaw sensors and high-resolution acceleration sensors integrated in the airbag ECU. The yaw sensor is the main sensor, while the y- and z-axis acceleration sensors are used both to check plausibility and to detect the type of rollover (slope, gradient, curb-impact or soil-trip rollover).

Depending on the rollover situation, yaw rate and lateral acceleration, the retention systems and actuators are activated and deployed after 30 to 3000 ms.

Pedestrian protection
This function is intended to avoid injuries as far as possible in the event of vehicles colliding with pedestrians. Leg and head injuries can be reduced by appropriate designs of bumpers and engine hood. In addition, in a crash situation the hood can be lifted or an external airbag can cushion the impact (Figure 7). The sensor technology for this purpose (acceleration sensors or a tube with pressure sensors, see Figure 1) is integrated in the bumper. Appropriate tests are an integral part for example of the Euro NCAP crash test.

Occupant sensing

There are various options on the market for occupant classification.

iBolt
Occupant classification can be performed with the iBolt (“intelligent” bolt), an absolute-weight-measuring method. These iBolts (see Figure 1) measure the forces involved and secure the seat frame (suspended seat) on the sliding base, replacing the four mounting screws that are otherwise used. They measure the weight-dependent change in the gap between the bolt sleeve and the internal bolt with integral Hall-element IC connected to the sliding base (Figure 8).

Seat-occupancy mats
Seat-occupancy mats combined with pressure-sensitive elements and matching sensor also perform this function (Figure 9). The information is sent to the ECU and incorporated in the triggering strategy for the means of protection. The seats can be adjusted when backrest angle and position are sensed with suitable actuators during the crash to better protect the occupants.

Deactivation of front-passenger airbag
A manually actuated deactivation switch can be used to disable the passenger airbag. This is required if certain child seats are used in this space.

There is an increasing availability of standardized anchoring systems (ISOFIX child seats). Switches integrated in the anchoring locks initiate an automatic front-passenger airbag deactivation, which must be indicated in the instrument cluster.

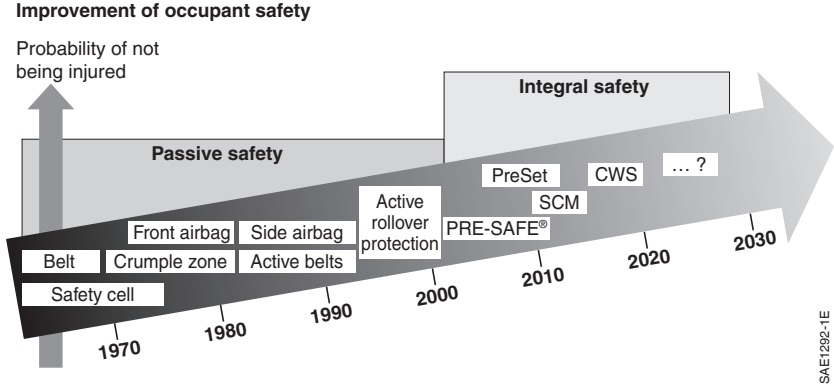
Out-of-position detection

In order to prevent injuries being caused by airbags to occupants who are “out of position” (e.g., are leaning far forwards) or to small children in reboard child seats (seat position pointing towards the rear), the triggering of the front airbag and its inflation must be adapted to the situation.

Enhanced detection of the occupant position and adaptation of the retention systems and their activation are important for future automated driving, since the challenges faced by passive safety increase with the freedom of movement gained by the occupants.

Integral-safety systems

Overview



The road to automated driving will be accompanied in the coming years by a marked increase in the market penetration of environment-sensor systems. The development of new assistance and driving functions necessitated by the introduction of automated driving leads to the availability of additional information on vehicle, environment, and occupants. This extended and networked data basis permits the development of new integral safety concepts with the aim of adapting the vehicle's protective measures to the respective accident situation in the event of unavoidable accidents. Predictive situation analysis in particular facilitates safety measures for preventing accidents or lessening the accident severity. The networking of active and passive safety measures creates the precondition for situational adaptation of the vehicle's automatic protective responses to the respective accident events.

Motivation

It has been possible in the past few years through numerous measures in the automotive industry, traffic research and legislation to reduce the number of traffic fatalities and serious injuries. The fitting prescribed by law of all new passenger cars with driving-dynamics control (Electronic Stability Program, ESP®; Electronic Stability Control, ESC), the introduction of antilock braking systems (ABS) for motorcycles, and lane- change warning systems are mentioned by way of example. Numerous serious accidents still occur despite these measures [1].

Accident protection does not lose in importance even when it comes to automated driving. There is a need for action, since integral safety forms the fallback level of automated driving. The integral-safety approach offers new solutions which will both take into account the individuality of the individual occupant and raise the traffic-safety level through the networking of sensor and safety systems.

PRE-SAFE®: Activation e.g. of reversible belt pretensioners and seat.
PreSet: Improved accident-severity determination by means of environment-sensor technology.
SCM: Secondary Collision Mitigation; braking of vehicle after primary collision to avoid secondary collision.
CWS: Collision Warning System; activation of reversible belt pretensioners when leaving the road in the direction of an extreme surface.

Technology of the present day
Integral safety is based on the networking of components and algorithms of various safety and comfort and convenience systems in the vehicle (e.g., passive-safety retention systems, driving-dynamics control, driver-assistance systems, passenger-compartment sensing). Here, the entire chain of events of an unavoidable accident before, during and after the collision is analyzed to minimize the risk of injury to vehicle occupants and other road users.

The first integral-safety systems were launched in 2002 by Mercedes-Benz under the name PRE-SAFE® in the S-Class. Since 2009 the front close-range radar sensors of the driver-assistance package have also been used with this system to detect potential collision objects with preventive reversible seat-belt tightening. In 2013 this principle was carried over to the vehicle rear end.

A further step in the direction of integral safety was made by the "PRE-SAFE impulse side" function introduced in 2016 for the front seats, in which for the first time pyrotechnics are activated exclusively on the basis of environment-sensor technology. Side-mounted radar-sensor technology detects an unavoidable side impact, whereupon an actuator integrated in the seat imparts to the occupant an impulse towards the center of the vehicle [2].

Figure 1 shows the timeline of the transition from classic passive safety to integral safety. Safety functions and safety components already introduced in the market are depicted.

Solution approaches

Challenges
Since the introduction of radar technology for driver-assistance functions like Adaptive Cruise Control (ACC) or Automatic Emergency Braking (AEB) in the automobile sector, new function ideas have arisen which are founded on the use of environment data to better estimate the accident severity (e.g., the PreSet function for determining accident severity). However, such functions have not been widely used due to the low equipment rate with Adaptive Cruise Control. This situation is changing, as Automatic Emergency Braking has since 2014 been rewarded in the Euro NCAP protocol. As a result, the proportion (equipment rate) of new cars fitted with radar sensors has increased. In spite of this conducive boundary condition there are hurdles for the market introduction of new integral-safety systems:

- Effects of new safety functions only become visible in the accident statistics after a delay, as the rising equipment rate in new-vehicle registrations is set against an old vehicle population.
- Dedicated environment sensors and processing units only for the integral-safety functions have not gained acceptance in the past for cost reasons, which hinders the introduction of independent integral-safety systems.
- Networked functions with numerous data interfaces between assistance and restraint systems entail additional application and validation outlay.

The penetration times of integral-safety systems will follow the market developments with regard to driver assistance, active safety, and automated driving. In the course of the introduction of automatic driving functions the equipment rate with environment and passenger-compartment sensors and with domain ECUs will increase [3]. The introduction of automatic driving functions will ensure the market introduction and market penetration of environment and passenger-compartment sensors and of appropriate domain ECUs. At the same time, occupant protection faces hitherto unknown challenges as a result of these functions. Possible new seating positions,

shifting of the occupant positions during automatic braking or steering operations or larger objects between occupants and airbags change the boundary conditions for the optimum use of retention systems in the event of a collision risk.

Even fundamental elements of present-day vehicles, such as function and E/E architecture, undergo a development process in the course of developments in the fields of electromobility, automated driving, and connectivity. New requirements with regard to safety, communication speed, computing outlay, latencies, and costs drive this development process, which is also useful in the introduction of integral-safety systems.

Application examples

Accident types with head-on collision

Head-on-accident scenarios as depicted in Figure 2 highlight an important sphere of activity for integral safety. The frequently occurring rear-end collision (Figure 2a) can already today be firmly detected in terms of its development by the use of environment-sensor technology. The growing number of vehicles which are equipped with an automatic emergency brake system will reduce the frequency and severity of this type of accident.

Intersection accidents with side collisions as pictured in Figure 2e constitute a further area of use for integral-safety functions. Injury severity is frequently in the middle range. Intersection-assistance systems with left turn-off assist and cross-traffic assist will greatly reduce the frequency of such accidents (see Driver-assistance systems).

The introduction of Electronic Stability Programs, lane-departure warning systems, and functions for detecting driver fatigue brought about a reduction of in collisions caused by the vehicle leaving the road (e.g., tree collision, Figure 2d). This accident type is nevertheless still very relevant today on account of the injury severity often associated with it.

Accidents involving oncoming vehicles exhibit a high injury probability (Figure 2c). Active-safety and automation measures prove to be the least effective in these accident scenarios. Integral safety is therefore focused on this accident type.

There is need for improvement in the case of accident types which are not reproduced by laboratory tests or for which conventional contact-sensor technology exhibits limitations. These conditions apply for example to driving under a truck

Figure 2: Relevant application cases in the area of head-on collisions (source: Bosch)

d) Tree collision,
e) Side collision.

(Figure 2b) or a central impact with a tree with a small overlap (Figure 2d). In both cases the sensors installed in the supporting frame respond only at a relatively late stage after the body has undergone marked deformation.

Function examples
The risk of injury increases if the moment of airbag deployment is not optimally matched to the forward displacement of the occupant. This situation ensues when the airbag is fired too late or when the occupant is too close to the airbag due to forward displacement caused by a braking operation ([4], [5]). Reference is made by way of example to two functions which address this problem: Integrated Collision Detection Front (IDF) and Pre-Crash Positioning (PCP).

Integrated Collision Detection Front (IDF)
The IDF function uses environment-sensor data (radar, video) in conjunction with conventional contact-sensor technology to trigger belt pretensioners and airbags at an earlier stage. Aside from an accurate estimation of the relative impact speed and the moment of impact, the merged sensor system offers the following advantages in terms of optimizing the efficiency of the retention systems:
– more precise description of the collision object,
– optimization of the interfaces between ADAS (Advanced Driver Assistance Systems) and restraint system.

Pre-Crash Positioning (PCP)
The PCP function coordinates in scenarios depicted in Figure 2 automated emergency braking with the restraint system. The chronological sequences of forces acting on the occupants, braking operations, and activations of the retention systems must be matched in such a way as to minimize the load on the occupants. A first instance of this function serves to position the occupants at the right time in the phase prior to the collision by means of reversible seatbelt tightening.

Further developments
Later versions of the IDF and PCP functions will, along similar lines to the further development of the automatic emergency brake systems, take into account more complex relationships. The first expansion stage handles the rear-end impact using front-sensor technology with the merging of radar and video. The same sensor configuration is used in the case of oncoming vehicles. However, this accident type requires the development of more complex decision algorithms and additional safeguarding effort to avoid bad decisions. Expansion to include intersection accidents necessitates the additional installation of Mid-Range-Radar (MRR) with a very large side beam width.

Individual safety
On account of legal regulations and consumer tests today's passive-safety systems are optimized for certain occupant heights and weights. Adaptive retention systems combined with suitable activation offer the potential for raising the safety level also for occupants that deviate from the standard sizes used in the tests. One possible solution approach uses occupant-specific variables such as age, height, weight or gender for the purpose of individually activating existing and future adaptive retention systems.

These data are acquired via passenger-compartment-sensor technology, supplemented by user inputs and plausibility checks. For example, the user enters once via his smart phone or an HMI (Human Machine Interface) integrated in the vehicle his personal data, which are linked with an image recorded by him. On each new entry into the vehicle a unique identification of the occupant is performed by means of passenger-compartment camera and image-processing algorithms with corresponding parameterization of the retention systems. If the occupant is not identified, the usual high safety level is still available in the default settings.

In view of the anticipated increase in the use of automatic and semi-automatic driving functions, an increase in the number of passenger-compartment cameras being installed is also to be expected. Personal optimization of the safety functions therefore does not require additional sensors. It is possible to fall back on passenger-compartment-sensor technology to be introduced to safeguard automated driving.

Safeguarding

A major challenge faced by integral-safety functions is environment and passenger-compartment sensing and correct situation assessment. As well as verifying correct functionality, particular attention is placed on safeguarding against unwanted false triggering of the retention systems. A typical situation that is to be avoided is the erroneous reporting of a collision object without such an object actually existing.

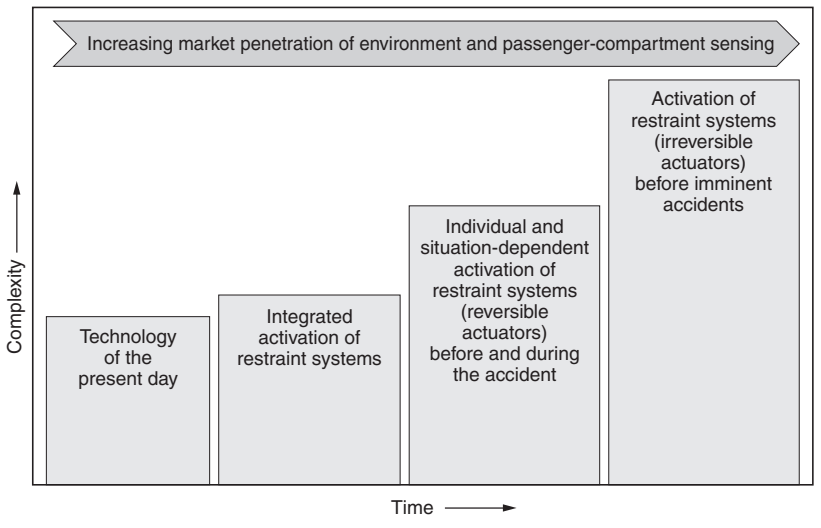
A further scenario to be avoided is as follows: An object is correctly detected, however an erroneous trajectory computation suggests a collision course and activates retention systems although the object is actually driving past the system vehicle. Falling into the same category are driving situations in which an object on a collision course is correctly detected, but after retention systems have been triggered the collision is not avoided [2].

In spite of data fusion and the associated redundancy, there are complex situations whose detection and correct interpretation must be verified. To guarantee this, the testing of integral-safety systems must record as wide a variety of real traffic situations as possible.

Testing of integral-safety system according to today's methodology exceeds both the cost and the time framework for release in the automotive industry. A first step towards reducing expenditure while simultaneously guaranteeing safety is to break down the wide range of real situations into a limited number of simulated test-track or laboratory situations which are representative of reality.

A supplementing approach is to use virtual instead of real test environments. Virtual test environments permit the evaluation of safety functions in the early development phase and thus fast prototype construction. Furthermore, they enable safeguarding of the functions to be developed in complex traffic situations that are hard to reproduce in real driving or test operation.

Outlook



Starting out from conventional vehicle safety with deployment of the airbags after an impact has been detected, the trend is towards adaptation of the trigger thresholds of retention systems on the basis of networked object data by environment sensors, passenger-compartment sensors, and driving-dynamics information. In this expansion stage of the integral-safety systems only reversible protection systems will be activated prior to the collision.

Functions with activation of irreversible actuators exclusively on the basis of data from environment sensors will constitute the next development stage of integral safety (Figure 3).

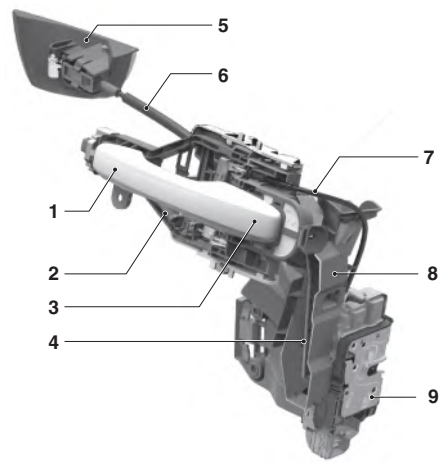
Locking systems

Task and design

The locking system of a vehicle includes all those components that facilitate authorized access to and exit from the vehicle. These components also prevent the inadvertent opening of doors, gates, and lids and unauthorized entry. The tasks they must perform are as follows:

– facilitating vehicle access (e.g., via the side doors) to all authorized persons and access to the interior (e.g., via engine hood, luggage compartment, glove compartment, or fuel filler cap),
– facilitating the opening of doors from the inside and outside,
– protecting occupants against inadvertent door opening,
– keeping doors, gates, and lids securely closed during vehicle operation and in crash situations and immobilizing,
– protecting the vehicle against theft when the vehicle is parked,
– detecting an opened or closed door.



The locking system can consist of the following components (Figure 1):

– identification system (mechanical key, remote key, Near Field Communication via chip in the remote key or smart phone),
– outer control (mechanical pull or flipper-type handle, pushbutton or proximity-type sensor),
– outer locking (mechanical lock barrel, pushbutton or proximity-type sensor),
– inner locking (mechanical pull handle, pushbutton or proximity-type sensor),
– inner locking (mechanical control, pushbutton or proximity-type sensor),
– lock (mechanical, mechanical-electric, electric),
– lock holder,
– connecting elements (rods, Bowden cables, electrical leads),
– door, gate, and lid drives,
– ECU (door ECU or central ECU).

The further types refer to the locking system in the side door, since it combines the most functions and the greatest complexity.
