Foreword to the 11th Edition

Automotive engineering has become an extremely complex field over the last few years and decades. It is becoming increasingly more difficult to command an overview of the entire field and to maintain constant access to the subjects which are significant to automotive engineering. Many of these new subjects have in the meantime been covered in great detail in the wealth of available specialist literature. However, for those readers who wish to approach one of these new subjects for the first time, the available literature is neither easily manageable nor is it readable within the available timeframe.

This is where the Automotive Handbook comes in useful. It is structured in such a way as to be easily accessible even to those readers who are new to any individual subject. The most important subjects relevant to automotive engineering have been compiled in a compact, easily understandable, and practically relevant form. This is possible because the contents have been written by experts who work at Bosch, at other automotive companies and suppliers, and in the university sector in the very specialist fields presented.

In this the 11th Edition in English many subjects have been included for the first time, completely revised or enhanced. The subjects revised have centered on electrification of the drive. The Handbook has however also been revised, expanded and updated in many other places to make the contents even more understandable to the reader. Thus, the subject of artificial intelligence, which is used in many fields, has been included. More than 260 pages have been added to this latest edition. In spite of the large number of contributing authors, every effort has been made to provide a uniform presentation and to maintain consistent classifications and nomenclature within its pages.

This individual chapters of this publication have been laid out gradually on receipt of the authors' manuscripts. Care has been taken to ensure that the graphics where possible are positioned in such a way that they appear with the accompanying text on the same page or the facing page and consequently both are visible to the reader in a single glance. Shifting the pagination at a later stage by one page would undo this text/graphic reference. This does however mean that there are blank pages in some places.

This latest edition could not have been completed without the outstanding support of many individuals. Firstly, we would like to thank the authors of the individual articles, who, with great care and patience, have succeeded in delivering on schedule chapters of the highest substance and quality. Finally, we would like to thank all those readers who have provided useful suggestions and advice on corrections.

Configuration of a starter 1511

Triggering the starter 1512
Starters for heavy commercial vehicles 1514
Application 1514
Power requirements 1514
Operating principle 1515
Special requirements for commercial-vehicle starters 1517
Wiring harnesses and plug-in connections 1518
Wiring harnesses 1518
Plug-in connections 1520
Electromagnetic compatibility 1524
Requirements 1524
Interference emission and interference immunity 1525
EMC-oriented development 1528
EMC measuring techniques 1529
EMC test methods 1530
EMC simulation 1533
Legal requirements and standards 1534
Symbols and circuit diagrams 1538
Circuit symbols 1538
Circuit diagrams 1545
Terminal designations 1557

Electrics for electric and hybrid drives
Vehicle electrical systems for hybrid and electric vehicles 1560
Vehicle electrical systems for mild- and full-hybrid vehicles 1560
Vehicle electrical systems for externally rechargeable hybrid and electric vehicles 1563
Charging strategy 1564
Electrical machines for motor-vehicle propulsion 1566
Requirements 1566
Design 1569
Types of electrical machines 1571
Influencing factors on operational performance 1574
Losses in electrical machines 1579
Cooling of the electrical machine 1580
Inverters for electric drives 1582
Area of application 1582
Function and circuitry 1583
Activation and control 1586
Software and functional safety 1589
Equipment mechanics 1591
DC-DC converters 1594
Application 1594
Non-isolating DC-DC converters 1595
Isolating DC-DC converters 1598
On-board charger 1600
Application 1600
Requirements 1601
Charging power 1602
Basic design and operating principle 1603
Batteries for electric and hybrid drives 1606
Requirements 1606
Storage technologies 1607
Basic structure of a battery system 1610
Components of a lithium-ion battery system 1610
Charging method for lithium-ion batteries 1615
Recycling of lithium-ion vehicle batteries 1615
Supercapacitors 1616
Application 1616
Electric double-layer capacitors 1617
Hybrid supercapacitors 1618

Automotive electronics
Electronic control unit (ECU) 1620
Functions 1620
Requirements 1621
ECU components 1624
Data processing 1632
Assembly and connection technology 1636
Software 1638
Application 1638
Functional safety 1639
EOL programming 1639
Mechatronics 1640
Mechatronic systems and components 1640
Development methodology 1642
Outlook 1645
Automotive software engineering 1646
Motivation 1646
Design of software in motor vehicles 1647
Important standards for software in motor vehicles 1647
The development process 1650
Quality assurance in software development 1654
Workflows of software development in motor vehicles 1654
Modeling and simulation of software functions 1656

Design and implementation of software functions 1659
Integration and testing of software and ECUs 1660
Calibration of software functions 1662
Outlook 1664
Architecture of electronic systems 1666
General 1666
Development of E/E architectures 1674
Summary and outlook 1680
Vehicle communication networks 1682
Bus systems 1682
Technical principles 1684
Buses in motor vehicles 1692
CAN 1692
FlexRay 1697
LIN 1700
Ethernet 1703
PSI5 1705
MOST 1707
Serial Wire Ring 1711
Automotive sensors 1716
Automotive applications 1716
Basic principles of classic sensors 1718
Position and angular-position sensors 1724
rpm sensors 1738
Oscillation gyrometers 1743
Flow meters 1746
Acceleration and vibration sensors 1750
Pressure sensors 1756
Temperature sensors 1760
Torque sensor 1764
Force sensor 1765
Gas and concentration sensors 1766
Optoelectronic sensors 1776

Infotainment
Infotainment and cockpit solutions 1780
History 1780
Infotainment systems 1781
Smartphone connection to the infotainment system 1782
Display and control 1784
Interaction channels 1784
Instrumentation 1785
Display types 1789
Voice control 1793
Radio and TV reception in motor vehicles 1794
Wireless signal transmission 1794
Radio tuners 1797
Traffic telematics 1801
Transmission paths 1801
Standardization 1801
Information recording 1802

Driver assistance and sensors
Driver-assistance systems 1804
Introduction – driver assistance 1804
Ultrasonic sensor system 1812
Ultrasonic sensor 1812
Distance measurement with ultrasound 1813
Radar-sensor system 1816
Application 1816
Radar principle 1817
Variants of radar sensors 1822
Homologation 1822
Lidar-sensor system 1824
Functions and applications 1824
Operating principle 1824
Properties and use 1827
Measurement principles 1828
Methods for increasing the number of pixels 1834
Video sensors 1838
Application 1838
Image sensor 1839
Objective 1842
Computer vision 1844
Sensor-data fusion 1860
Introduction 1860
Sensors 1861
Fusion types 1862
AI-based sensor-data fusion 1865

Driver-assistance systems
Vehicle navigation 1872
Navigation systems 1872
Functions of navigation 1872
Digital map 1875
Night-vision systems 1876
Applications 1876
Far-infrared systems 1876
Near-infrared systems 1877
Parking and maneuvering systems 1882
Application 1882
Ultrasonic parking aid 1882
Ultrasonic parking assistant 1884
Video systems 1886
Adaptive Cruise Control 1890
Function 1890
Design and function 1890
Control algorithms 1892

Area of application and functional expansions 1893
Current ongoing developments 1895
Information and warning systems 1896
Rearview-camera system 1896
Multi-camera system 1897
Digital exterior-mirror system 1898
Road-sign recognition 1899
Driver-drowsiness detection 1900
Rear cross-traffic warning 1900
Turn collision warning for trucks 1901
Moving-off information system for heavy commercial vehicles 1902
Wrong-way driver warning 1904
Lane assistance 1906
Lane departure warning 1906
Lane-keeping support 1908
Lane centering assist for heavy trucks 1908
Emergency lane-keeping support for heavy trucks 1909
Roadworks assistant 1909
Bottleneck/constriction assistant 1910
Lane-change assistant 1912
Blind-spot assistant 1912
Lane-change assistant 1913
Evasive steering support 1914
Further developments 1914
Emergency-braking systems 1916
Emergency-braking systems in longitudinal traffic 1916
Maneuver emergency braking 1919
Automatic emergency braking for unprotected road users 1920
Intersection assistant 1924
Motivation 1924
Left-turn assistant 1925
Cross-traffic assistant 1926
Traffic-light and stop-sign assistants 1927
Intelligent headlamp control 1928
Motivation 1928
System designs 1928
Advanced rider-assistance systems for two-wheelers 1930
Adaptive cruise control 1930
Forward collison warning 1931
Blind-spot detection 1931
Interior-monitoring systems 1932
Camera-based interior monitoring 1932

Future of automated driving
Future of automated driving 1934
Automation levels 1934
Obstacles to automated driving 1935
Stages on the road to autonomous driving 1936

Appendices
Technical terms 1940
Abbreviations 2031

Authors

Unless otherwise stated,
the authors are employees of Bosch.

Motor vehicles
Overall motor-vehicle system
Dipl.-Ing. Karl-Heinz Dietsche

Basic principles
Quantities and units
Dipl.-Ing. Karl-Heinz Dietsche
Prof. Dr. rer. nat. Susanne Schandl,
Duale Hochschule Baden-Württemberg,
Ravensburg, Campus Friedrichshafen

Basic principles of mechanics
Prof. Dr.-Ing. Horst Haberhauer,
Hochschule Esslingen

Fluid mechanics
Prof. Dr.-Ing. Horst Haberhauer,
Hochschule Esslingen

Vibrations and oscillations
Dipl.-Ing. Sebastian Loos,
Rheinisch-Westfälische Technische
Hochschule (RWTH) Aachen

Acoustics
Dipl.-Ing. Hans-Martin Gerhard,
Dr. Ing. h.c. F. Porsche AG, Weissach

Optical technology
Dr. rer. nat. Stefanie Mayer

Thermodynamics
Dr.-Ing. Ingo Stotz

Electrical engineering
Dipl.-Ing. Herbert Bernstein,
Freelance author
Dr.-Ing. Hans Roßmanith,
Friedrich-Alexander-Universität
Erlangen-Nuremberg
Prof. Dr.-Ing. Klemens Gintner,
Hochschule Karlsruhe – Technik und
Wirtschaft

Electronics
Prof. Dr.-Ing. Klemens Gintner,
Hochschule Karlsruhe – Technik und
Wirtschaft
Dr. rer. nat. Ulrich Schaefer

Basic principles of electrical machines
Prof. Dr.-Ing. Jürgen Ulm,
Reinhold-Würth-Hochschule, Künzelsau
Reinhardt Erli, M. Sc.,
Reinhold-Würth-Hochschule, Künzelsau

Chemistry
Dr. rer. nat. Jörg Ullmann

Mathematics and methods
Mathematics, Technical statistics
Prof. Dr.-Ing. Matthias E. Rebhan,
Hochschule München

Finite-element method
Prof. Dipl.-Ing. Peter Groth,
Hochschule Esslingen

Control engineering
Dr.-Ing. Wolf-Dieter Gruhle,
ZF Friedrichshafen AG, Friedrichshafen

Artificial intelligence
Dr. phil. Christoph Peylo
Dr.-Ing. Bastian Bischoff
Dr.-Ing. Mathias Bürger

Materials
Materials
Dr.-Ing. Hagen Kuckert
Dr. rer. nat. Jörg Ullmann
Dr. rer. nat. Witold Pieper
Dr. rer. nat. Waldemar Draxler
Dipl.-Ing. Angelika Schubert
Dipl.-Ing. Gert Lindemann
Dr.-Ing. Carsten Tüchert
Dr.-Ing. Sven Robert Raisch
Dr.-Ing. Reiner Lützeler
Dr. rer. nat. Jörg Bettenhausen
Dr.-Ing. Gerrit Hülder
Dipl.-Ing. Cornelius Gaida
Dipl.-Phys. Klaus-Volker Schütt

Heat treatment of metallic materials
Dr.-Ing. Thomas Waldenmaier
Dr.-Ing. Jochen Schwarzer

Corrosion and corrosion protection
Dipl.-Ing. (FH) Thomas Jäger

Deposits and coatings
Dr. Helmut Schmidt
Dipl.-Ing. (FH) Hellmut Schmid
Dipl.-Ing. (FH) Susanne Lucas

Machine parts
Tolerances, axles and shafts, springs, friction bearings
Prof. Dr.-Ing. Horst Haberhauer,
Hochschule Esslingen

Roller bearings
Dr.-Ing. Zhenhuan Wu

Seals
Dipl.-Ing. (FH) Ulrich Schmid
Dipl.-Ing. Sascha Bürkle
Thorsten Nitze, M. Eng.
Claudius Göller, MBE (DHBW)
Dipl.-Ing. Wolfgang Böhler
Frank Kleemann
Sergio Amorim, M. Sc.
Felix Schädler
All authors of the chapter "Seals" from Trelleborg Sealing Solutions Germany GmbH, Stuttgart.

Joining and bonding techniques
Detachable connections
Prof. Dr.-Ing. Horst Haberhauer,
Hochschule Esslingen
Dipl.-Ing. Rolf Bald
Dr.-Ing. Sven Robert Raisch

Permanent joints
Dr.-Ing. Knud Nörenberg,
Volkswagen AG, Wolfsburg
Dr. rer. nat. Patrick Stihler

Vehicle physics
Vehicle motion, running resistances
Dipl.-Ing. Marc Birk,
Mercedes-Benz AG, Stuttgart

Motor-vehicle dynamics
Dipl.-Ing. Marc Birk,
Mercedes-Benz AG, Stuttgart
Prof. Dr. rer. nat. Ludger Dragon,
Mercedes-Benz AG, Sindelfingen
Dr. Michael Hilgers,
Daimler Truck AG
Dr. Darko Meljnikov,
Daimler Truck AG

Driving-dynamics test procedures
Dr. Michael Hilgers,
Daimler Truck AG
Dr. Darko Meljnikov,
Daimler Truck AG

Energy demand for drives
Dipl.-Ing. Marc Birk,
Mercedes-Benz AG, Stuttgart
Dipl.-Ing. Martin Rauscher

Vehicle aerodynamics
Dipl.-Ing. Michael Preiß,
Dr. Ing. h.c. F. Porsche AG, Weissach

Vehicle acoustics
Dipl.-Ing. Hans-Martin Gerhard,
Dr. Ing. h.c. F. Porsche AG, Weissach

Operating fluids
Lubricants
Dr. rer. nat. Gerd Dornhöfer

Coolants for internal-combustion engines
Dr. rer. nat. Oliver Mamber,
MAHLE Behr GmbH & Co. KG, Stuttgart

Brake fluids
Dr. rer. nat. Michael Hilden
Dr. rer. nat. Harald A. Dietl,
BASF Ludwigshafen

Fuels
Dr. rer. nat. Jörg Ullmann

Urea/water solution
Thilo Schulz, M. Sc.
Dipl.-Ing. (FH) Manfred Fritz

Refrigerants for air-conditioning systems
Prof. Dr.-Ing. Stephan Engelking,
Duale Hochschule Baden-Württemberg,
Ravensburg, Campus Friedrichshafen

Drivetrain
Drivetrain with internal-combustion engine
Dipl.-Ing. Jürgen Wafzig, M. Sc.,
ZF Friedrichshafen AG, Friedrichshafen
Dipl.-Ing. Karl-Heinz Dietsche
Dipl.-Ing. (BA) Rolf Lucius Dempel

Power take-up elements
Dipl.-Ing. Jürgen Wafzig, M. Sc.,
ZF Friedrichshafen AG, Friedrichshafen
Dipl.-Ing. Karl-Heinz Dietsche
Dipl.-Ing. (BA) Rolf Lucius Dempel

Step-up gear units
Dipl.-Ing. Jürgen Wafzig, M. Sc.,
ZF Friedrichshafen AG, Friedrichshafen
Dipl.-Ing. Karl-Heinz Dietsche
Dipl.-Ing. (BA) Rolf Lucius Dempel
Ard van de Wiel, B Eng,
Bosch Transmission Technology B.V

Differentials
Dipl.-Ing. Jürgen Wafzig, M. Sc.,
ZF Friedrichshafen AG, Friedrichshafen

Electronic transmission control
Alexander Fuchs, M. Sc.
Dr.-Ing. Heiko Michel
Dipl.-Ing. (FH) Thomas Müller

Internal-combustion engines
Internal-combustion engines, mixture formation,
charge cycle and supercharging,
reciprocating-piston engine
Prof. Dr. sc. techn. Thomas Koch,
Karlsruher Institut für Technologie (KIT)
Tobias Michler, M. Sc.,
Karlsruher Institut für Technologie (KIT)
Dipl.-Ing. Heijo Oelschlegel,
Mercedes-Benz AG, Stuttgart
Dr.-Ing. Otmar Scharrer,
MAHLE Behr GmbH & Co. KG, Stuttgart

Exhaust-gas emissions
Dr.rer.nat. Christoph Osemann
Dr.-Ing. Hartmut Lüders

Belt drives
Dipl.-Ing. (FH). Mario Backhaus,
Gates GmbH, Aachen

Chain drives
Dr.-Ing. Thomas Fink,
iwis motorsysteme GmbH & Co. KG,
Munich
Dr.-Ing. Peter Bauer,
iwis motorsysteme GmbH & Co. KG,
Munich

Engine cooling
Dipl.-Ing. (FH) Ralf-Holger Schink,
MAHLE Behr GmbH & Co. KG, Stuttgart
Dr.-Ing. Otmar Scharrer,
MAHLE Behr GmbH & Co. KG, Stuttgart

Engine lubrication
Dipl.-Ing. Markus Kolczyk,
MANN+HUMMEL GmbH, Ludwigsburg
Dr.-Ing. Harald Banzhaf,
MANN+HUMMEL GmbH, Ludwigsburg

Air-intake systems and intake manifolds
Dipl.-Ing. Andreas Weber,
MANN+HUMMEL GmbH, Ludwigsburg
Dipl.-Ing. Andreas Pelz,
MANN+HUMMEL GmbH, Ludwigsburg
Dipl.-Ing. Markus Kolczyk,
MANN+HUMMEL GmbH, Ludwigsburg
Dipl. Ing. (FH) Alexander Korn,
MANN+HUMMEL GmbH, Ludwigsburg
Dipl. Ing. (FH) Matthias Alex,
MANN+HUMMEL GmbH, Ludwigsburg
Dr.-Ing. Matthias Teschner,
MANN+HUMMEL GmbH, Ludwigsburg
Dipl. Ing. (FH) Mario Rieger,
MANN+HUMMEL GmbH, Ludwigsburg
Dipl. Ing. Christof Mangold,
MANN+HUMMEL GmbH, Ludwigsburg
Dipl.-Ing. Hedwig Schick,
MANN+HUMMEL GmbH, Ludwigsburg

Turbochargers and superchargers
Dr.-Ing. Gunter Winkler,
BMTS Technology GmbH & Co. KG,
Stuttgart

Exhaust-gas system
Dr. rer. nat. Rolf Jebasinski,
J. Eberspächer GmbH & Co. KG,
Esslingen

Management for gasoline engines
Management for gasoline engines
Dipl.-Ing. Armin Hassdenteufel
Dr.-Ing. Henning Heikes

Cylinder charge
Dr.-Ing. Martin Brandt
Dr.-Ing. Henning Heikes
Dipl.-Ing. (FH) Thomas Kortwittenborg
Dipl.-Ing. Frank Walter

Fuel supply
Dipl.-Ing. Timm Hollmann
Dipl.-Ing. Thomas Herges
Dipl.-Ing. Johannes Högl
Dipl.-Ing. Karsten Scholz
Dipl.-Ing. Michael Kuehn
Dipl.-Ing. Zdenek Liner
Dr.-Ing. Thomas Kaiser
Dipl.-Ing. Serdar Derikesen
Dipl.-Ing. Uwe Müller
Dipl.-Ing. (FH) Horst Kirschner

Mixture formation
Dipl.-Ing. Andreas Binder
Dipl.-Ing. Anja Melsheimer
Dipl.-Ing. Markus Gesk
Dipl.-Ing. Andreas Glaser
Dr.-Ing. Tilo Landenfeld

Ignition
Dr.-Ing. Martin Brandt
Dipl.-Ing. Walter Gollin
Dipl.-Ing. Werner Häming
Dipl.-Ing. Tim Skowronek
Dr.-Ing. Grit Vogt
Dr.-Ing. Matthias Budde

Catalytic exhaust-gas treatment
Dipl.-Ing. Klaus Winkler
Dipl.-Ing. Detlef Heinrich
Dr.-Ing. Frank Meier

Motor sport
Dipl.-Red. Ulrich Michelt,
Bosch Engineering GmbH, Abstatt

Gasoline-engine operation with alternative fuels
LPG operation
Dipl.-Ing. Iraklis Avramopoulos,
IAV GmbH, Berlin

Engines fueled by natural gas
Dipl.-Ing. (FH) Thorsten Allgeier

Engines fueled by alcohol
Dipl.-Ing. Andreas Posselt

Management for diesel engines
Management for diesel engines
Dipl.-Ing. Klaus Schwarze

Low-pressure fuel supply
Dipl.-Ing. (FH) Stefan Kieferle
Dr.-Ing. Thomas Kaiser
Dipl.-Ing. Serdar Derikesen

Common-rail injection system
Dipl.-Ing. Felix Landhäußer
Dipl.-Ing. (FH) Andreas Rettich
Dr. rer. nat. Matthias Schnell
Dipl.-Ing. Thilo Klam
Dr.-Ing. Holger Rapp
Anees Haider Bukhari, B. Eng, MBA
Dipl.-Ing. (FH) Herbert Strahberger

Time-controlled single-cylinder pump system
Dipl.-Ing. (BA) Jürgen Crepin,
ETAS GmbH, Stuttgart

Diesel-distributor injection pumps
Dipl.-Ing. (BA) Jürgen Crepin,
ETAS GmbH, Stuttgart

Start-assist systems
Dipl.-Ing. (FH) Steffen Peischl
Dipl.-Ing. Friedrich Schmid,
Mercedes-Benz AG, Stuttgart

Exhaust-gas treatment
Dr. rer. nat. Christoph Osemann
Dr.-Ing. Hartmut Lüders

Electrification of the drive
Electrification of the drive
Dipl.-Ing. Karl-Heinz Dietsche
Dr. rer. nat. Anselm Stüken
Benjamin Heinz, B. Eng.
Martin Kuehnemund, M. Sc.
Dr. Thomas Weil

Control of electric drives
Dipl.Ing. (FH) Harald Paulhart
Dipl.Ing. (FH) Arno Hafner

Hybrid drives
Dipl.-Ing. Thomas Huber
Dipl.-Ing. Rasmus Frei
Dipl.-Ing. Karl-Heinz Dietsche

Control of hybrid drives
Ph.D. James Girard
Dipl.-Ing. (FH) Arno Hafner
Dipl.-Ing. (FH) Harald Paulhart

Electric final drive
Dipl.-Ing (FH) Matthias Herrmann
Dr.-Ing. Andreas Wuensch
Dipl.-Ing (FH) Bernd Spielmann

Electric drives with fuel cells
Dipl.-Ing. (FH) Jan-Michael Grähn
Dr. rer. nat. Michael G. Marino
Tiffany Mittelstenscheid, M. Sc.

Electromobility for two-wheelers
Sven Digele, M.Sc.

Emission-control and diagnosis legislation
Emission-control Legislation
Dr.-Ing. Matthias Tappe
Dipl.-Ing. Michael Bender

Exhaust-gas measuring techniques
Dipl.-Phys. Martin-Andreas Drühe
Felix Reinke, B.Sc.
Dipl.-Ing. Andreas Weiß
Dipl.-Ing. (BA) Marc Rottner
Dipl.-Ing. Andreas Kreh
Dipl.-Ing. Bernd Hinner
Dr.-Ing. Matthias Tappe
Dr.-Ing. Christelle Oediger

Diagnostics
Dr.-Ing. Markus Willimowski
Dr. Richard Holberg
Dr. rer. nat. Hauke Wendt
Dipl.-Ing. Sani Dzeko

Chassis systems
Chassis systems
Univ.-Prof. Dr.-Ing. Ralph Mayer,
Technische Universität Chemnitz
Prof. Dr. rer. nat. Ludger Dragon,
Mercedes-Benz AG, Sindelfingen

Suspension, shock absorbers and vibration absorbers, wheel suspension
Univ.-Prof. Dr.-Ing. Ralph Mayer,
Technische Universität Chemnitz
Dipl.-Ing. Fridtjof Körner,
Technische Universität Chemnitz

Wheels
Dipl.-Ing. Martin Lauer,
Mercedes-Benz AG, Sindelfingen
Dipl.-Ing. Werner Hann,
Mercedes-Benz AG, Sindelfingen
Dipl.-Hdl. Martin Bauknecht,
MAN Nutzfahrzeuge Group

Tires
Dipl.-Ing. Dirk Vincken,
Agentur für Text&Bild, Eurasburg
Dipl.-Ing. Reimund Müller,
Michelin Reifenwerke AG & Co. KGaA
Karlsruhe
Thilo Balcke,
Michelin Reifenwerke AG & Co. KGaA
Karlsruhe
Dipl.-Ing. Norbert Polzin
Frank Kleemann,
Trelleborg Sealing Solutions

Steering
Dipl.-Ing. Peter Brenner,
Robert Bosch Automotive Steering GmbH
Schwäbisch Gmünd

Brake systems
Dr. rer. nat. Jürgen Bräuninger
Werner Schneider

Brake systems for passenger cars
Werner Schneider
Dipl.-Ing. Isabell Maier
Dipl.-Ing. Andreas Burg
Dipl.-Ing. Andreas Mayer
Dipl.-Ing. Hubertus Wienken
Dipl.-Ing. Frank Bährle-Miller
Dipl.-Ing. Bernhard Kant
Dipl.-Ing. Urs Bauer

Brake systems for commercial vehicles
Werner Schneider
Dr.-Ing. Falk Hecker,
Knorr-Bremse SfN, Schwieberdingen
Dipl.-Ing. Frank Schwab,
Knorr-Bremse SfN, Schwieberdingen
Dr.-Ing. Dirk Huhn,
ZF Friedrichshafen AG, Friedrichshafen

Wheel brakes
Werner Schneider
Dipl.-Ing. Andreas Burg
Dipl.-Ing. Andreas Mayer
Dr. Christof Gente
Dr.-Ing. Falk Hecker,
Knorr-Bremse SfN, Schwieberdingen

Chassis control
Wheel-slip control systems
Dr.-Ing. Falk Hecker,
Knorr-Bremse SfN, Schwieberdingen
Dipl.-Ing. Frank Schwab,
Knorr-Bremse SfN, Schwieberdingen

Driving-dynamics control system
Dr.-Ing. Gero Nenninger
Dipl.-Ing. (FH) Jochen Wagner
Dr.-Ing. Falk Hecker,
Knorr-Bremse SfN, Schwieberdingen

Motorcycle Stability Control
Dr. rer. nat. Markus Lemejda
Dr.-Ing. Fevzi Yildirim

Integrated driving-dynamics control systems
Dr.-Ing. Michael Knoop

Vehicle bodies
Vehicle bodies, passenger cars
Dr.-Ing. Jochen Bisinger,
Mercedes-Benz AG
Dr. rer. pol. Dipl.-Ing. Thomas M. Neff,
Mercedes-Benz AG
Dipl.-Ing. (FH) Hubert Kazmaier,
Mercedes-Benz AG
Dipl.-Ing. Matthijs Ravestein,
Mercedes-Benz AG

Vehicle bodies, commercial vehicles
Dipl.-Ing. Georg Stefan Hagemann,
Mercedes-Benz AG, Stuttgart

Lighting equipment
Dipl.-Ing. Doris Boebel,
Automotive Lighting Reutlingen GmbH
Dipl.-Ing. Gert Langhammer,
Automotive Lighting Reutlingen GmbH
Dr.-Ing. Michael Hamm,
Audi AG, Ingoldstadt

Automotive glazing
Caroline Hermsdorff, M.A.
Saint-Gobain Sekurit Deutschland
GmbH & Co.KG, Herzogenrath

Windshield, rear-window and headlamp cleaning systems
Dr. techn. Günter Kastinger

Comfort and convenience
Passenger-compartment climate control
Dipl.-Ing. Peter Kroner,
MAHLE Behr GmbH & Co. KG, Stuttgart
Dipl.-Ing. (FH) Thomas Feith,
MAHLE Behr GmbH & Co. KG, Stuttgart
Dipl.-Ing. Günter Eberspach,
Eberspächer Climate Control Systems
GmbH & Co. KG, Esslingen
Ulrich Karl Weber,
Eberspächer Climate Control Systems
GmbH & Co. KG, Esslingen
Dipl.-Betriebsw. Marcel Bonnet

Comfort and convenience systems in the door and roof areas
Dipl.-Ing. (FH) Walter Haußecker
Dipl.-Ing. (FH) Siegfried Reichmann

Comfort and convenience functions in the passenger compartment
Mattias Hallor, M. Sc.

Safety systems in the motor vehicle
Safety systems in the motor vehicle
Dipl.-Ing. Robert Krott
Dipl.-Ing Karl-Heinz Dietsche

Occupant-protection systems
Dipl.-Ing. Robert Krott

Integral-safety systems
Dr.-Ing. Dagobert Masur

Vehicle security systems
Locking systems
Dr.-Ing. Ulrich Nass,
Brose Schließsysteme GmbH & Co. KG,
Wuppertal
Michael Bergmann, M. Eng.
Emre Inal, M. Sc.

Anti-theft systems
Dipl.-Ing. (FH) Manuel Wurm,
ZF Friedrichshafen AG, Friedrichshafen
Dipl.-Ing. (FH) U. Götz

Automotive electrics
12 V vehicle electrical systems
Dipl.-Ing. Eberhard Schoch
Dipl.-Ing. Clemens Schmucker
Dipl.-Ing. Markus Beck

Vehicle electrical systems for commercial vehicles
Dipl.-Ing. Christian Bohne
Dr.rer.nat. Felix Hoos
Dipl.-Ing. Matthias Horn

12 V starter batteries
Dr. rer. nat. Richard Aumayer

Alternators
Dipl.-Ing. Reinhard Meyer,
SEG Automotive Germany GmbH

Starters for passenger cars and light commercial vehicles
Dipl.-Ing. Oliver Capek,
SEG Automotive Germany GmbH
Andreas Brosche, M. Sc.,
SEG Automotive Germany GmbH

Starters for heavy commercial vehicles
Dipl.-Ing. Henning Stoecklein,
SEG Automotive Germany GmbH

Wiring harnesses and plug-in connections
Dr.-Ing. Eckhardt Philipp

Electromagnetic compatibility (EMC)
Dr.-Ing. Wolfgang Pfaff

Symbols and circuit diagrams
Dipl.-Ing. Karl-Heinz Dietsche

Electrics for electric and hybrid drives
Vehicle electrical systems for hybrid and electric vehicles
Dr.-Ing. Hans-Peter Groeter

Electric machines as drives
Dr.-Ing. Marcus Alexander
Dr.-Ing. Arndt Kelleter
Dr.-Ing. Stephan Usbeck
Dipl.-Ing Uwe Knappenberger
Dr.-Ing. Marc Brück

Inverters for electric traction drives
Dr.-Ing. Hans-Peter Groeter

DC-DC converters
Dipl.-Ing. (FH) Wolfgang Haas

On-board charger
Dr.-Ing. Christoph van Booven

Batteries for electric and hybrid drives
Dr. rer. nat. Richard Aumayer

Supercapacitors
Dr. Volker Doege

Automotive electronics
ECUs
Dipl.-Ing. Klaus Schwarze
Dipl.-Ing. Axel Aue

Mechatronics
Dipl.-Ing. Hans-Martin Heinkel
Dr.-Ing. Klaus-Georg Bürger

Automotive software engineering
Dipl.-Ing. (BA) Jürgen Crepin,
ETAS GmbH, Stuttgart
Dr. rer. nat. Kai Pinnow,
ETAS GmbH, Stuttgart
Dipl.-Ing. Jörg Schäuffele,
ETAS GmbH, Stuttgart

Architecture of electronic systems
Dr.-Ing. Ralf Machauer,
Bosch Engineering GmbH, Abstatt
Andreas Hörtling, M. Sc.,
Bosch Engineering GmbH, Abstatt
Andreas Ehrhart, M. Sc.,
Bosch Engineering GmbH, Abstatt

Vehicle communication networks
Dr. rer. nat. Harald Weiler
Dr.-Ing. Tobias Lorenz
Dipl.-Ing. Karl-Heinz Dietsche

Buses in motor vehicles
Dr. rer. nat. Harald Weiler
Dr.-Ing. Tobias Lorenz
Dipl.-Ing. Oliver Prelle
Dipl.-Ing. Dieter Thoss

Automotive sensors
Dr.-Ing. Erich Zabler
Dipl.-Ökon. Frauke Ludmann
Dr. rer. nat. Peter Spoden
Dipl.-Ing. (FH) Cyrille Caillié
Dr.-Ing. Uwe Konzelmann
Dr.-Ing. Tilmann Schmidt-Sandte

Dr.-Ing. Reinhard Neul
Dr. Berndt Cramer
Dipl.-Ing. Dipl.-Wirt.-Ing. Nils Kaiser
Dipl.-Ing. Karl-Heinz Dietsche

Infotainment
Infotainment and cockpit solutions
Dipl.-Ing. Karl-Heinz Dietsche

Display and control
Prof. Dr.-Ing. Peter Knoll
Dipl.-Ing. Karl-Heinz Dietsche

Radio and TV reception in motor vehicles
Dr.-Ing. Jens Passoke

Traffic telematics
Dr.-Ing. Michael Weilkes

Driver assistance and sensor system
Driver-assistance systems
Dr.-Ing. Thomas Michalke
Dr.-Ing. Frank Niewels
Dipl.-Math. (FH) Thomas Lich
Dr.-Ing. Thomas Maurer

Ultrasonic sensor system
Prof. Dr.-Ing. Peter Knoll

Radar-sensor system
Dipl.-Ing. Joachim Selinger,
M. Sc. (University of Colorado)
Dr.-Ing. Michael Schoor

Lidar-sensor system
Dr.-Ing. Jan Sparbert

Video sensors
Dr. sc. Moritz Eßlinger
Christian Schwarz, M. Sc.
Dr.-Ing. Stjepan Dujmovic

Sensor-data fusion
PD Dr.-Ing. habil. Alexandru Paul
Condurache
Dr.-Ing. André Treptow

Driver-assistance systems
Vehicle navigation
Dipl.-Ing. Ernst Peter Neukirchner

Night-vision systems
Prof. Dr.-Ing. Peter Knoll

Parking and maneuvering systems
Prof. Dr.-Ing. Peter Knoll

Adaptive Cruise Control
Dipl.-Ing. Gernot Schröder
Prof. Dr.-Ing. Peter Knoll

Information and warning systems
Dipl.-Ing. Karl-Heinz Dietsche
Dr. Benjamin Schoen

Lane assistance
Dipl.-Ing. Karl-Heinz Dietsche
Dr.-Ing. Thomas Michalke
Dr. rer. nat. Lutz Bürkle

Lane-change assistant
Dipl.-Ing. Karl-Heinz Dietsche
Dr.-Ing. Thomas Michalke
Dr. rer. nat. Lutz Bürkle

Emergency-braking systems
Dipl.-Ing. Karl-Heinz Dietsche
Dr.-Ing. Thomas Gussner
Dr.-Ing. Steffen Knoop
Dr.-Ing. Falk Hecker,

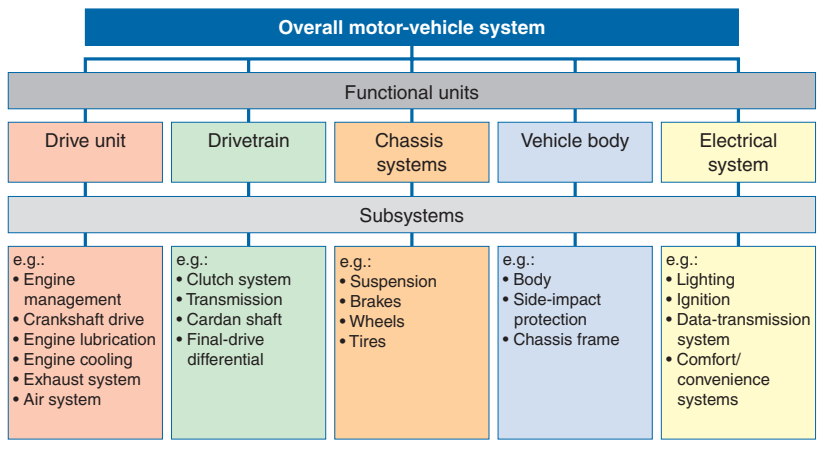
Overall motor-vehicle system

Definition of motor vehicle

The International Convention on Road Signs and Signals [1] defines a motor or power-driven vehicle as a self-propelled road vehicle. Rail-borne vehicles and country-specifically mopeds which are not treated as motorcycles are exceptions. A second definition in this convention limits the term motor vehicle to those vehicles which are used for carrying persons or goods or for drawing on the road vehicles used for the carriage or persons or goods. Electrically powered non-rail-borne trolley-buses are included in this definition. This definition however does not cover vehicles, such as agricultural tractors, which are only incidentally used for carrying persons or goods.

An appropriate definition is established for example in the German Road Traffic Act (§1 StVG [2]) and in the laws of other countries.



Functional units of a motor vehicle

A motor vehicle consists of a number of functional units (Figure 1). These are usually classified into drivetrain, drive unit, chassis, vehicle body, and electrical system. This classification is however not standardized.

The functional units are composed of the subsystems, which are interconnected. But there is also an interaction between the functional units. Thus, for example, the drive unit acts on the transmission unit with the transmission subsystem, which drives the wheels of the chassis functional unit via the drive shafts and the final-drive differential.

Electrical and electronic systems have gradually found their way into all areas of a motor vehicle. They have replaced mechanical systems or else created completely new possibilities. Electrification of the drive and further developments in the field of automated driving have major impacts on motor-vehicle development.

Figure 1: System network of a motor vehicle

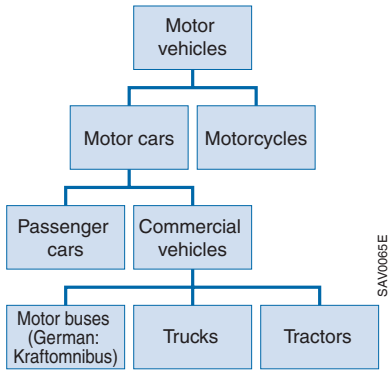
Classification of motor vehicles

Motor vehicles include motor cars, but also single-track motorcycles (Figure 2). In the case of two- or multiple-track motor cars, a distinction is made between passenger cars and commercial vehicles (or goods vehicles). Commercial vehicles included trucks, motor buses, and tractors.

Determination of motor vehicles

Passenger cars

Passenger cars have at least four wheels. They are also called automobiles. Passenger cars serve to transport persons and additionally luggage, but also goods. A trailer can also be towed.



Commercial vehicles

Commercial vehicles serve to transport persons and goods and to tow trailer vehicles.

Motorcycles

Motorcycles are single-track motor vehicles, but may also have a sidecar attached.

Figure 2: Classification of motor vehicles

Country-specific classification

EC vehicle categories

Motor vehicles are classified according to their determination into vehicle categories. There are different classifications depending on the legislation. Table 1 provides an overview of the vehicle categories in Europe. This classification applies to the countries of the European Union and all other European countries.

Off-road vehicles are a special case. Vehicles in category N1 with a gross weight rating of not more than 2 tons and vehicles in category M1 are considered in accordance with Directive 87/403/EEC [3] to be off-road vehicles (off-road cars) if they are equipped as follows:

- They have at least one front axle and at least one rear axle, both of which can be driven simultaneously (all-wheel drive). The drive to one of the axles can be disengaged.
- A differential lock or a mechanism that has a similar effect must be fitted.
- As a solo vehicle (without a trailer) they must be able to climb a gradient of 30 % (verified by calculation).
- There are also further requirements for example with regard to ground clearance.

Table 1: EC vehicle categories

L	L vehicles	
	L1e-A	Powered cycle (pedelec)
	L1e-B	Two-wheel moped
	L2e	Three-wheel moped, sub-categorized by special use (-P, -U)
	L3e	Two-wheel motorcycle, sub-categorized by performance (-A1, -A2, -A3) and special use (-AxE, -AxT)
	L4e	Two-wheel motorcycle with sidecar (motorcycle combination), subcategories according to L3e
	L5e	Powered tricycle, sub-categorized by special use (-A, -B)
	L6e-A	Light on-road quad, sub-categorized by performance (-A, -B) and special use (-BU, -BP)
	L7e	Heavy on-road quad (max. effective power 15 kW, curb weight up to 400 kg, up to 600 kg for carriage of goods, in each case without batteries for electric vehicles), sub-categorized by special use

SUVs (sport utility vehicles) are based in terms of design on off-road vehicles, but do not satisfy all the above-mentioned requirements. Off-road capability varies from model to model. In fact, they are for the most part not used in off-road applications at all.

CARB vehicle categories
Table 2 provides an overview of the vehicle categories of the CARB legislation. This applies to the US state of California and some other states.

EPA vehicle categories
All other states are covered by the EPA legislation. The EPA vehicle categories are listed in Table 3.

Table 1: EC vehicle categories (continued)

M	Motor vehicles for carriage of passengers with at least four wheels	
	M1	Vehicles with no more than eight seats (in addition to driver's seat) Carriage of standing passengers is not possible
	M2	Vehicles with more than eight seats having a GVW not exceeding 5 tons Carriage of standing passengers in addition to the sitting passengers is possible
	M3	Vehicles with more than eight seats having a GVW exceeding 5 tons Carriage of standing passengers in addition to the sitting passengers is possible
N	Motor vehicles for carriage of goods with at least four wheels	
	N1	Vehicles with a GVW not exceeding 3.5 tons
	N2	Vehicles with a GVW not exceeding 12 tons
	N3	Vehicles with a GVW exceeding 12 tons
O	Trailers for carriage of goods or passengers, including semi-trailers	
	O1	Trailers not exceeding 750 kg (light trailers)
	O2	Trailers not exceeding 3.5 tons
	O3	Trailers not exceeding 10 tons
	O4	Trailers exceeding 10 tons

Vehicle categories of other countries
Japanese legislation follows the classification of CARB. China and India follow the EU classification.

Body types and segments of passenger cars
Various demands are placed on passenger cars, depending on their use. This gives rise in all markets to different segments with different body types. For the M categories the following different body types exist [4]:
– AA Sedan/saloon,
– AB Fastback sedan/saloon,
– AC Station wagon/estate car,
– AD Coupé,
– AE Convertible sedan/saloon,
– AF Multipurpose vehicle (e.g., fire truck, ambulance),
– AG Passenger-car pick-up.

The classification of vehicles into segments is fluid since there is no official definition. This can be attributed among other things to the fact that over time new vehicle models have always been brought onto the market. The following designations have become established:
– mini,
– subcompact,
– lower mid-size category (compact category with transversally mounted front engine, fastback with tailgate),
– mid-size category,
– upper mid-size category,
– luxury class,
– SUV,

Table 2: CARB vehicle categories

PC	Passenger car for carriage of up to 12 persons	
LDT	Light-duty truck for transport purposes	
	LDT1	Vehicles with maximum LVW (loaded vehicle weight) of 3,750 pounds
	LDT2	Vehicles with maximum GVWR (gross vehicle weight rating) of 8,500 pounds
MDV	Medium-duty vehicle, GVWR of 8,501 to 14,000 pounds	
HDV	Heavy-duty vehicle with GVPR > 8500 pounds, except PC	

– off-road vehicle,
– van (small vans and large vans).

There are also vehicles with dedicated body types:
– SA Recreational vehicles,
– SB Armored,
– SC Ambulances,
– SD Hearses,
– SG Miscellaneous,
– SH Wheelchair-accessible.

Table 3: EPA vehicle categories

LDV	Light-duty vehicle (passenger car) for carriage of up to 12 persons	
LLDT	Light light-duty truck with GVWR < 6,000 lbs (gross vehicle weight rating) LDT1 and LDT2 is combined in LLDT	
HLDT	Heavy light-duty truck with GVWR > 6,000 lbs LDT3 and LDT4 is combined in HLDT	
LDT	Light-duty truck, vehicle with GVWR < 8,500 lbs or curb weight < 6,000 lbs or frontal surface area less than 45 square feet; for transport of property or carriage of more than 12 persons or with properties for off-road operation	
	LDT1	LLDT with LVW < 3,750 lbs (loaded vehicle weight)
	LDT2	LLDT with LVW > 3,750 lbs
	LDT3	HLDT with ALVW < 5,750 lbs
	LDT4	HLDT with ALVW > 5,750 lbs
Full Size Pickup Truck	Light truck with passenger compartment and open freight box, towing capability > 5,000 lbs, payload > 1,700 lbs	
MDPV	Medium-duty passenger vehicle, Heavy-duty vehicle with GVWR <10,000 lbs for carriage of up to 12 persons	
HDV	Heavy-duty vehicle with GVWR > 8,500 lbs, or curb weight > 6,000 lbs, or frontal surface area greater than 45 square feet

Quantities and units

In order to be able to express the values of physical quantities, a system of units is required which serves as the yardstick for every measurement. The value of the physical quantity is taken as the product of numerical value and unit. Such a system of units is the SI system, which was established in 1960 by the 11th General Conference on Weights and Measures (Conférence Générale des Poids et Mesures, CGPM). It has since then been adopted by over 50 countries.

In Germany the management of units is by law under the control of the Physikalisch-Technische Bundesanstalt (PTB, based in Braunschweig), Germany's national metrology institute. International responsibility lies with the International Bureau of Weights and Measures (BIPM, Bureau International des Poids et Mesures) in Sèvres near Paris.

Further units which are to this day commonly used (e.g., liter, metric ton, hour, degree Celsius) are in Germany likewise permitted by law and are mentioned here as such.

Units permitted in other countries (e.g., inch, ounce, degree Fahrenheit) or obsolete units are discussed in a separate section.

Table 1: Base SI units

Base quantity and symbol		Base SI unit	
		Name	Symbol
Length	l	meter	m
Mass	m	kilogram	kg
Time	t	second	s
Electric current	I	ampere	A
Thermodynamic temperature	T	kelvin	K
Amount of substance	n	mole	mol
Luminous intensity	I	candela	cd

SI units

SI means "Système International d'Unités" (International System of Units). The system is laid down in ISO 80000 [1] (ISO: International Organization for Standardization) and for Germany in DIN 1301 [2] (DIN: German Institute for Standardization).

Table 1 lists the seven base SI units.

Definition of the base SI units

In 2018 a fundamental change was made to the SI at the 26th General Conference, this change being adopted on 20 May 2019: Seven "defining constants" now form the foundation of the SI and therefore provide the basis for the definition of the base units and all further SI units (source: [3]).

Second (time)

The second, symbol s, is the SI unit of time. It is defined by taking the fixed numerical value of the cesium frequency $\Delta\nu_{Cs}$, the unperturbed ground-state hyperfine-transition frequency of the cesium-133 atom to be 9 192 631 770 when expressed in the unit Hz, which is equal to s^{-1}.

In other words, one second is equal to the duration of 9 192 631 770 periods of the radiation corresponding to the energy of the transition between the two hyperfine levels of the unperturbed ground state of the ^{133}Cs atom.

Meter (length)

The meter, symbol m, is the SI unit of length. It is defined by taking the fixed numerical value of the speed of light in a vacuum c to be 299 792 458 when expressed in the unit m/s, where the second is defined in terms of $\Delta\nu_{Cs}$.

In other words, one meter is the length of the path traveled by light in a vacuum during a time interval with duration of 1/299 792 458 of a second.

Kilogram (mass)
The kilogram, symbol kg, is the SI unit of mass. It is defined by taking the fixed numerical value of the Planck constant h to be $6.62607015 \times 10^{-34}$ when expressed in the unit J s, which is equal to kg m^2 s^{-1}, where the meter and the second are defined in terms of c and $\Delta\nu_{Cs}$.

In other words, the unit kg is linked with the action, a quantity in theoretical physics with the unit kg m^2 s^{-1}. Together with the definitions of the second and the meter this leads to a definition of the kilogram as a function of the Planck constant h.

Ampere (electric current)
The ampere, symbol A, is the SI unit of electric current. It is defined by taking the fixed numerical value of the elementary charge e to be $1.602176634 \times 10^{-19}$ when expressed in the unit C, which is equal to A s, where the second is defined in terms of $\Delta\nu_{Cs}$.

In other words, an ampere is the current corresponding to the flow of $1 / (1.602176634 \times 10^{-19})$ elementary charges (electrons) per second.

Kelvin (thermodynamic temperature)
The kelvin, symbol K, is the SI unit of thermodynamic temperature. It is defined by taking the fixed numerical value of the Boltzmann constant k to be 1.380649×10^{-23} when expressed in the unit J K^{-1}, which is equal to kg m^2 s^{-2} K^{-1}, where the kilogram, the meter and the second are defined in terms of h, c and $\Delta\nu_{Cs}$.

In other words, one kelvin is equal to the change of thermodynamic temperature that results in a change of thermal energy (kT) by $1.380649 \cdot 10^{-23}$ J.

Mole (amount of substance)
The mole, symbol mol, is the SI unit of amount of substance. One mole contains exactly $6.02214076 \times 10^{23}$ elementary entities. This number is the fixed numerical value of the Avogadro constant N_A when expressed in the unit mol^{-1} and is called the Avogadro number. The amount of substance, symbol n, of a system is a measure of the number of specified elementary entities. An elementary entity may be an atom, a molecule, an ion, an electron, any other particle or a group of such particles of precisely specified composition.

In other words, a mole is the amount of substance of a system that contains $6.02214076 \cdot 10^{23}$ specified elementary entities.

Candela (luminous intensity)
The candela, symbol cd, is the SI unit of luminous intensity in a given direction. It is defined by taking the fixed numerical value of the luminous efficacy K_{cd} of monochromatic radiation of frequency 540×10^{12} Hz to be 683 when expressed in the unit lm W^{-1}, which is equal to cd sr W^{-1} or cd sr kg^{-1} m^{-2} s^3, where the kilogram, the meter and the second are defined in terms of h, c and $\Delta\nu_{Cs}$.

In other words, one candela is the luminous intensity (in a given direction) of a source that emits monochromatic radiation of frequency 540×10^{12} Hz and has a radiant intensity in that direction of 1/683 W sr^{-1}.

Decimal fractions and multiples of SI units
Decimal fractions and multiples of SI units (base SI units and derived SI units) are denoted by prefixes before the name of the unit (e.g., milligram) or by prefix symbols before the unit symbol (e.g., mg) (Table 2). The prefix symbol is placed without a gap in front of the unit symbol to form a coherent unit.

Prefixes are not used before further units of angle (degree, min, second), of time (minute, hour), and of temperature (degree Celsius).

Table 2: Prefixes for unit of measurements in acc. with DIN 1301 [2]

Prefix	Prefix symbol	Factor	Name of factor
yokto	y	10^{-24}	septillionth
zepto	z	10^{-21}	sextillionth
atto	A	10^{-18}	trillionth
femto	F	10^{-15}	thousand billionth
pico	p	10^{-12}	billionth
nano	N	10^{-9}	thousand millionth
micro	µ	10^{-6}	millionth
milli	m	10^{-3}	thousandth
centi	C	10^{-2}	hundredth
deci	d	10^{-1}	tenth
deca	da	10^{1}	ten
hecto	H	10^{2}	hundred
kilo	K	10^{3}	thousand
mega	m	10^{6}	million
giga	G	10^{9}	thousand million[1]
tera	T	10^{12}	billion[1]
peta	p	10^{15}	thousand billion
exa	E	10^{18}	trillion
zetta	z	10^{21}	sextillion
yotta	y	10^{24}	septillion

[1] In the USA: 10^9 = 1 billion, 10^{12} = 1 trillion.

Derived SI units

SI units are the seven base SI units and all the units derived from them, i.e., which can be represented as a product of powers of the base units. Thus, for example, the unit of force is obtained from Newton's Law $F = m\,a$ as

$$1\ \text{kg}\ \frac{\text{m}}{\text{s}^2} = 1\ \text{N (Newton)}.$$

If the power product contains only the factor 1, the units are referred to as coherently derived units. There are a total of 22 coherently derived units, which like the newton have been assigned their own names (Table 3).

Table 3: Derived SI units with special names

Quantity	Unit	Unit symbol	Expressed in other SI units
Plane angle	radian	rad	1
Solid angle	steradian	sr	1
Frequency	hertz	Hz	1 Hz = 1/s
Force	newton	N	1 N = 1 kg m/s^2 = 1 J/m
Pressure	pascal	Pa	1 Pa = 1 N/ m^2
Energy, work, quantity of heat	joule	J	1 J = 1 N m = 1 W s
Power	watt	W	1 W = 1 J/s = 1 V A
Celsius temperature	degree Celsius	°C	
Voltage	volt	V	1 V = 1 W/A
Electrical conductance	siemens	s	1 S = 1 A/V = 1/Ω
Electrical resistance	ohm	Ω	1 Ω = 1 V/A
Electric charge	coulomb	C	1 C = 1 A s
Electrical capacitance	farad	F	1 F = 1 C/V
Inductance	henry	H	1 H = 1 Wb/A
Magnetic flux	weber	Wb	1 Wb = 1 V s
Magnetic flux density, induction	tesla	T	1 T = 1 Wb/m^2
Luminous flux	lumen	lm	1 lm = 1 cd sr
Luminous intensity	lux	lx	1 lx = 1 lm/m^2
Radioactivity	becquerel	Bq	1 Bq = 1/s
Absorbed dose	gray	Gy	1 Gy = 1 J/kg
Dose equivalent	sievert	Sv	1 Sv = 1 J/kg
Catalytic activity	katal	kat	1 kat = 1 mol/s

Legal units

The German Units in Metrology and Determination of Time Act (EinhZeitG), rewritten on 22 February 1985, last amended on 18 July 2016 (as at 2021), stipulates the use of legal units in business and official transactions in Germany. Legal units are:

- the SI units,
- decimal fractions and multiples of SI units,
- other permitted units; see the overview on the following pages and [3].

The following tables provide an overview in accordance with DIN 1301 [2].

Table 4: Legal units

Quantity and symbol	Legal units SI	Others	Name	Relationship	Remarks and units not to be used, incl. their conversion
1. Length, area, volume.					
Length l	m		meter		
Area A	m^2		square meter		
		A	are	1 a = 100 m^2	
		ha	hectare	1 ha = 100 a = 10^4 m^2	
Volume V	m^3		cubic meter		
		l, L	liter	1 l = 1 L = 1 dm^3 = 10^3 cm^3 = 10^{-3} m^3	
2. Angle.					
(Plane) angle[1] α, β etc.	rad		radian	1 rad = $\frac{1\text{ m ar}}{1\text{ m radius}}$	1^g (centesimal degree) = 1 gon; 1^c (centesimal minute) = 10^{-2} gon; 1^{cc} (centesimal second) = 10^{-4} gon
		°	degree	1° = $\frac{\pi}{180}$ rad	
		′	minute	1° = 60′ = 3,600″	
		″	second		
	gon	gon	gon	1 gon = $\frac{\pi}{200}$ rad	
Solid angle[1] Ω	sr		steradian	1 sr = $\frac{1\,m^2\text{ spherical surface}}{1\,m^2\text{ sphere radius}^2}$	

[1] The units rad and sr can be replaced by the numeral 1 in calculations.

Quantity and symbol	Legal units SI	Others	Name	Relationship	Remarks and units not to be used, incl. their conversion
3. Mass.					
Mass m (weight)[1]	kg		kilogram		
		G	gram	1 g = 10^{-3} kg	
		T	metric ton	1 t = 10^3 kg	
Density ρ	kg/m^3			1 kg/m^3 = 1 g/dm^3	Weight of unit volume γ (kp/dm^3 or p/cm^3) $\gamma = \rho\, g$
Moment of inertia J (mass moment, 2nd order)	kg m^2			$J = m\, r^2$ r = radius of gyration	Flywheel effect $G\, D^2$ in kp m^2 $D = 2r$, $G = m\, g$ $G\, D^2 = 4 J\, g$
4. Time quantities.					
Time t Duration Interval[2]	s		second		In energy management one year is calculated as 8,760 hours
		min	minute	1 min = 60 s	
		h	hour	1 h = 60 min	
		d	day	1 d = 24 h	
		a	year		
Frequency f	Hz		hertz	1 Hz = 1/s	
Rotational speed (rotational frequency) n	s^{-1}			1 s^{-1} = 1/s	rpm and r/min (revolutions per minute) are still permissible for expressing rotational speed, but is better replaced by min^{-1} (1 rpm = 1 r/min = 1 min^{-1})
		min^{-1} 1/min		1 min^{-1} = 1/min = (1/60) s^{-1}	
Angular frequency ω	s^{-1}			$\omega = 2\pi f$	
Velocity v	m/s	km/h		1 km/h = (1/3.6) m/s	
Acceleration[4] a	m/s^2			Normal acceleration of free fall $g \approx 9.80665$ m/s^2	
Angular velocity[3] ω	rad/s				
Angular acceleration[3] α	rad/s^2				

[1] The term "weight" is ambiguous in everyday usage; it is used to denote mass as well as weight (DIN 1305 [4]).

[2] Clock times: h, min, s written as superscripts. Example: $3^h\ 25^m\ 6^s$.

[3] The unit rad can be replaced by the numeral 1 in calculations.

[4] Acceleration is sometimes expressed in m/s^2 as a multiple of gravitational acceleration g.

Quantity and symbol	Legal units SI	Others	Name	Relationship	Remarks and units not to be used, incl. their conversion
5. Force, energy, power.					
Force F Force due to weight G	N N		newton	1 N = 1 kg m/s^2	1 kp (kilopond) ≈ 9.80665 N
Impulse p	N s			1 N s = 1 kg m/s	
Pressure, gen. p	Pa		pascal	1 Pa = 1 N/m^2	1 at (techn. atmosphere) = 1 kp/cm^2 ≈ 0.980665 bar p ≈ 1.01325 bar ≈ 1,013.25 hPa (standard value of air pressure)
		bar	bar	1 bar = 10^5 Pa	
Mechanical stress σ, τ	N/m^2			1 N/m^2 = 1 Pa	1 kp/m^2 ≈ 9.80665 N/m^2
		N/mm^2		1 N/mm^2 = 1 MPa	
Hardness	Brinell and Vickers hardness are no longer given in kp/mm^2. Instead, an abbreviation of the relevant hardness is written as the unit after the numerical value used previously (including an indication of the test force, etc., where applicable).				Examples: Previously Now HB = 350 kp/mm^2 350 HB HV30 = 720 kp/mm^2 720 HV30 HRC = 60 60 HRC
Energy E Work W	J		joule	1 J = 1 N m = 1 W s = 1 kg m^2/s^2	1 kcal (kilocalorie) = 4.1868 kJ
Heat, quantity of heat[1] Q		W s	watt-second	1 W s = 1 J	
		kW h	kilowatt-hour	1 kW h = 3.6 MJ	
		eV	electron-volt	1 eV = 1.602176634 · 10^{-19} J	
Torque M	N m		newton meter		1 kp m (kilopondmeter) ≈ 9.80665 N m
Power P Heat flow $\dot{Q}$ Radiated power Φ	W		watt	1 W = 1 J/s = 1 N m/s	1 kp m/s ≈ 9.80665 W 1 hp (horsepower) ≈ 0.7355 kW
Apparent power P_s	VA		volt-ampere	1 VA = 1 W	
Reactive power P_q	var		var	1 var = 1 W	

[1] The quantity of heat is expressed in joules.

Quantity and symbol	Legal units SI	Others	Name	Relationship	Remarks and units not to be used, incl. their conversion
6. Viscosimetric quantities.					
Dynamic viscosity η	Pa s		pascal-second	1 Pa s = 1 N s/m^2 = 1 kg/(s m)	1 P (poise) = 0.1 Pa s
Kinematic viscosity ν	m^2/s			1 m^2/s = 1 Pa s/(kg/m^3)	1 St (stokes) = 10^{-4} m^2/s
7. Temperature and heat.					
Temperature T	K	kelvin		$\vartheta = (T - 273.15\ \mathrm{K})\,\frac{°C}{K}$	
Temperature ϑ		°C	degree Celsius		
Temperature difference ΔT	K		kelvin	1 K = 1 °C	In the case of composite units, express temperature differences in K
Temperature difference $\Delta\vartheta$		°C	degree Celsius		
For quantity of heat and heat flow, refer to 5					
Specific heat capacity (spec. heat) c	J/(kg K)				1 kcal/(kg K) = 4.1868 kJ/(kg K)
Molar heat capacity C	J/(mol K)				
Thermal conductivity λ	W/(m K)				1 kcal/(m h K) = 1.163 W/(m K)
8. Electrical quantities.					
Electric current I	A		ampere		
Electric potential (voltage) U	V		volt	1 V = 1 W/A	
Electrical conductance: Conductance G Susceptance B Admittance Y	s		siemens	1 S = 1 A/V = 1/Ω	
Electrical resistance: Resistance R Reactance X Impedance Z	Ω		ohm	1 Ω = 1/S = 1 V/A	
Quantity of electricity, electric charge Q	C		coulomb	1 C = 1 A s	
		A h	ampere-hour	1 A h = 3,600 C	
Electrical capacitance C	F		farad	1 F = 1 C/V	

Quantity and symbol	Legal units SI	Others	Name	Relationship	Remarks and units not to be used, incl. their conversion
Electrical flux density, displacement D	C/m^2			$1\ C/m^2 = 1\ A\,s/m^2$	
Electric field strength E	V/m			$1\ V/m = 1\ W/(A\,m)$	

9. Magnetic quantities.

Inductance L	H		henry	$1\ H = 1\ Wb/A$	
Magnetic flux Φ	Wb		weber	$1\ Wb = 1\ V\,s$	$1\ M\ (maxwell) = 10^{-8}\ Wb$
Magnetic flux density, induction B	T		tesla	$1\ T = 1\ Wb/m^2$	$1\ G\ (gauss) = 10^{-4}\ T$
Magnetic field strength H	A/m			$1\ A/m = 1\ N/Wb$	$1\ Oe\ (oersted) = \frac{10^3}{(4\pi)}\ \frac{A}{m}$

10. Photometric quantities.

Luminous intensity I	cd		candela		
Luminance L	cd/m^2				$1\ sb\ (stilb) = 10^4\ cd/m^2$ $1\ asb\ (apostilb) = 1/\pi\ cd/m^2$
Luminous flux Φ	lm		lumen	$1\ lm = 1\ cd\ sr$ (sr = steradian)	
Illuminance E	lx		lux	$1\ lx = 1\ lm/m^2$	

11. Acoustic quantities.

Sound pressure p	Pa		pascal		
Sound intensity I	W/m^2				
Sound pressure level L_p	Np		neper	$1\ Np = 1$ (nondimensional)	$L_p = \ln(p_1/p_2)\ Np$ $= L_I = 0.5 \ln(I_1/I_2)\ Np$
Sound intensity level L_I		dB	decibel	$1\ dB = \frac{1}{20} \ln 10\ Np \approx 0.1151\ Np$	$L_p = 20 \lg(p_1/p_2)\ dB$ $= L_I = 10 \lg(I_1/I_2)\ dB$ At $f = 1{,}000$ Hz the (physiological) loudness level is measured in "phon": 1 phon = 1 dB and the loudness in "sone": 1 sone = 40 phon
		B	bel	$1\ B = 10\ dB \approx 1.151\ Np$	

Quantity and symbol	Legal units SI	Others	Name	Relationship	Remarks and units not to be used, incl. their conversion
Sound pressure level L_{pA}		dB (A)			Frequency-dependent weighting tuned to the human ear at 20 to 40 phon
Sound power level A-weighted L_{WA}					

12. Quantities used in atom physics and other quantities.

Energy W		eV	electron-volt	1 eV = $1.602176634 \cdot 10^{-19}$ J	
Activity of a radioactive substance A	Bq		becquerel	1 Bq = 1 s^{-1}	1 Ci (curie) = $3.7 \cdot 10^{10}$ Bq
Absorbed dose D	Gy		gray	1 Gy = 1 J/kg	1 rd (rad) = 10^{-2} Gy
Dose equivalent D_q	Sv		sievert	1 Sv = 1 J/kg	1 rem = 10^{-2} Sv
Absorbed dose rate $\dot{D}$	Gy/s			1 Gy/s = 1 W/kg	1 rd/s = 10^{-2} Gy/s
Ion dose J	C/kg				1 R (roentgen) = $258 \cdot 10^{-6}$ C/kg
Ion dose rate $\dot{J}$	A/kg				
Amount of substance n	mole		mole		
Catalytic activity	kat		katal	1 kat = 1 mol/s	

Further units

Table 5: Conversion of units

Units of length

Name	*Conversion*
micron	1 µ = 1 µm
typographical point	1 p = 0.376065 mm
inch	1 in = 25.4 mm
foot	1 ft = 12 in = 0.3048 m
yard	1 yd = 3 ft = 0.9144 m
mile	1 mile = 1,760 yd = 1.609344 km
nautical mile (international mile)	1 NM = 1 sm = 1.852 km (≈ 1′ of degree of longitude)

Anglo-American units of length:

microinch	1 µin = 0.0254 µm
milliinch	1 mil = 0.0254 mm
link	1 link = 201.17 mm
rod	1 rod = 1 pole = 1 perch = 5.5 yd = 5.0292 m
fathom	1 fathom = 2 yd = 1.8288 m
chain	1 chain = 22 yd = 20.1168 m
furlong	1 furlong = 220 yd = 201.168 m

Units of area

Name	*Conversion*
square inch (sq in)	1 in^2 = 6.4516 cm^2
square foot (sq ft)	1 ft^2 = 144 in^2 ≈ 0.0929 m^2
square yard (sq yd)	1 yd^2 = 9 ft^2 ≈ 0.8361 m^2
acre	1 ac = 4840 yd^2 ≈ 4,046.856 m^2
square mile (sq mile)	1 $mile^2$ = 640 acre ≈ 2.59 km^2
barn	1 b = 10^{-28} m^2

Units of volume

Name	*Conversion*
cubic inch (cu in)	1 in^3 = 16.3871 cm^3
cubic foot (cu ft)	1 ft^3 = 1,728 in^3 = 0.02832 m^3
cubic yard (cu yd)	1 yd^3 = 27 ft^3 = 0.76456 m^3

Further units in the United Kingdom (UK):

fluid ounce	1 fl oz ≈ 0.028413 *l*
pint	1 pt ≈ 0.56826 *l*
quart	1 qt = 2 pt ≈ 1.13652 *l*
gallon	1 gal = 4 qt ≈ 4.5461 *l*
barrel (crude oil)	1 bbl = 35 gal ≈ 159.1 *l*
barrel (other liquids)	1 bbl = 36 gal ≈ 163.6 *l*

Further units in the United States (US):

fluid ounce	1 fl oz ≈ 0.029574 *l*
liquid pint	1 liq pt ≈ 0.47318 *l*
liquid quart	1 liq qt = 2 liq pt ≈ 0.94635 *l*
gallon	1 gal = 4 liq qt ≈ 3.7854 *l*
liquid barrel	1 liq bbl = 31,5 gal ≈119.24 *l*
barrel petroleum	1 barrel petroleum = 42 gal ≈ 158.99 *l* (for crude oil)

Velocities

Name	*Conversion*
kilometer per hour	1 km/h = (1/3.6) m/s ≈ 0.2778 m/s
miles per hour	1 mile/h ≈ 1.6093 km/h
knot	1 kn = 1 NM/h = 1 sm/h = 1.852 km/h ≈ 0.5144 m/s
Mach number Ma	The Mach number Ma is the quotient of velocity and velocity of sound.

Units of mass

Name	*Conversion*
Pfund (pound)	1 Pfund = 0.5 kg
Zentner (metric hundredweight)	1 Ztr = 50 kg
Doppelzentner (metric quintal)	1 dz = 100 kg
Gamma	1 γ = 1 µg
metric carat (for precious stones only)	1 Kt = 0.2 g
atomic unit of mass	1 u ≈ 1.660539·10^{-27} kg
grain	1 gr = 64.79891 mg
pennyweight	1 dwt = 24 gr ≈ 1.5552 g
dram	1 dr ≈ 1.77184 g
ounce	1 oz = 16 dram ≈ 28.3495 g
troy ounce	1 oz tr (US) = 1 oz tr (UK) ≈ 31.1035 g
pound	1 lb = 16 oz ≈ 453.592 g
stone (UK)	1 st = 14 lb ≈ 6.35 kg
quarter (UK)	1 qr = 28 lb ≈ 12.7 kg
slug (mass accelerated by 1 ft/s^2 when 1 lbf is exerted on it)	1 slug ≈ 14.4939 kg
hundredweight (US)	1 cwt = 1 cwt sh (short cwt) = 1 quintal = 100 lb ≈ 45.3592 kg
hundredweight (UK)	1 cwt = 1 cwt l (long cwt) = 112 lb ≈ 50.8023 kg
ton (US)	1 ton (US) = 1 tn sh (short ton) ≈ 0.90718 t
ton (UK)	1 ton (UK) = 1 tn l (long ton) = 1 ton dw (ton deadweight) ≈ 1.01605 t
–	1 t dw = 1 t

Density

Name	*Conversion*
	1 lb/ft^3 = 16.018 kg/m^3
	1 lb/gal (UK) = 99.776 kg/m^3
	1 lb/gal (US) = 119.83 kg/m^3

Areometer degrees n are a measure of the density ρ of a liquid relative to the density of water at 15 °C.
$n = 144.3(\rho - 1\ kg/l)/\rho$ °Bé (degree Baumé)
$n = (141.5\ kg/l - 131.5 \cdot \rho)/\rho$ °API
(API: American Petroleum Institute)

Units of force

Name	*Conversion*
pond	1 p ≈ 9.80665 mN
kilopond	1 kp ≈ 9.80665 N
dyne	1 dyn = 10^{-5} N
sthène (French)	1 sn = 1 kN
poundforce	1 lbf = 4.44822 N
poundal (force which accelerates a mass of 1 lb by 1 ft/s^2)	1 pdl = 0.138255 N

Units of pressure and stress

Name	*Conversion*
microbar	1 µbar = 0.1 Pa
millibar	1 mbar = 1 hPa = 100 Pa
bar	1 bar = 10^5 Pa
–	1 kp/mm^2 ≈ 9.80665 x 10^6 Pa
technical atmosphere	1 at = 1 kp/cm^2 ≈ 9.80665 · 10^4 Pa
physical atmosphere	1 atm = 1.01325 · 10^5 Pa
torr	1 torr = 1 mm Hg (mercury column) = 133.322 Pa
–	1 mm water column = 1 kp/m^2 ≈ 9.80665 Pa

The following units are derived from the technical atmosphere:
p_{abs} (absolute pressure): 1 ata
p_{amb} (ambient pressure)
$p_e = p_{abs} - p_{amb}$ (gage pressure): 1 atpaa for $p_{abs} > p_{amb}$
$p_e = p_{amb} - p_{abs}$ (vacuum): 1 atpba for $p_{abs} < p_{amb}$

Anglo-American and other units:	
poundforce per square inch	1 lbf/in^2 = 1 psi = 6894.76 Pa
poundforce per square foot	1 lbf/ft^2 = 1 psf = 47.8803 Pa
tonforce per square inch (UK)	1 tonf/in^2 = $1.54443 \cdot 10^7$ Pa
poundal per square foot	1 pdl/ft^2 = 1.48816 Pa
barye (French)	1 barye = 0.1 Pa
pièce (French)	1 pz = 1 sn/m^2 (sthène/m^2) = 1,000 Pa

Units of energy

Name	*Conversion*
erg	1 erg = 10^{-7} J
calorie[1]	1 cal = 4.1868 J
	1 kp · m = 9.80665 J
	1 HP · h = $2.6478 \cdot 10^6$ J
therm	1 therm = $105.50 \cdot 10^6$ J

Anglo-American and other units:	
inch ounceforce	1 in ozf = 7.062 mJ
foot poundal	1 ft pdl = 0.04214 J
inch poundforce	1 in lbf = 0.11299 J
foot poundforce	1 ft lbf = 1.35582 J
British thermal unit[2]	1 Btu = 1,055.06 J
therm	1 therm = 10^5 Btu
horsepower hour	1 hp · h = $2.685 \cdot 10^6$ J
thermie (French)	1 thermie = 1,000 frigories = 1,000 kcal = 41.868 MJ
kg coal equivalents	1 kg CE = 29.3076 MJ (for the calorific value H_i = 7,000 kcal/kg coal)
tonne of coal equivalents	1 t CE = 1,000 kg CE

Units of power

Name	*Conversion*
kilocalorie per hour	1 kcal/h = 1.163 W
calorie per second	1 cal/s = 4.1868 W
–	1 kp · m/s = 9.80665 W
horsepower, cheval vapeur (French)	1 HP = 1 ch = 735.499 W

Anglo-American units:

–	1 ft · lbf/s = 1.35582 W
horsepower	1 hp = 745.70 W
–	1 Btu/s = 1,055.06 W

Fuel consumption

Name	*Conversion*
–	1 g/(HP · h) = 1.3596 g/(kW h)
–	1 lb/(hp · h) = 608.277 g/(kW h)
–	1 liq pt/(hp · h) = 634.545 cm^3/(kW h)

x mile/gal (US) $\triangleq \frac{235.21}{x}$ *l*/100 km

x mile/gal (UK) $\triangleq \frac{282.48}{x}$ *l*/100 km

y *l*/100 km $\triangleq \frac{235.21}{y}$ mile/gal (US)

y *l*/100 km $\triangleq \frac{282.48}{y}$ mile/gal (UK)

[1] The quantity of heat which is required to heat 1 g water from 15 °C to 16 °C.
[2] The quantity of heat which is required to heat 1 lb water from 63 °F to 64 °F.

Units of temperature

Name	*Conversion*
K (kelvin)	
°C (degree Celsius)	$\vartheta/°C = T/K - 273.15$ This scale is based on the freezing point of water at 0 °C and the boiling point at 100 °C, at normal pressure in each case
°F (degree Fahrenheit)	$T_F/°F = 1.8 \cdot T/K - 459.67$ The freezing point of water is 32 °F, human body temperature is 96 °F
°Ra (degree Rankine)	$T_{Ra}/°Ra = 1.8 \cdot T/K$ This scale begins with the absolute temperature zero point at 0 K and uses a graduation like the Fahrenheit
°Re (degree Réaumur)	$T_{Re}/°Re = 0.8 \cdot (T/K - 273.15)$ The freezing point of water is 0 °Re, the boiling point is 80 °Re
Temperature differences	1 K ≙ 1 °C ≙ 1.8 °F ≙ 1.8 °Ra ≙ 0.8 °Re

Units of viscosity (kinematic)

Name	*Conversion*
	1 ft^2/s = 0.092903 m^2/s Measurement is carried out by viscosimeter in accordance with the standard DIN EN ISO 2431 [5]
A-seconds	Runout time from flow cup
Engler number	Relative runout time from Engler device: 1 °E ≈ 7.6 mm^2/s
RI seconds	Runout time from Redwood-I viscosimeter (UK): 1 R″ ≈ 4.06 mm^2/s
SU seconds	Runout time from Saybolt Universal viscosimeter (US): 1 S″ ≈ 4.63 mm^2/s

Natural constants

It is currently assumed that the physical limits apply equally at any place in our world. These describe the natural constants which both contain physical quantities (e.g., speed of light in vacuum, masses of elementary particles) and represent the connections between them (e.g., field constants of gravitation, electricity and magnetism). Their values depend on the system of units and must be experimentally determined.

Since the 26th CGPM seven constants have formed the foundation of the SI international system of units. These constants are used to define the base units and for this reason are referred to as defining constants (Table 6). The numerical values of these constants can thus be specified precisely.

Table 6: Defining constants

Hyperfine frequency of the cesium atom	$\Delta\nu_{Cs}$	9 192 631 770 Hz
Speed of light (in vacuum)	c	299 792 458 $\frac{m}{s}$
Planck constant	h	$6.626\,070\,15 \cdot 10^{-34}$ J s
Elementary charge	e	$1.602\,176\,634 \cdot 10^{-19}$ C
Boltzmann constant	k	$1.380\,649 \cdot 10^{-23}$ $\frac{J}{K}$
Avogadro constant	N_A	$6.022\,14076 \cdot 10^{23}$ mol^{-1}
Luminous efficacy of radiation		683 lm W^{-1}

Table 7: Selection of derived, exact constants

Faraday constant	F	$F = e\,N_A$ = 96 485.333 12… $\frac{C}{mol}$
Universal gas constant	R	$R = k\,N_A$ = 8.314 462 6318… $\frac{J}{mol \cdot K}$
Stefan-Boltzmann constant	σ	$5.670\,374\,419\ldots \cdot 10^{-8}$ $\frac{W}{m^2 \cdot K^4}$

Table 8: Further natural constants

Loschmidt number	N_L	$N_L = \frac{N_A}{V_{m0}}$ $\approx 2.6867805(24) \cdot 10^{25}\ \mathrm{m^{-3}}$ V_{m0}: Molar volume of an ideal gas under normal conditions
electric field constant	ε_0	$\frac{1}{\mu_0\ c^2}$ $\approx 8.854\,187\,817\,62 \cdot 10^{-12}\ \frac{\mathrm{F}}{\mathrm{m}}$
magnetic field constant	μ_0	$4\pi \cdot 10^{-7}\ \frac{\mathrm{V\,s}}{\mathrm{A\,m}}$ $\approx 12.566\,370\,614 \cdot 10^{-7}\ \frac{\mathrm{H}}{\mathrm{m}}$
gravitation constant	G	$6.674\,2(10) \cdot 10^{-11}\ \frac{\mathrm{m^3}}{\mathrm{kg \cdot s^2}}$
atomic unit of mass	u	$1.660\,538\,86(28) \cdot 10^{-27}$ kg
rest mass of electron	m_e	$9.109\,382\,6(16) \cdot 10^{-31}$ kg
rest mass of proton	m_p	$1.672\,621\,71(29) \cdot 10^{-27}$ kg

Constants derived from these defining constants can also be specified precisely (Table 7).

Table 8 lists further important natural constants (source: [3]). The digits in parentheses after a numerical value denote the uncertainty in the last places of the value.

Basic principles of mechanics

Rectilinear and rotary motion

Forces, moments and energies are required to move bodies with mass. Any number of motions can be composed of rectilinear motions (translation) and rotary motions (rotation). The most important basic equations for these motions are set out in Table 2. The quantities used are listed in Table 1.

Mass and moment of inertia

Mass m is a property of matter and the cause of the inertia which sets a resistance against a change of velocity (acceleration) in the case of a rectilinear motion. The moment of inertia J (also called mass moment of inertia or rotating mass) causes a resistance in the case of a rotary motion (Table 3).

Path, velocity and acceleration

Path s is a limited distance, velocity v is the path covered during a specific time t. For a rotary motion angular velocity ω is obtained from the angle φ covered during a specific time. A uniform motion exists when velocity v or rotational speed n (or angular velocity ω) is constant. In this case, acceleration (a or α) equals zero.

A body is accelerated when there is a change of velocity. A motion is uniformly accelerated if acceleration is constant. In the case of negative acceleration, the motion is decelerated or braked.

Force and moment

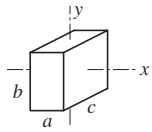
A force accelerates or deforms a body. It is referred to in classic physics as the time rate of change of linear momentum p. If a mass m is rotated at centroidal dis-

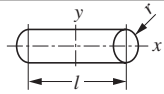
Table 1: Symbols and units

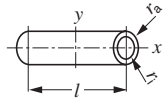
Quantity		Unit
A	Area	m^2
E	Modulus of elasticity	N/mm^2
E_k	Kinetic energy	J = N m
E_p	Potential energy	J = N m
E_{rot}	Rotational energy	J = N m
F	Force	N
F_G	Weight	N
F_m	Mean force during impulse period	N
F_R	Frictional force	N
F_U	Peripheral force	N
F_Z	Centrifugal force	N
H	Rotational impulse	$N m \cdot s = kg \cdot m^2/s$
I	Force impulse	$N s = kg \cdot m/s$
J	Moment of inertia	$kg \cdot m^2$
L	Angular momentum	$N m \cdot s$
M_t	Torque	N m
$M_{t,m}$	Mean torque during impulse period	N m
P	Power	W = N m/s
R_e	Yield point	N/mm^2
R_m	Tensile strength	N/mm^2
V	Volume	m^3
W	Work, energy	J = N m
a	Acceleration	m/s^2

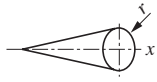
Quantity		Unit
a_Z	Centrifugal acceleration	m/s^2
d	Diameter	m
e	Base of natural logarithms ($e \approx 2.781$)	–
g	Acceleration of free fall ($g \approx 9.81$)	m/s^2
h	Height	m
i	Radius of gyration	m
l	Length	m
m	Mass	kg
n	Rotational speed	1/s
p	Linear momentum	N s
p	Surface pressure	N/mm^2
r	Radius	m
s	Length of path	m
t	Time	s
v	Velocity	m/s
α	Angular acceleration	rad/s^2
β	Wrap angle	°
γ	Wedge angle	°
ε	Elongation	%
μ	Coefficient of friction	–
ν	Transverse contraction	–
ρ	Density	kg/m^3
φ	Angle of rotation	rad
ω	Angular velocity	1/s

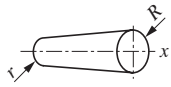
tance r about a rotational axis at angular velocity ω, this generates a centrifugal force F_Z which acts radially outwards from the center. A force which is applied at distance r from a center of rotation generates a moment. An accelerated rotary motion with rotating mass J causes a moment in the form of an acceleration or braking torque.

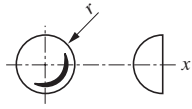


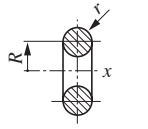












Work and energy

When a force F moves a body by path s, work W is performed which is stored as energy in this body. Energy is therefore defined in physics as stored work. Conversely, an energy can perform work. A distinction is made in mechanics between kinetic and potential energy. Kinetic energy is the work that must be expended to accelerate a body with mass m or rotating mass J to velocity v or angular velocity ω. Potential energy is the work that must be expended to raise a body to a height h. When a spring is tensioned, potential energy is stored which can perform work again when the spring is released.

Table 2: Rectilinear and rotary motion

Rectilinear motion (translation)		Rotary motion (rotation)	
Mass		**Moment of inertia** (Table 3)	
$m = V\rho$		$J = m\,i^2$	
Path		**Angle**	
$s = \int v(t)\,dt$		$\varphi = \int \omega(t)\,dt$	
$s = v\,t$	[v = const.]	$\varphi = \omega\,t = 2\pi n$	[n = const.]
$s = {}^1\!/_2\,a\,t^2$	[a = const.]	$\varphi = {}^1\!/_2\,\alpha\,t^2$	[α = const.]
Velocity		**Angular velocity**	
$v = ds(t)/dt$		$\omega = d\varphi(t)/dt$	
$v = s/t$	[v = const.]	$\omega = \varphi/t = 2\pi n$	[n = const.]
$v = a\,t = \sqrt{2\,a\,s}$	[a = const.]	$\omega = \alpha\,t = \sqrt{2\,\alpha\,\varphi}$	[α = const.]
		Peripheral velocity	
		$v = r\,\omega$	
Acceleration		**Angular acceleration**	
$a = dv(t)/dt$		$\alpha = d\omega(t)/dt$	
$a = (v_2 - v_1)/t$	[α = const.]	$\alpha = (\omega_2 - \omega_1)/t$	[α = const.]

$E_p = F_G\,h$			
Power		**Power**	
$P = dW/dt = F\,v$		$P = dW/dt = M_t\,\omega = M_t \cdot 2\,\pi\,n$	
Linear momentum		**Angular momentum**	
$p = m\,v$		$L = J\,\omega = J \cdot 2\,\pi\,n$	
Force impulse		**Rotational impulse**	
$I = \Delta p = F_m\,(t_2 - t_1)$		$H = M_{t,\,m}\,(t_2 - t_1)$	

Table 3: Moments of inertia

Type of solid	Moments of inertia (J_x about the x-axis[1], J_y about the y-axis[1])
Right parallelepiped, cuboid 	$J_x = m\frac{b^2+c^2}{12}$, $J_y = m\frac{a^2+c^2}{12}$ $J_x = J_y = m\frac{a^2}{6}$ (cube with side length a)
Regular cylinder 	$J_x = m\frac{r^2}{2}$, $J_y = m\frac{r^2+l^2}{12}$
Hollow regular cylinder 	$J_x = m\frac{r_a^2+r_i^2}{2}$ $J_y = m\frac{r_a^2+r_i^2+\frac{l^2}{3}}{4}$
Circular cone 	$J_x = m\frac{3r^2}{10}$ $J_x = m\frac{r^2}{2}$ Envelope of cone (excluding end base)
Truncated circular cone 	$J_x = m\frac{3(R^5-r^5)}{10(R^3-r^3)}$ $J_x = m\frac{(R^2+r^2)}{2}$ Envelope of cone (excluding end faces)
Sphere and hemisphere 	$J_x = m\frac{2r^2}{5}$ $J_x = m\frac{2r^2}{3}$ Surface area of sphere
Hollow sphere r_a Outer sphere radius r_i Inner sphere radius	$J_x = m\frac{2(r_a^5-r_i^5)}{5(r_a^3-r_i^3)}$
Torus  UAN0007-2Y	$J_x = m(R^2+\frac{3}{4}r^2)$

[1] The moment of inertia for an axis parallel to the x-axis or y-axis at a distance a is: $J_A = J_x + m\,a^2$ or $J_A = J_y + m\,a^2$.

Conservation of energy
The law of conservation of energy states that the total energy in a closed system is constant. Energy can be neither created nor destroyed, but instead converted between different forms of energy (e.g. kinetic energy to thermal energy) or transmitted from one body to another.

Power
Power is the work performed during a specific period of time. Because every power transfer is associated with loss, the output power is always less than the input power. The ratio of output to input power is called efficiency η and is therefore always less than 1.

$$\eta = \frac{P_{out}}{P_{in}}.$$

Linear momentum and impulse
Linear momentum p describes the motion of a body with mass, and is calculated as the product of moving mass m and velocity v. Every moving body can transmit its linear momentum during an impulse process to another body, as happens for example in a collision between two vehicles. The force acting on a body gives rise to a change of linear momentum, which is called force impulse I.

During a rotary motion angular momentum L is obtained from the product of rotating mass J and angular velocity ω. A rotational impulse H is generated for example when two disks are jerkily coupled.

Conservation of momentum
The law of conservation of momentum states that the total momentum in a closed system is constant. It follows from this that the total momentum before and after an impulse must be equal.

Statics

Statics is the science of equilibrium on a rigid body. A body is in equilibrium when it is at rest or is moving uniformly or in a straight line. Equilibrium prevails when the sum of the applied forces and moments in all directions is equal to zero.

Plane system of forces
Forces are vectors which are determined by size and direction. They are geometrically (vectorially) added:

$$\vec{F}_{res} = \vec{F}_1 + \vec{F}_2 .$$

Two forces are composed with a parallelogram of forces or a triangle of forces (Figure 1a). If there are several forces, the resultant force F_{res} is determined by means of a polygon of forces (Figure 1b). When the polygon of forces is closed, the system of forces is in equilibrium.

Figure 1: Composition of forces

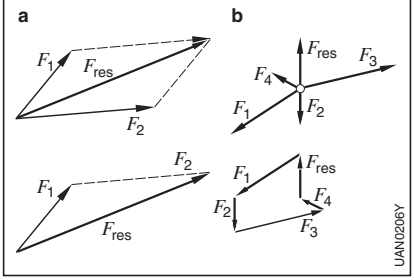
b) Closed polygon of forces (system in equilibrium).
F Force,
F_{res} Resultant force.



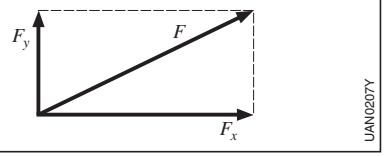


Figure 2. Force resolution
F Force,
F_x Force in x-direction,
F_y Force in y-direction.

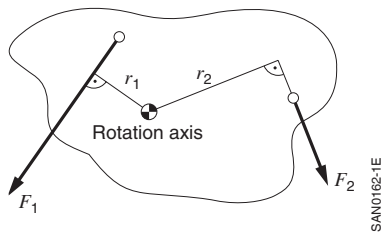
A force can also be resolved into components. A resolution into orthogonal components is sensible (Figure 2).

Transmission of force
Mechanical machines for the transmission of force can be reduced to the "lever" and "wedge" principles.

Lever
The lever principle can be derived from the equilibrium condition "sum of the moments is equal to zero". Disregarding friction, the system in Figure 3 is in equilibrium for the following condition:

$M_{t1} = M_{t2}$ or $F_1 r_1 = F_2 r_2$.

Figure 3: Lever principle
F Force, r Radius.



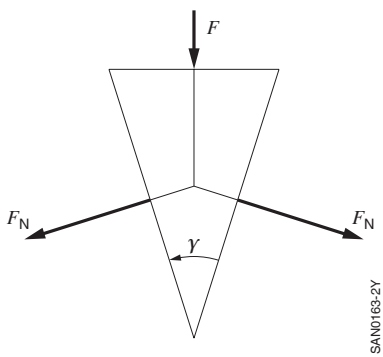


Figure 4: Forces on the wedge
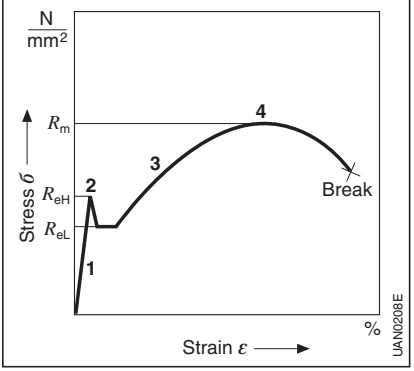
F Insertion force, F_N Normal force,
γ Wedge angle.



The lever principle is encountered in many applications, ranging from simple pliers, scales and wrenches through gear wheels and belt drives, right down to the connecting rods in piston engines.

Wedge
With the wedge principle, depending on the wedge angle γ, small forces (insertion force F) can be translated into large normal forces F_N (Figure 4). Without allowing for friction, the following applies:

$$F_N = \frac{F}{2 \sin \frac{\gamma}{2}} .$$

Very large application forces can be introduced in the smallest of spaces with the aid of wedges. Examples include wedges in shaft/hub connections and tapered connections for transmitting torques. However, both the screw and the clamping eccentric work according to the classic wedge principle.

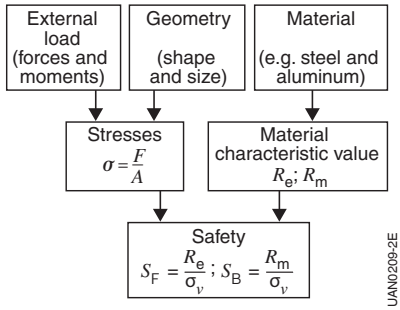
R_{eL} Lower yield point,
R_{eH} Upper yield point,
R_m Tensile strength
(maximum load before break).

Calculation of strength

Hooke's law



In response to an external load a body is deformed and stresses are generated inside the material (Figure 5). Metals have linear-elastic behavior until the yield point is reached. In other words, within this Hooke's range the component assumes its original length again when the load is reduced. The yield point R_e is the limit between elastic and plastic deformation. Above the yield point the material begins to "creep" and then remains permanently deformed. The tensile strength R_m is the maximum load before the component cracks or breaks.

In the case of ductile materials with a pronounced yield point R_e is always specified as the limit for dimensioning. The tensile strength is used for dimensioning only in the case of brittle materials which do not have a pronounced yield point (e.g. gray cast iron).

The linear area is known as Hooke's straight line, in which the ratio of stress σ and strain (elongation) ε is constant. With the proportionality constant E, which is termed the modulus of elasticity, Hooke's law for the mono-axial stress state is:

$$\sigma = E\varepsilon \ .$$

Figure 6: Strength verification

Strength verification

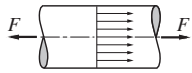
The aim of strength verification is to dimension components reliably and appropriately for the material involved. Strength verification in accordance with Figure 6 is conducted in four stages:

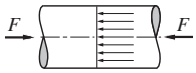
1. Determination of the external load (forces and moments),
2. Calculation of the existing stress,
3. Choice of the material characteristic value,
4. Comparison of the existing stress with the material characteristic value.

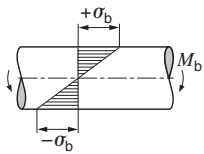
If the external forces and moments are known, the stresses in the component can be calculated in accordance with Table 4. Because tensile, compressive and bending stresses (normal stresses) lie in one plane or act in the same direction, they can be cumulatively superimposed. Even the shear and torsional stresses can be added. However, if normal and shear stresses occur simultaneously in a component, a reduced stress must be created with a strength hypothesis because the material characteristic values were calculated from mono-axial tensile and vibration fatigue tests.

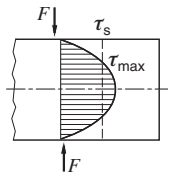
There are different hypotheses to suit the material behavior (ductile or brittle). For ductile materials (most metals) the deformation energy hypothesis is used. For the mono-axial stress state (bar) the reduced stress is calculated in accordance with Table 4.

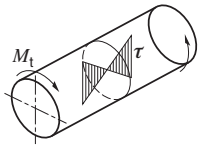
Surface pressure

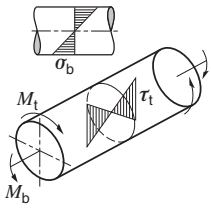












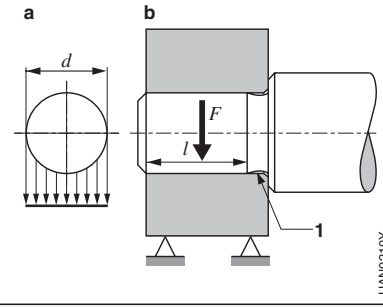
Surface pressure is a compressive stress. It is generated when a force F is transmitted from one solid body to another. For effective surface areas pressure p is equal to the ratio of force F to contact surface A.

Pressure on the face of a hole

When journal and bore or shaft and friction bearing are paired, the pressure on the face of a hole is usually used for calculation. Here the load is referred to the projected area A_{proj} (Figure 7):

$$p = \frac{F}{A_{proj}} = \frac{F}{dl} \leq p_{perm} \ .$$

Table 4: Basic equations of strength calculation



Loading	Stress
Tensile stress 	$\sigma_z = \frac{F}{A}$
Compressive stress  UAN0214Y	$\sigma_d = \frac{F}{A}$
Bending stress  UAN0215Y	$\sigma_b = \frac{M_b}{W_b}$ W_b from Table 5
Shear stress  UAN0216Y	$\tau_s = \frac{F}{A}$
Torsional stress  UAN0217Y	$\tau_t = \frac{M_t}{W_t}$ W_t from Table 5
Reduced stress  UAN0218Y	$\sigma_v = \sqrt{\sigma^2 + 3\tau^2}$

Hertzian stress

In reality, however, the maximum stress where the surfaces are curved is greater and can be calculated according to Hertz's theory. The maximum Hertzian stress is dependent on the deformation (flattening) of the touching surfaces (Figure 8). This in turn is dependent on the radii, on the modulus of elasticity E and

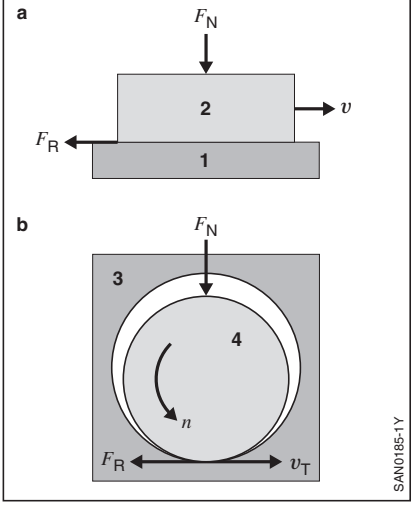
Friction

Coulomb friction



When touching bodies move relative to each other, friction acts as mechanical resistance acting in the opposite direction to the motion at velocity v (Figure 9). The force of resistance, known as frictional force F_R, is proportional to the normal force F_N. Static friction exists as long as the external force is less than the frictional force and the body remains at rest. When static friction is overcome, and the body is set in motion, frictional force is governed by Coulomb's law of sliding friction:

$$F_R = \mu F_N .$$

Coefficient of friction

The coefficient of friction μ always denotes a system property and not a material property. Coefficients of friction are, among other things, depending on material pairing (see Table 7), temperature,

Figure 9: Coulomb friction
a) Linear motion,
b) Rotary motion.

F_N Normal force, F_R Friction force,
v Velocity, n Rotational speed,
v_T Tangential velocity at the point of contact.

surface condition, sliding velocity, the surrounding medium (e.g. water or CO_2, which can be adsorbed by the surface), and the intermediate material (lubricant). For this reason, coefficients of friction always fluctuate between limit values and may have to be calculated experimentally. Static friction is generally greater than sliding friction. In special cases, the friction coefficient can exceed 1, for example with very smooth surfaces where cohesion forces are predominant or with racing tires featuring an adhesion or suction effect.

Friction on the wedge
Allowing for friction, the insertion force is governed by (Figure 10):

$$F = 2\left(F_N \sin\frac{\gamma}{2} + F_R \cos\frac{\gamma}{2}\right)$$

The normal force is then

$$F_N = \frac{F}{2\left(\sin\frac{\gamma}{2} + \mu\cos\frac{\gamma}{2}\right)}.$$

Rope friction
Motions and moments can be transmitted with elastic, pliable ropes or belts (Figure 11). Sliding friction occurs in the event of relative motion between rope and pulley (e.g. belt brake or bollard with running rope). Static friction exists when rope and pulley are at rest relative to each other (e.g. belt drive, belt brake as holding brake, bollard with rope at rest). The coefficient of sliding friction μ or the static friction μ_H must be applied accordingly.

According to Euler's rope-friction formula, the force in the pulling strand (taut strand):

$$F_1 = F_2 e^{\mu\beta}.$$

The peripheral force F_U or frictional force F_R is calculated as

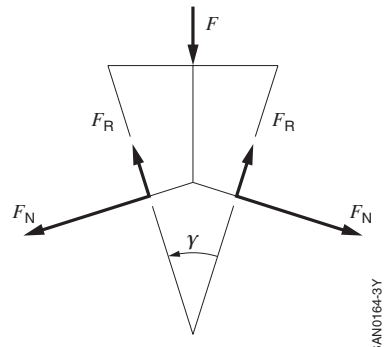
$$F_U = F_R = F_1 - F_2$$

and the transmittable friction torque as

$$M_R = F_R\, r.$$

Rolling friction
Rolling friction occurs when a ball, a caster or a wheel rolls on a track or roadway. Typical examples of this are the roller bearing, the pairing of wheel flange and rail for railroads or the pairing of tire and roadway for motor vehicles. Both rolling body and base are subjected to elastic deformation during rolling. This generates asymmetrical pressure (Figure 12). The equilibrium condition is used to calculate

Figure 10: Friction on the wedge
F_N Normal force,
F_R Frictional force,
γ Wedge angle.



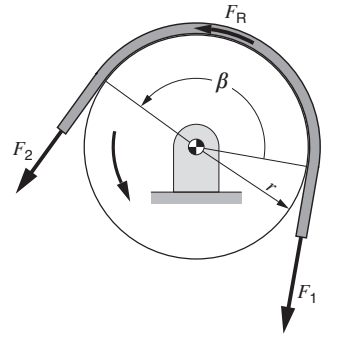


Figure 11: Rope friction
F_1 Force in taut strand,
F_2 Force in slack strand,
r Radius of pulley,
β Wrap angle.

frictional force F_R for the dry state (i.e. without lubrication):

$$F_R = \frac{x}{R} F_N = \mu_R F_N .$$

Ratio x/R can be calculated as frictional resistance or coefficient of rolling friction μ_R. From this it can be seen that large rolling bodies roll more easily than small rolling bodies. Hard surfaces (roller bearing and railroad) give rise to small deformations and therefore result in very low coefficients of friction; soft surfaces, as in the tire/roadway pairing, on the other hand result in higher coefficients of friction. While frictional resistances of μ_R = 0.0015 can be achieved for ball bearings, the coefficients of friction of a car tire on asphalt are μ_R = 0.015.

Fluid mechanics

Hydrostatics

Density and pressure

Although fluids are compressible to a lesser extent, they can be viewed as being incompressible for most problems. In addition, since density is only slightly dependent on temperature, it can be taken as constant for many applications.

Pressure $p = dF/dA$ is non-directional in fluids which are at rest. If the pressure component produced by the difference in height (geodetic pressure) is negligible, the hydrostatic pressure is uniformly high everywhere (e.g. in a hydrostatic press).

Fluid at rest in an open vessel

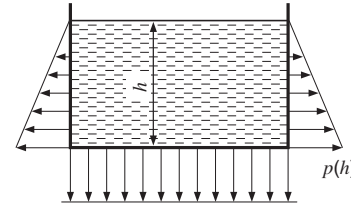
In the case of open vessels, the pressure in the fluid is only dependent on the depth of the fluid (Figure 1).Closed vessels with pressure compensation, such as fuel tanks and brake-fluid reservoirs, can also be considered as open vessels. The following applies:

Pressure: $p(h) = \rho g h$
Force acting on bottom: $F_B = A_B \rho g h$
Force acting on sides: $F_S = 0.5 A_S \rho g h$

Hydrostatic press

By way of example, power amplification in vehicle brakes and hydraulic power-assisted steering systems functions according to the hydrostatic-press principle (Figure 2). The following relationships apply to the pressure p and the piston forces F:

Figure 1: Pressure distribution in fluid at rest
p Pressure,
h Depth of fluid.



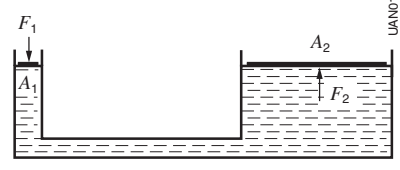


Figure 2: Hydrostatic press
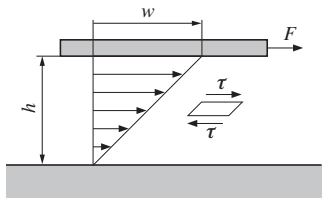
F Force,
A Cross-sectional area.

Pressure: $p = \frac{F_1}{A_1} = \frac{F_2}{A_2}$.

Piston forces: $F_1 = pA_1 = F_2\frac{A_1}{A_2}$,

$$F_2 = pA_2 = F_1\frac{A_2}{A_1}.$$



Buoyancy
Buoyancy is a force acting against gravity and acts on the center of gravity of the volume of the displaced fluid. It corresponds to the weight of the fluid displaced by the submerged body:

$F_A = m_F g = V_F \rho g$.

A body will float if $F_A = F_G$.

The amount of fuel available can be easily and reliably measured by analog sensors (floats) in the fuel tank with the aid of buoyancy.

Figure 3: Shear stresses in fluids
τ Shear stress,
w Flow velocity,
h Height,
F Force.

Flow mechanics

Basic principles
An ideal fluid (generic term for gases and liquids) is incompressible and frictionless. This means that no shear stresses occur in the fluid, and the pressure on a fluid element is uniform in all directions. In actual fact, however, a resistance must be overcome in fluids if deformations occur that are caused by displacement of fluid elements (Figure 3). The resulting shear stress complies with Newton:

$$\tau = \frac{F}{A} = \eta\,\frac{w}{h}.$$

The proportionality factor η is called the dynamic viscosity and is greatly dependent on temperature. In practice, however, the kinematic viscosity

$$\nu = \frac{\eta}{\rho}$$

is often used, as it can be measured very easily with a capillary viscometer.

Flows without turbulence, in which the individual fluid layers move separately in parallel and which are predominantly determined by viscosity, are known as laminar flows. If the flow velocity exceeds a limit value, adjacent layers start to swirl, resulting in a turbulent flow. In addition to the flow velocity, the transition point between laminar and turbulent flow is also dependent on the Reynolds number

$$R_e = \frac{\rho L w}{\eta} = \frac{L w}{\nu}$$

In the case of a flow within a pipe, the pipe diameter is used for L. Flow in a pipe becomes unstable or turbulent at $R_e > 2300$.

Since, in the case of gases with low flow velocities (up to 0.5 times the velocity of sound), compression is negligible in many flow processes, they are also governed by the laws of incompressible fluids.

Basic equations of flow mechanics

The most important basic equations of flow mechanics are the continuity equation and the Bernoulli equation. They describe the conservation of mass and energy in flowing fluids.

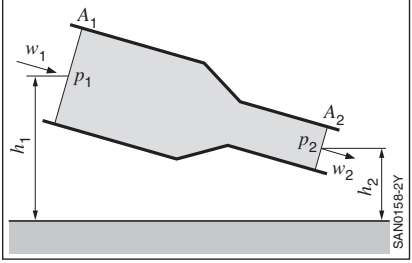
Continuity equation

In a steady state, mass conservation requires that in a flow the mass flow rate be of equal magnitude in each cross-section (Figure 4):

$$\dot{m} = \rho A_1 w_1 = \rho A_2 w_2 = \text{const.}$$

In the case of incompressible fluids (ρ = konst.), the volumetric flow must also be constant:

$$Q = A_1 w_1 = A_2 w_2 = \text{konst.}$$



Bernoulli equation

From the continuity equation, it follows that an acceleration takes place between A_1 and A_2. This results in an increase in kinetic energy, which must be effected by a pressure drop, where $p_1 > p_2$ (Figure 4). According to the law of conservation of energy, the sum of the static pressure p, kinetic pressure, and geodetic pressure is constant in a flowing fluid. Ignoring friction losses, the following applies accordingly to the flowing fluid in a non-horizontal pipe:

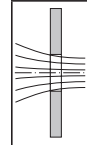
$$p_1 + \frac{1}{2}\rho w_1^2 + \rho g h_1 = p_2 + \frac{1}{2}\rho w_2^2 + \rho g h_2 .$$

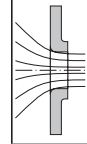
Figure 4: Continuity and Bernoulli equations

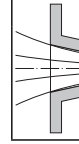
A Cross-sectional area, h Height, p Pressure, w Flow velocity.

Discharge from a pressure vessel

Under the precondition that the cross-sectional area of the discharge end is very much smaller than that of the vessel (Figure 5), the velocity w_1 is negligible according to the continuity equation. As derived from Bernoulli equation, the discharge velocity is governed by the following:







$$w_2 = \varphi\sqrt{\frac{2}{\rho}(p_1 - p_2) + 2gh} .$$

The velocity coefficient φ takes into account the losses that occur. The jet constriction must also be taken into account for the volumetric flow or the discharge volume; this constriction is dependent on the contraction coefficient α. The following then applies to the discharge volumetric flow:

$$Q = \alpha\varphi A_2\sqrt{\frac{2}{\rho}(p_1 - p_2) + 2gh} .$$

Velocity coefficient and contraction coefficient are often expressed together as the discharge coefficient $\mu = \alpha\varphi$ (Table 2).

Table 2: Discharge openings

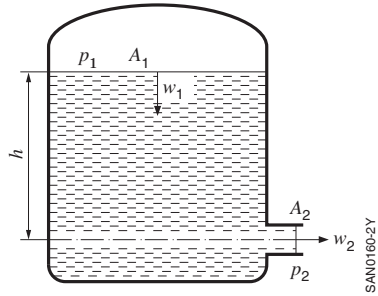
Resistance of bodies submerged in a fluid flow

A pressure differential occurs across a body submerged in a fluid flow (e.g. the vehicle body), resulting in a resistance force

$$F_W = \frac{1}{2} c_W A \rho w^2 .$$



Here, A is the cross-sectional area of the body on which the fluid flow is acting and c_d an undefined coefficient of resistance, which is dependent on the shape of the body submerged in the fluid flow.

As it is extremely complex to calculate exactly the resistance to flow even for simple bodies, resistance to flow is usually determined experimentally. If the dimensions are large, the measurements are taken on downscaled models. As well as geometrical similarity, the forms of energy that occur (kinetic energy, frictional work) in the original fluid flow and in the model flow must be proportional. This proportion is denoted by the Reynolds number R_e.

Basically: Two flows are similar in fluid-dynamic terms if their Reynolds numbers R_e are identical. Because even complex geometries are composed of simple basic bodies, streamlined surfaces can already be derived during the modeling phase as per Table 3.

Vibrations and oscillations

Terms

(Symbols and units in Table 1, see also DIN 1311, [1] and [2]).

Vibration or oscillation
A vibration or oscillation is the change in a physical quantity which repeats at more or less regular time intervals and whose direction changes with similar regularity (Figure 1).

Period
The period T is the time taken for one complete cycle of a single oscillation.

Amplitude
The amplitude $\hat{y}$ is the maximum instantaneous value (peak value) of a sinusoidally oscillating physical quantity.

Frequency
The frequency f is the number of oscillations in one second, the reciprocal value of the period of oscillation T.

Angular frequency
The angular frequency ω is 2π times the frequency f.

Particle velocity
Particle velocity v is the instantaneous value of the alternating velocity of a vibrating particle in its direction of vibration. It must not be confused with the velocity of propagation of a traveling wave (e.g. the velocity of sound).

Figure 1: Sinusoidal oscillation

Fourier series
Every periodic function, which is piecewise monotonic and smooth, can be expressed as the sum of sinusoidal harmonic components.

Beats
Beats occur when two sinusoidal oscillations, whose frequencies do not differ greatly, are superposed ($f_1 \approx f_2$). They are periodic. Their basic frequency is the difference between the frequencies of the superposed sinusoidal oscillations.

Natural frequency
The natural frequency is that frequency f at which an oscillating system can oscillate freely after being excited once (natural oscillation). It is dependent only on the properties of the oscillating system.

Damping
Damping is a measure of the energy losses in an oscillatory system when one form of energy is converted into another. The consequence is a decay of the oscillation (Figure 2).

Damping ratio
The damping ratio D is the measure for the degree of damping.

Logarithmic decrement
The logarithmic decrement Λ is the natural logarithm of the relationship between two extreme values of a damped natural oscillation which are separated by one period.

Forced oscillations
Forced oscillations arise under the influence of an external physical force (excitation), which does not change the properties of the oscillator. The frequency of forced oscillations is determined by the frequency of the excitation.

Transfer function
The transfer function is the quotient of amplitude of the observed state or output variable and the amplitude of excitation, plotted against the excitation frequency f or the excitation-circuit frequency ω.

Resonance
A resonance occurs when the transfer function attains its maximum value as the excitation frequency approaches the natural frequency.

Resonant frequency
The resonant frequency is the excitation frequency at which the oscillator state variable attains its maximum value. Disregarding the damping, the resonant frequency is equal to the natural frequency.

Half-value width
The half-value width is the difference between the frequencies at which the level of the observed variable has dropped to $1/\sqrt{2} \approx 0.707$ of the maximum value.

Resonance sharpness
The resonance sharpness Q (or quality factor) is the maximum value of the transfer function.

Coupling
If two oscillatory systems are coupled together – mechanically by mass or elasticity, electrically by inductance or capacitance – a periodic exchange of energy takes place between the systems.

Wave
A wave is a spatial and temporal change of state of a continuum, which can be expressed as a unidirectional transfer of location of a certain state over a period of time. The matter that may be present in the space is not necessarily also transported.

There are transversal waves (e.g. waves in rope and water) and longitudinal waves (e.g. sound waves in air).

Interference
The principle of undisturbed superposition of waves is called interference. At every point in space, the instantaneous value of the resulting wave is equal to the sum of the instantaneous values of the individual waves.

Plane wave
A plane wave is a wave in which the surfaces of the same phase (e.g. maxima or wave fronts) form a plane, i.e. the wave propagates linearly. The wave fronts are vertical to the direction of propagation.

Standing waves
Standing waves occur as a result of interference between two waves of equal frequency, wavelength, and amplitude traveling in opposite directions. In contrast to a propagating wave, the amplitude of the standing wave is constant at every point; nodes (zero amplitude) and antinodes (maximum amplitude) occur. Standing waves occur, for example, when a plane wave is reflected on a plane wall which is vertical to the direction of wave propagation.

Rectification value
The rectification value y_{rec} is the arithmetic mean value, linear in time, of the values of a periodic signal:

$$y_{rec} = \frac{1}{T}\int_0^T |y|\, dt.$$

For a sine curve:

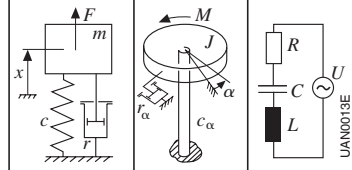
$$y_{rec} = \frac{2\hat{y}}{\pi} \approx 0.637\,\hat{y}.$$

Effective value
The effective value y_{eff} is the time virtual value of a periodic signal. It is also known as the RMS value (root mean square):

$$y_{eff} = \sqrt{\frac{1}{T}\int_0^T y^2\, dt}.$$

For a sine curve:

$$y_{eff} = \frac{\hat{y}}{\sqrt{2}} \approx 0.707\,\hat{y}.$$



Harmonic factor
The harmonic factor is the ratio of y_{eff} to y_{rec}. For a sine curve the harmonic factor is $y_{eff}/y_{rec} \approx 1.111$.

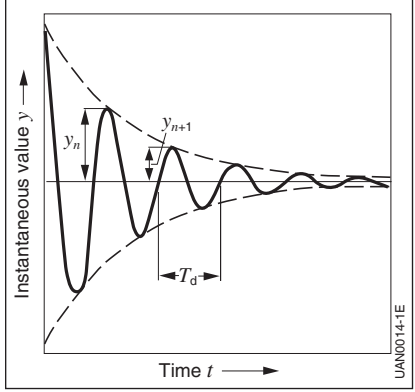
Peak factor
For a sine curve the peak factor is $\hat{y}/y_{eff} = \sqrt{2} \approx 1.414$.

Equations

The following equations apply to simple oscillators (Table 2) if the general quantity designations in the formulas are replaced by the relevant physical quantities.

Table 2: Simple oscillatory systems

	Mechanical		Electrical
	Translational	Rotational	
			
Des.	Physical quantity		
y	x	α	Q
$\dot{y}$	$\dot{x} = v$	$\dot{\alpha} = \omega$	$\dot{Q} = I$
$\ddot{y}$	$\ddot{x} = \dot{v}$	$\ddot{\alpha} = \dot{\omega}$	$\ddot{Q} = \dot{I}$
F_Q	F	M	U
a	m	J	L
b	r	r_α	R
c	c	c_α	$1/C$



Differential equation

$$a\ddot{y} + b\dot{y} + cy = F_Q(t) = \hat{F}_Q \sin \Omega t,$$

Period $T = 1/f$,
Angular frequency $\omega = 2\pi f$.

Sinusoidal oscillation: $y = \hat{y} \sin \omega t$.

Figure 2: Free oscillation and damping for $0 < D < 1$

Free oscillations ($F_Q = 0$)
Logarithmic decrement (Figure 2):

$$\Lambda = \ln\left(\frac{y_n}{y_{n+1}}\right) = \frac{\pi b}{\sqrt{ca - \frac{b^2}{4}}},$$

Decay coefficient $\delta = \frac{b}{2a}$,

Damping ratio $D = \frac{\delta}{\omega_0} = \frac{b}{2\sqrt{ca}}$,

$$D = \frac{\Lambda}{\sqrt{\Lambda^2 + 4\pi^2}} \approx \frac{\Lambda}{2\pi} \text{ (low level of damping).}$$

Angular frequency of undamped oscillation ($D = 0$): $\omega_0 = \sqrt{c/a}$.

Angular frequency of damped oscillation ($0 < D < 1$): $\omega_d = \omega_0\sqrt{1-D^2}$.

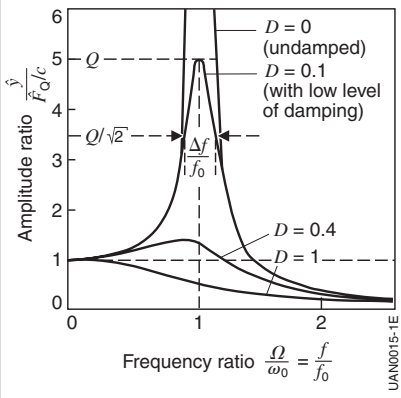
For $D \geq 1$ no oscillations, but creepage.

Forced oscillations
Quantity of transfer function:

$$\frac{\hat{y}}{\hat{F}_Q} = \frac{1}{\sqrt{(c - a\Omega^2)^2 + (b\,\Omega)^2}}$$

$$= \frac{1}{c\sqrt{\left(1 - \left(\frac{\Omega}{\omega_0}\right)^2\right)^2 + \left(\frac{2D\Omega}{\omega_0}\right)^2}},$$

Resonant frequency $f_g = f_0\sqrt{1-2D^2} < f_0$,



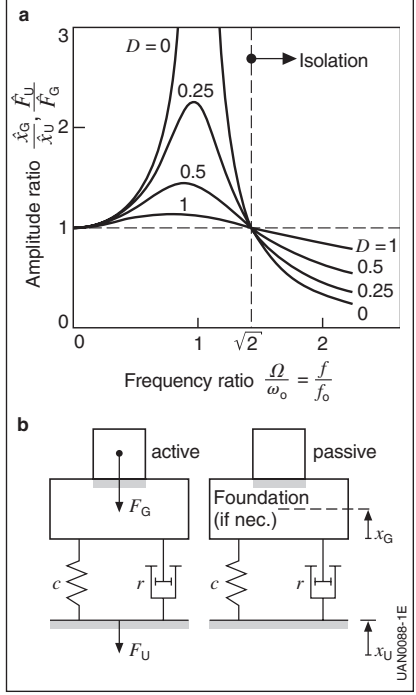
Resonance sharpness $Q = 1/\left(2D\sqrt{1-D^2}\right)$,

Resonant frequency $f_g \approx f_0$ (for $D \leq 0.1$),

Resonance sharpness $Q \approx \frac{1}{(2D)}$ (for $D \leq 0.1$),

Half-value width $\Delta f = 2Df_0 = \frac{f_0}{Q}$.

Figure 3: Standardized transfer function



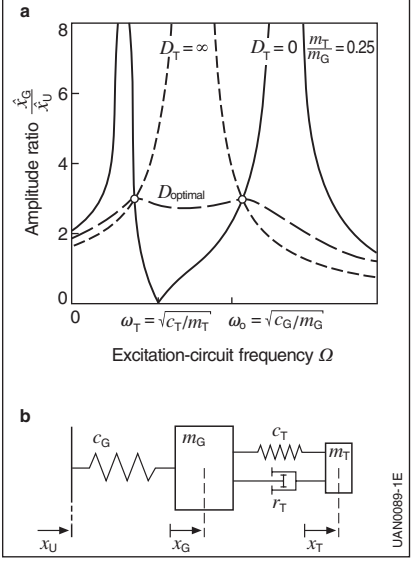
Vibration reduction

Vibration damping
If damping can only be carried out between the machine and a quiescent point, damping must be at a high level (Figure 3).

Vibration isolation
Active vibration isolation
The machines to be isolated are to be mounted so that the dynamic forces transmitted to the base support are small.

One measure to be taken: The bearing point should be set below resonance so that the natural frequency lies below the lowest excitation frequency. Damping impedes insulation. Low values can result in excessively high vibrations during run-up when the resonant range is passed through (Figure 4).

Figure 4: Vibration isolation
a) Transfer function,
b) Low setting.



Passive vibration isolation
The machines to be isolated are to be mounted so that vibrations and shocks reaching the base support are only transmitted to the machines to a minor extent.

The measures to be taken are the same as those for active isolation. In many cases, flexible suspension or extreme damping is not practicable. To prevent the occurrence of resonance, the machine attachment should be so rigid that the natural frequency is far enough in excess of the highest excitation frequency which can occur (Figure 4).

Vibration absorption
Vibration absorber
with fixed natural frequency
By tuning the natural frequency f_T of an absorption mass with a flexible, loss-free coupling to the excitation frequency, vibrations acting on the machine are completely absorbed (Figure 5). Only the absorption mass still vibrates. The effectiveness of the absorption decreases as the excitation frequency changes. Damping prevents complete absorption. However, appropriate tuning of the absorber frequency and an optimum damping ratio produce broadband vibration reduction, which remains effective when the excitation frequency changes.

Figure 5: Vibration absorption
a) Transfer function of machine,
b) Schematic.

Vibration absorber
with varying natural frequency
Rotational oscillations with excitation frequencies proportional to the rotational speed (e.g. orders of balancing in IC engines) can be absorbed by absorbers with natural frequencies proportional to the rotational speed (pendulum in the centrifugal-force field). The vibration absorption is effective at all rotational speeds. Vibration absorption is also possible for oscillators with several degrees of freedom and interrelationships, as well as by the use of several absorption masses.

Modal analysis

The dynamic behavior (natural-oscillation characteristics) of oscillating systems is determined by means of modal analysis. It is used among other things in design to optimize structures with regard to the oscillatory characteristics and to identify problem areas, and in acoustics to analyze structure-borne noise ([3]).

The oscillating structure, which as a continuum has infinitely many degrees of freedom, is replaced in a clearly defined manner by a finite number of single-mass oscillators. The modal model of the structure created in this way is described by the modal parameters
– natural-oscillation shapes (also eigenvector or mode),
– natural frequencies (also eigenvalues),
– and the associated modal damping values.

A time-invariant and linear-elastic structure is an essential precondition for model creation. Every oscillation of the structure can be represented from the eigenvectors and eigenvalues. It is, however, only observed at a limited number of points in the possible oscillation directions (degrees of freedom) and at defined frequency intervals.

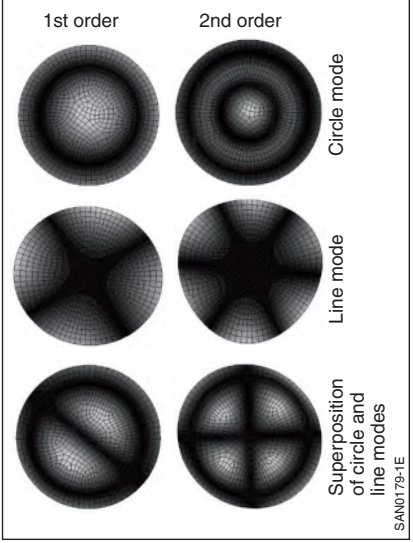
The substructure-coupling process collates modal models of various structures into an overall model.

Numerical modal analysis
The geometry, material data, and marginal conditions must be known. The basis for numerical modal analysis is a multibody-system or finite-element model of the structure. Eigenvalues and eigenvectors can be calculated from this by solving an eigenvalue problem.

Numerical modal analysis manages without a prototype of the structure and can already be used at an early stage of development. However, it is often the case that precise knowledge concerning the structure's fundamental properties (damping, marginal conditions) are lacking, which means that the modal model can sometimes be inaccurate. As well as this, the error is unidentified. One remedy is to adjust the model with the results of an experimental modal analysis.

Experimental modal analysis
A prototype of the structure is required for experimental modal analysis. Analysis is based on measurements of transfer functions. To this end, either the structure is excited at one point in the frequency range of interest and the oscillation responses measured at several points, or it is excited at many points in succession, where the oscillation responses are always measured at the same point. The modal model is derived from the matrix of the transfer function (it describes the response model). An impulse hammer or an electrodynamic or hydraulic "shaker" is used as the means of excitation. The response is measured with acceleration sensors or a laser vibrometer.

Experimental modal analysis can also be used to validate numerical analysis. Simulation calculations can then be carried out on the validated numerical model. In the response calculation, the response of the structure to a defined excitation is calculated, an excitation which corresponds, for example, to test-bay conditions.



By means of structure modifications (changes in mass, damping or stiffness), the vibrational behavior can be optimized to the level required by operating conditions. When the modal models produced by both processes are compared with each other, the modal model resulting from an analytical modal analysis is more detailed than that from an experimental modal analysis, due to the greater number of degrees of freedom in the analytical process. This applies in particular to simulation calculations based on the model.

The natural-oscillation shapes resulting from a modal analysis can be shown in graphic form or animated (examples in Figure 6). The different gray stages describe the excursion vertically to the plane of projection. The partial distortion of the disks results from these excursions.

Acoustics

Acoustics (Greek “to hear”) is a branch of the general science of vibration and oscillation concerned with the vibration of air particles audible to humans. This process of vibration gives rise to pressure differences in air which the human ear can detect. Vibrations are generated on an automobile by a variety of excitations which partly excite the airborne noise directly or can propagate via the vehicle structure and from there to the airborne noise.

Table 1: Quantities and units
(see also DIN EN ISO 80000-8 [2])

Quantity		SI unit
c	Velocity of sound	m/s
f	Frequency	Hz
I	Sound intensity	W/m^2
L_I	Sound intensity level	dB
L_Aeq	Equivalent continuous sound level, A-weighted	dB (A)
L_den	Noise indices	dB (A)
L_pA	Sound pressure level, A-weighted	dB (A)
L_r	Rating sound level	dB (A)
L_WA	Sound power level, A-weighted	dB (A)
L_S	Loudness level	phon
S	Loudness	sone
P	Sound power	W
p	Sound pressure	Pa
S	Surface area	m^2
v	Particle velocity	m/s
Z	Acoustic impedance	Pa · s/m
α	Sound absorption coefficient	1
λ	Wavelength	m
ρ	Density	kg/m^3
ω	Angular frequency (= 2 πf)	1/s
SEL	Sound exposure level	dB (A)

General terminology

(Symbols and units in Table 1, see also DIN 1320 [1])

Sound
Mechanical vibrations and waves in an elastic medium in the audible frequency band (16 to 20,000 Hz) are called sound.

Ultrasound
High-frequency vibrations above the frequency range of human hearing are called ultrasound.

Infrasound
Infrasound is the range of very low frequencies which can no longer be detected by the human hear, but can still be felt by the body.

Sound pressure
Sound pressure p is the alternating pressure generated in a medium by the vibration of sound.

Particle velocity
Particle velocity v is the alternating velocity of a vibrating particle. In a free sound field:

$$v = \frac{p}{Z}\,.$$

Specific acoustic impedance
Specific acoustic impedance Z denotes the wave impedance of a medium and is a measure of the ability of a medium to transmit sound waves.

In a free field the relationship between sound pressure, particle velocity and acoustic impedance is:

$$Z = \frac{p}{v} = \rho\, c\,.$$

Figuratively speaking, the formula describes the coupling of a vibrating particle to its neighboring particles. The coupling is much less pronounced in gases than in solid media; the particles can vibrate more freely.

Hearing dynamics
Hearing dynamics is the ability of the human ear to perceive noises from the threshold of audibility up to the pain threshold. It corresponds to pressure differences from the threshold of audibility, which is generally defined as 20 µPa, up to the pain threshold of approx. 200 pascal. This results in very high hearing dynamics of around 1:10,000,000.

Decibel dB
The decibel is not a unit, but the logarithmic ratio of a measured quantity to a reference value. The use of decibels makes it easier to handle the large dynamic range.

The sound pressure level is given in dB referred to the reference pressure of the threshold of audibility (p_{ref} = 20 µPa):

$$L_p = 20 \log_{10}\left(\frac{p}{p_{ref}}\right).$$

Frequency
Frequency f specifies the number of vibrations per second. The unit is the hertz (Hz) and is defined as follows:

1 Hz = 1/s.

Velocity of sound
Velocity of sound c is the velocity of propagation of a sound wave in a medium (Table 2).

Table 2: Sound velocities and wavelengths in different materials

Material/medium	Sound velocity c in m/s	Wavelength λ in m at 1,000 Hz
Air, 20 °C, 1,014 hPa	343	0.343
Water, 10 °C	1,440	1.44
Rubber (acc. to hardness)	60–1,500	0.06–1.5
Aluminum (rod)	5,100	5.1
Steel (rod)	5,000	5.0

Wavelength
The distance between two wave crests is called the wavelength. It is linked to the frequency:

$$\lambda = \frac{c}{f} = \frac{2\pi c}{\omega}.$$

Propagation of sound
In general, sound propagates spherically from its source. In a free sound field, the sound pressure level decreases by 6 dB each time the distance from the sound source is doubled (20log2). Reflecting objects influence the sound field, and the rate at which the sound level is reduced as a function of the distance from the sound source is lower. Moving vehicles have a spherical propagation of sound, but are considered to be line sources. The damping of sound each time the distance is doubled is considerably less and ranges, depending on the vehicle and the computing model, between 3 dB and 4.5 dB each time the distance is doubled.

Sound power
Sound power P is the sound energy output by a sound source per unit of time. It is not dependent on space and distance.

Sound intensity
Sound intensity I is the sound power through a plane vertical to the direction of propagation:

$$I = \frac{P}{S}.$$

In a sound field:

$$I = \frac{p^2}{\rho} c = v^2 \rho c.$$

Doppler effect
For moving sound sources: As the sound source approaches the observer, the perceived pitch is higher than the actual pitch; as distance increases, the perceived pitch falls.

Sound spectrum
Every noise is a mixture of components with different frequencies and levels. The sound-pressure level components can be broken down by frequencies with a frequency analysis. These spectra are distinguished from each other, depending on the type of frequency resolution.

Octave band spectrum
The sound pressure levels are determined and represented in terms of octave bandwidth. In the case of the octave, the fundamental frequencies behave in a ratio (f_1, f_2) of 1:2. The mean frequency of the octave is:

$$f_m = \sqrt{f_1 f_2}\ .$$

Third-octave band spectrum
The sound pressure levels are determined and represented in terms of third-octave bandwidth. In the case of the third, the fundamental frequencies behave in a ratio of $1:2^{1/3}$. The bandwidth referred to the center frequency is relatively constant, as in the case of the octave band spectrum.

The frequencies are defined in DIN EN 61260 [3]. Frequency analyses in the octave and third-octave ranges produce bar charts with the frequency on the x-axis and the associated levels on the y-axis.

Narrow-band spectrum
Unlike the above spectra, it is possible to use Fourier analysis [4] to analyze frequency components with constant frequency bandwidths. This results in very many finer frequency resolutions compared with the above spectra. These are shown as line graphs, which strictly speaking are not correct, but enable different analyses to be compared.

Such narrow-band analyses are also frequently linked with a further piece of information such as, for example, the rotational speed of an engine so that a frequency analysis is available for each rotational speed (for example when the engine is revved up). Such analyses are shown in three-dimensional form, either as “waterfall charts” or today frequently in color spectra, with the x-axis showing the rotational speed, the y-axis the frequency, and the z-axis in its aspect the color coding.

Sound insulation
Sound insulation is achieved by interposing a reflecting (insulating) wall (e.g. a building wall) between the sound source and the impact location. This reduces the effect of the sound source.

Sound damping, sound absorption
In the case of sound damping and sound absorption, sound energy can penetrate into the medium. Here, energy is converted into heat when reflected on peripheries, but also during propagation in the medium.

Modern noise baffles work on the principle of sound damping, i.e. sound is reflected. But parts of the sound energy are also absorbed by the baffles.

Sound absorption coefficient
The sound absorption coefficient α is the ratio of non-reflected to incident sound energy. With total reflection, $\alpha = 0$; with total absorption, $\alpha = 1$.

Low-noise design
A low-noise design is a design which is structurally optimized in accordance with acoustic considerations in order to minimize the inherent sound radiation and the propagation of sound within the structure. Simulation techniques for calculating and optimizing acoustic properties are frequently used.

Noise reduction
Noise reduction involves reducing the noise emissions of a complete system, primarily by means of low-noise designs and, secondly, through the reduction of sound propagation through the use of insulating, damping and absorbing materials.

Measured quantities for noise emissions

Sound-field quantities are usually given as effective values. Because humans perceive frequencies with varying loudness, weighting filters are used to adapt the measured levels in each frequency range to the human hearing properties. The most common weightings are A for sound as encountered, for example, in the automobile sector, and C for clearly louder noises such as, for example, in the aviation field. The corresponding weighting is appended to the symbol, such as, for example, dB(A).

Sound power level
The sound power of a sound source is described by the sound power level L_w. It is equal to ten times the logarithm to the base 10 of the ratio of the calculated sound power to the reference sound power $P_0 = 10^{-12}$ W:

$$L_w = 10 \log\left(\frac{P}{P_0}\right),$$

where log here and also in the following means the logarithm to the base 10.

Sound power cannot be measured directly. It is calculated based on quantities of the sound field which surrounds the source. The sound pressure levels L_p or the sound intensity levels L_I are usually used for the calculation.

Sound pressure level
The sound pressure level L_p is ten times the logarithm to the base 10 of the ratio of the square of the effective sound-pressure value and the square of the reference sound pressure $p_0 = 20$ µPa:

$$L_p = 10 \log\left(\frac{{p_{eff}}^2}{{p_0}^2}\right) \text{ or}$$

$$L_p = 20 \log\left(\frac{p_{eff}}{p_0}\right).$$

The sound pressure level is given in decibels (dB). The frequency-dependent, A-weighted sound pressure level L_{pA} as measured at a distance of d = 1 m is frequently used to characterize sound sources.

Sound intensity level
The sound intensity level L_I is ten time the logarithm to the base 10 of the ratio of sound intensity and reference sound intensity $I_0 = 10^{-12}$ W/m^2:

$$L_I = 10 \log\left(\frac{I}{I_0}\right).$$

The sound intensity can be measured directly with a probe.

Interaction of two or more sound sources
If two independent sound fields are superimposed, their sound intensities or the squares of their sound pressures must be added. The overall sound level is then determined from the individual sound levels in accordance with Table 3.

Table 3: Overall sound level with superimposition of independent sound fields

Difference between 2 individual sound levels	Overall sound level = higher individual sound level + allowance of:
0 dB	3.0 dB
1 dB	2.5 dB
2 dB	2.1 dB
3 dB	1.8 dB
4 dB	1.5 dB
6 dB	1.0 dB
8 dB	0.6 dB
10 dB	0.4 dB

Measured quantities for noise immissions

Excessive noise
Excessive noise is the classification of a noise as an undesirable sound event and is dependent on the following factors:
– on the noise itself, measurable by physical variables (e.g. frequency, sound pressure level, or sound power),
– on the subjective attitude to the noise of the person affected,
– on the personal state of the person affected, and
– on the concrete situation in which the noise occurs.

Protection against excessive noise and in particular environmental noise is gaining increasing importance as an environmental theme. The recording and evaluation of noise immissions forms the basis for efficient noise reduction.

Rating sound level
The effect of noise on a human being is evaluated using the rating sound level L (see also DIN 45645-1 [5]; an ISO standard is currently being worked on). This is a measure of the mean noise immission over a period of time (e.g. eight working hours). With fluctuating noises it is either measured directly with integrated measuring instruments or calculated from individual sound-pressure-level measurements and the associated periods of time of the individual sound effects (see also DIN 45641, [6]). Noise-immission parameters such as pulsation (short strong deviations of the sound level from the mean level) and tonal quality (heavy dominance of one or more discrete frequencies) can be taken into account through level allowances.

Energy-equivalent continuous sound level
In the case of noises which fluctuate over time, the mean A-weighted sound pressure level resulting from the individual sound pressure levels and the individual exposure times equals the energy-equivalent continuous sound level L_{Aeq} (see also DIN 45641).

Table 4 provides guide values for the rating sound level (Germany; TI Noise [7]), measured outside the nearest residential building (0.5 m in front of an open window).

Noise indices
The EU Directive 2002/49/EC [8] defines the noise indices binding on the EU L_{den} and L_{night} as standard descriptors for offending noise over a full day (L_{den} for day, evening, night) and a night (L_{night}) along similar lines to the above-described L_{Aeq}. The assessment period here is one calendar year. Crashes for evening (5 dB) and night (10 dB) are taken into consideration for L_{den} in contrast to L_{Aeq}.

$$L_{den} = 10 \log \frac{1}{24} \cdot \left(12 \cdot 10^{\frac{L_d}{10}} + 4 \cdot 10^{\frac{L_e+5}{10}} + 8 \cdot 10^{\frac{L_n+10}{10}}\right)$$

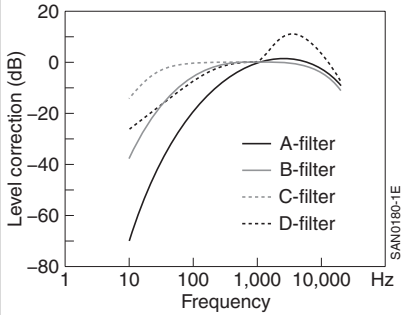
where L_d, L_e and L_n are the values for day, for evening, and for night.

Sound exposure level
The sound exposure level SEL is used to evaluate individual excessive-noise events (e.g. an airplane starting) in sensitive conservation areas. For the purpose of calculation the sound energy of the complete event is recorded and its energy is then distributed to 1 second. It is therefore done as though the event always happens within a period of one second. The sound level is then calculated on this basis.

Table 4: Guide values for permissible noise pollution as per TI Noise [7]

	Day	Night
Purely industrial areas	70 dB (A)	70 dB (A)
Areas with predominantly commercial/industrial premises	65 dB (A)	50 dB (A)
Mixed areas	60 dB (A)	45 dB (A)
Areas with predominantly residential premises	55 dB (A)	40 dB (A)
Purely residential areas	50 dB (A)	35 dB (A)
Health resorts, hospitals, etc.	45 dB (A)	35 dB (A)

Perceived sound levels



The human ear can distinguish approximately 300 levels of acoustic intensity and 3,000 to 4,000 different frequencies (pitch levels) in rapid temporal succession and evaluate them according to complex patterns. However, there is not necessarily any direct correlation between perceived loudness levels and (energy-oriented) technically defined sound levels. Corrections (A-, B- and C-weighting) take into account the dependence on frequency of human hearing (Figure 1).

The phon unit and the definition of loudness in "sone" provide a rough approximation of subjective sound-level perception. Sound-level measurements alone do not suffice to define the nuisance and disturbance potential of noise emanating from machinery and equipment. A hardly perceptible ticking noise can thus be perceived as extremely disturbing, even in an otherwise loud environment.

Loudness level

The loudness level L_S is a comparative measure of the intensity of the subjective perception of a sound, measured in "phon". The loudness level of a sound (pure tone or noise) is the sound pressure level of a standard pure tone which, under standard listening conditions, is judged by a normal observer to be equally loud. The standard noise level is a plane sound wave at a frequency of 1,000 Hz impinging on the observer's head from the front.

Figure 1: Frequency-dependent correction values for the sound level to take into account human hearing

This is known internationally as the "loudness level". A difference of 8 to 10 phon is perceived as twice or half as loud.

Phon

The standard pure tone judged as being equally loud has a specific value in dB. This value is given as the loudness level of the tested sound, and has the designation "phon". As human perception of sound is frequency-dependent, the dB values of the tested sound for notes, for example, do not agree with the dB values of the standard pure tone. The connection between curves of equal sound-level perception and sound pressure in decibels is always empirically determined. These curves were published for the first time in 1933 by Fletcher and Munson. They provided the basis for the isophone curves in accordance with DIN ISO 226 [9] used today. Figure 2 shows curves based on this standard.

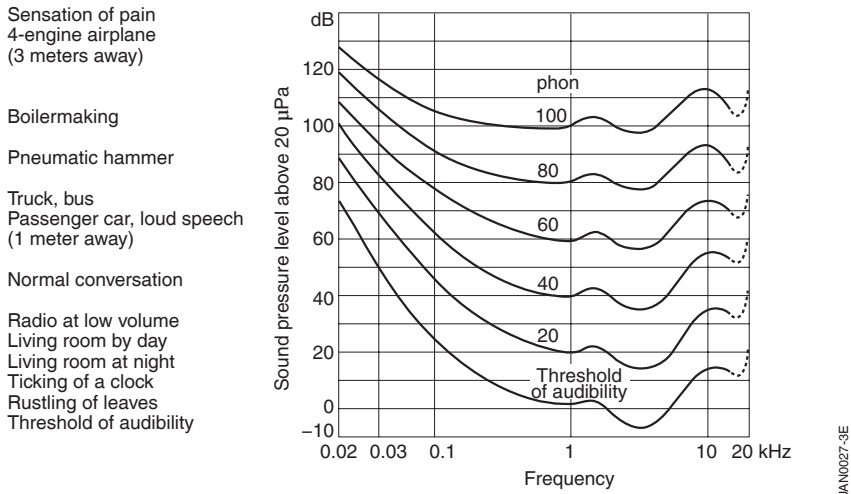
Loudness in "sone"

The loudness S is the measure used to define subjective noise levels. The starting point for defining the sone is: How much higher or lower is the perceived level of a particular sound relative to a specific standard. Definition: Loudness level of L_S = 40 phon corresponds to a loudness S = 1 sone. Doubling or halving the loudness is equivalent to a variation in the loudness level of approx. 10 phon.

There is a DIN loudness standard for calculating stationary sound using tertiary levels (Zwicker method [10]). This procedure takes into account both frequency weighting and the screening effects of hearing.

Pitch, sharpness

The spectrum of perceptible sound can be divided into 24 hearing-oriented frequency groups (bark). The Bark scale is a psychoacoustic scale for perceived pitch. The loudness/pitch distribution can be used to quantify other subjective aural impressions – such as the sharpness (e.g. metallic harmonic distortion) of a noise.



Articulation index

The basic prerequisite for recognizing speech is the correct transmission wherever possible of the sound waves of what is spoken from the sender (mouth) to the receiver (ear). The articulation index (AI) offers a computing model for predicting speech intelligibility in the event of interference noise. It is assumed here that the speech information is distributed to the different frequency bands of the acoustic signal. Each band then makes a contribution to speech intelligibility. If a band has a signal-to-noise ratio of more than 15 dB, the speech component in this band is evaluated as being intelligible. The sum total of all the bands with this noise ratio is multiplied by their specific weighting factor to give the articulation index AI in %.

Optical technology

Electromagnetic radiation

Electromagnetic radiation denotes the wave nature of visible light, but also of radiation that is not visible to the human eye (e.g. ultraviolet light, X-radiation, radiation in the infrared range). Thus, electromagnetic radiation is subdivided by reference to its wavelength λ (Table 2).

Table 1: Quantities and units

Quantity		SI unit
A	Area A_1 Radiating area A_2 Illuminated area	m^2
E_e	Irradiance	W/m^2
I_e	Radiant intensity	W/sr
L_e	Radiance	$W/(m^2 sr)$
M_e	Radiant excitance	W/m^2
P_e	Power	W
Q_e	Radiant energy	Ws
R	Reflection coefficient	%
H_e	Irradiation	Ws/m^2
$K(\lambda)$	Absolute spectral sensitivity	lm/W
$V(\lambda)$	Spectral luminous efficiency	–
Φ_e	Radiant flux	W
r	Distance	m
t	Time	s
ε_1	Angle, incident ray (to normal of a surface)	°
ε_2	Angle, refracted ray	°
ε_3	Angle, reflected ray	°
$\varepsilon_{1,max}$	Angle of total reflection	°
η	Luminous efficiency	lm/W
Ω	Solid angle	sr
λ	Wavelength	nm
E_{phot}	Photon energy	eV
h	Planck's quantum of action	Js
c	Speed of light in a vacuum	m/s
n	Refractive index	–

Geometric optics

The description of optical systems can be limited to two models – geometric optics and wave optics. Geometric optics (also called ray model) describes the propagation of light and its deflection by imaging elements with simple geometric considerations. But this is only permitted provided the imaging elements (e.g. mirrors, lenses) are much larger than the wavelength of light.

Effects such as interference, diffraction and polarization are described in physics by wave optics. This is concerned with the propagation of light in the form of a wave.

Basic principles of geometric optics
A large part of the imaging systems used in optics can be described by geometric optics. Radiation propagation is explained by "light beams" and can be described by means of simple geometric laws.

Table 2: Ranges of electromagnetic radiation

Designation	Wavelength range
Gamma radiation	0.1…10 pm
X-radiation	10 pm to 10 nm
Ultraviolet radiation	10…380 nm
Visible radiation	380…780 nm
Infrared radiation	780 nm to 1 mm
Millimeter waves (EHF)	1…10 mm
Centimeter waves (SHF)	10…100 mm
Decimeter waves (UHF)	100 mm to 1 m
Ultrashort waves (VHF)	1…10 m
High-frequency waves (HF)	10…100 m
Medium waves (MF)	100 m to 1 km
Long waves (LF)	1…10 km
Myriameter waves (VLF)	10…100 km

Basic axioms of geometric optics
Fermat's principle is the basic principle for geometric optics. The basic axioms of geometric optics can be derived from the basic statement of this principle to the effect that light always chooses the shortest path between two points [1]:
– Light beams are straight in homogenous media.
– At the boundary between two homogenous materials the beams are deflected according to the law of reflection and the law of refraction.
– Each beam path is reversible.
– Light beams can cross without influencing each other.

Law of refraction
Snell's law of refraction [2] can also be derived from Fermat's principle. This law describes the transition of a light beam from one medium (e.g. air) to another medium (e.g. glass). At the interface of the two media the light is deflected due to the change of refractive index. An incident ray is split into a refracted ray and a reflecting ray (Figure 1). The refracted ray is governed by the law of refraction:

$$n_1 \sin \varepsilon_1 = n_2 \sin \varepsilon_2 .$$

For vacuum and dielectric media (e.g. air, glass, plastics) the refractive indices n are real numbers (Table 3). Materials with a large refractive index n are referred to as optically thick, materials with a small refractive index as optically thin.

The characteristic of refractive indices of being dependent on the wavelength is called dispersion. In most cases they decreases as the wavelength increases.

Law of reflection
The following formula applies to the direction of the reflecting ray (law of reflection):

$$\varepsilon_3 = \varepsilon_1 .$$

Figure 1: Refraction of a light beam at the interface between two media with different refractive indices

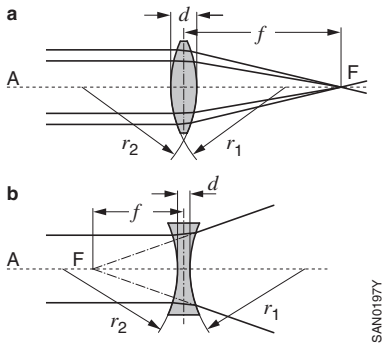
Table 3: Refractive index n of some media
(For yellow light of wavelength λ = 589.3 nm)

Vacuum, air	1.00
Ice (0 °C)	1.31
Water (20 °C)	1.33
Quartz glass	1.46
Polymethylmethacrylate	1.49
Standard glass for optics (BK 7)	1.51673
Window glass	1.52
Glass for headlamp lenses	1.52
Polyvinylchloride	1.54
Polycarbonate	1.58
Polystyrene	1.59
Epoxy resin	1.60
Gallium arsenide (depending on doping)	approx. 3.5

Figure 2: Dependence of the reflection coefficient on the angle of incidence
Medium 1 with refractive index n_1 = 1.00,
Medium 2 with refractive index n_2 = 1.52.



The angle of reflection is therefore equal to the angle of incidence. The intensity ratio of reflected to incident radiation (degree of reflection, reflection coefficient) is described by the Fresnel formula [3] and is dependent on the angle of incidence ε_1 and on the refractive indices of the adjoining media (Figure 2). In the transition from air (n_1 = 1.00) to glass (n_2 = 1.52) the upshot is that, in the case of vertical ray incidence (ε_1 = 0), 4.3 % of the ray energy is reflected.

Total reflection

In the transition from an optically thicker to an optically thinner medium ($n_1 > n_2$) the angle of refraction ε_2 attains for a specific angle of incidence ε_1 its highest possible value (90°). This angle of incidence $\varepsilon_{1,max}$ is called the critical angle for total reflection. According to the law of refraction, the following is obtained for total reflection:

$$\sin \varepsilon_{1,max} = \sin 90° \frac{n_2}{n_1} = \frac{n_2}{n_1} .$$

Figure 3: Beam path for spherical lenses

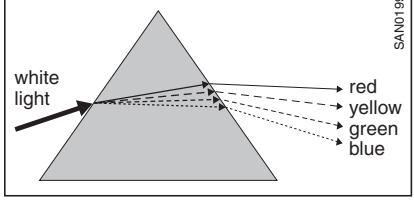
Optical components

Spherical lenses

The optical effect and the imaging property of a lens are determined by the shape of the interfaces and by the refractive index of the lens material [4]. The imaging properties of light beams can be determined using Snell's law of refraction.

The functioning principle of a lens is divided into two subgroups based on its shape (Figure 3). Lenses that bring light to a focal point are called convergent lenses (convex lenses). In contrast, parallel beams of rays are spread out by divergent lenses (concave lenses).



Prisms

In the case of a prism, the dependence of the refractive index on the wavelength of the incident light is utilized (dispersion). Thus, blue light (λ = 420 to 490 nm) is refracted at a different angle ε_2 from red light (λ = 650 to 750 nm). When white light shines onto a prism, it is broken down into different component parts (color components) (Figure 4).

This effect also appears in rainbows. The different color components of sunlight are refracted differently on water droplets in the air.

Vehicle headlights use lenses (elements comprising cylindrical lenses and prisms) to favorably influence the radiation coming from the reflector.

Figure 4: Beam path for a prism

Reflectors
Reflectors (mirrors) are used in optics to divert light in a particular direction (Figure 5). Reflectors are used in among other things headlights, where they specifically direct and concentrate light.

The function of reflector is to capture light from the headlight bulb, to achieve as great a range as possible, and to influence the distribution of the light on the road in such a way as to satisfy the legal requirements. Design (e.g. when installed in the bumper) places additional demands on the headlights.

Whereas previously almost exclusively paraboloids were used for reflectors, the above-mentioned, partly contradictory requirements can today sometimes only be satisfied by stepped reflectors, free-form surfaces or new headlight concepts (see Lighting equipment).

Basically speaking, the larger the lens aperture area, the greater the headlight range that can be achieved. On the other hand, the luminous efficiency increases with the size of the solid angle captured by the reflector.

Color filters
For special applications, e.g. lights and lamps on vehicles, there are precise regulations regarding the wavelength of the light used to suit the specific purpose (turn-signal lamp, stop lamp). Color filters are used here to attenuate or suppress unwanted spectral ranges.

Wave optics

The previous considerations only took into account macroscopic systems, i.e. the imaging elements considered were much larger than the wavelength of the observed light beam. Wave optics is concerned with systems in which light is described as an electromagnetic wave. The color of the radiation is defined by the wavelength. Thus, monochromatic light is made up only of light waves of one wavelength, whereas white lights contains light waves of different wavelengths.

Polarization
Polarization is also taken into account when a system is considered from the wave-optics standpoint. This describes the orientation of the waves or the oscillations in relation to the plane of incidence. There are three different types of polarization: linear, circular and elliptical. In the case of linear polarization, the amplitude of the electric field varies with a constant direction of propagation; in the case of circular polarization, the direction varies while the amplitude of the electric field remains constant. Elliptical polarization describes a mixed form of linear and circular polarization.

Linear polarization is further subdivided into s-polarization (perpendicular to the plane of incidence) and p-polarization (in the plane of incidence).

As shown in Figure 6, the characteristic of the Fresnel equations calculated in Figure 2, taking into account s- and

Figure 5: Beam path for a parabolic reflector

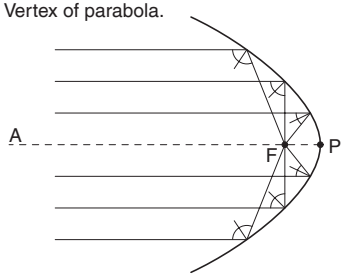
P Vertex of parabola.



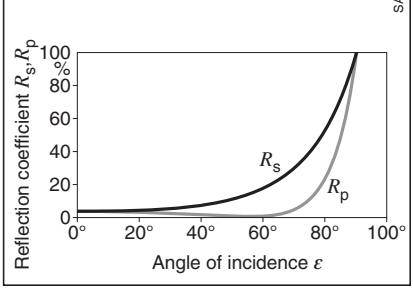


Figure 6: Reflection coefficient
Medium 1 with refractive index n_1 = 1.00,
Medium 2 with refractive index n_2 = 1.50.

p-polarization, is divided into two different curves. The plane perpendicular to the plane of propagation is called the plane of oscillation. It follows that only waves whose electric field components oscillate in the plane of oscillation are polarizable. These are also called transversal waves (light). In contrast, longitudinal waves (e.g. sound) oscillate in the direction of propagation and are therefore not polarizable.

Interference

The superposition of two waves of equal wavelength can lead to interference. According to the superposition principle, places of constructive and places of destructive interference are formed here. An interference pattern with interference maxima and interference minima is produced. An established example of this is Young's doubles-slit experiment [4], which proved for the first time the wave nature of light.

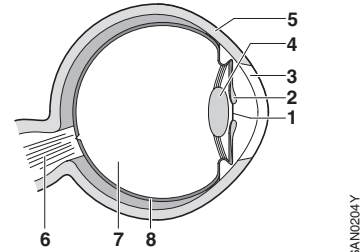
L Lens,
S_1, S_2 Point sources,
x_1, x_2 Imaging of point sources,
δ_{min} Minimum resolving angle,
$I(x)$ Intensity profile.

Diffraction

Diffraction phenomena of light waves can also be described using wave optics. The term diffraction is used to refer to the situation where an optical wave encounters an obstacle (e.g. aperture, single slit). The light wave is deflected at the obstacle and new elementary waves are created in accordance with Huygens'principle [4]. These waves interfere with each other and a diffraction pattern is produced in response to interference effects. Thus light penetrates into areas which should be dark according to geometric optics.

Diffraction at a single slit produces in response to interference effects the intensity curve $I(x)$ shown in Figure 7.

When diffraction is considered at an aperture plate or at a circular aperture, the resulting electric field after the aperture can be described by the Bessel functions of the first kind $J_1(2\pi\, r)$ [5]:



$$E(r) = \frac{E_0}{\pi r} J_1(2\pi\, r)\,.$$

The resulting intensity distribution after diffraction at the aperture is obtained from

$$I(r) \sim E^2(r).$$

Figure 9: Structure of the eye

1 Pupil, 2 Iris, 3 Cornea, 4 Lens,
5 Sclera, 6 Optic nerve,
7 Vitreous humor, 8 Retina.

Assuming that only very weak (especially the radius) secondary maxima develop as a result of diffraction at a circular aperture, the magnitude of the principal maxima can be determined from the zero point of the Bessel function. This is obtained at $r = 0.6098$.

If diffraction is disregarded, optical systems can achieve an infinite resolution. Diffraction significantly reduces the resolving capacity of any optical system (e.g. lenses, objectives). Resolving capacity U denotes the smallest still perceptible distance between two point sources (S1 and S2).

Basically, optical elements are limited by a circular aperture. The resolving capacity of any optical system can thus be calculated from the size of the diffraction pattern of a circular aperture. The intensity curve $I(x)$ is obtained for each point source. The minimum angle δ_{min} up to which the points on the screen can still be perceived separately (Figure 8) is calculated as described in the following equation from the wavelength λ of the observed radiation and the opening diameter D:

$$\sin \delta_{min} = 1.22 \frac{\lambda}{D}.$$

Since the diameter of the aperture opening is calculated from the double radius, the factor 1.22 was determined from the zero point of the Bessel function. The resolving capacity of the system can be determined from δ_{min} at $U = 1/\delta_{min}$.

The human eye can also be considered to be an optical system. In this case the focal plane is the pupil and the shown intensity profile $I(x)$ of a point light source is imaged on the retina (Figure 9). The opening diameter D is determined by the size of the pupil. For a wavelength of $\lambda = 550$ nm and a pupil size of 1.5 mm (daylight vision) $\delta_{min} = 0.02°$ is obtained for the minimum angle. From this, at a distance of 25 cm to the eye, the minimum resolvable distance between S_1 and S_2 is calculated at 0.11 mm.

Lighting quantities

Light sources have – on the basis of their nature – radiation of different intensities and different wavelengths. The light source is classified by reference to the characteristic wavelength into the wavelength spectrum.

Physical characteristic quantities have become established for the change in intensity of the light source and to describe the effect of light on human beings. A distinction is made here between radiometric and photometric characteristic quantities. In photometry the human eye is evaluated as a detector. This is confined to the ultraviolet (UV) and the visible spectral ranges. In radiometry the power of the light source measured by a detector is determined, thereby also providing measurements in the infrared and ultraviolet ranges and with gamma rays. The lighting quantities in radiometry (radiation quantities) are identified for improved intelligibility by the indices “e” (“e” for energy).

Radiation quantities

Radiant energy Q_e

The radiant energy Q_e comprises the total energy of the light wave.

Radiant flux Φ_e

Radiant flux Φ_e denotes the amount of energy dQ_e that is transported per time unit dt by the light wave:

$$\Phi_e = \frac{dQ_e}{dt}.$$

Irradiance E_e

The proportion of the radiant flux $d\Phi_e$ which strikes a defined surface area dA is called irradiance E_e:

$$E_e = \frac{d\Phi_e}{dA}.$$

The totality of the radiated energy that strikes a bright surface element dA is determined.

Radiant intensity I_e
Radiant intensity I_e denotes the radiant flux $d\Phi_e$ emitted by a point wave in a particular direction (solid angle $d\Omega$).

$$I_e = \frac{d\Phi_e}{d\Omega}.$$

Radiance L_e
Radiance L_e denotes the radiant intensity on a vertical surface.

$$L_e = \frac{dI_e}{dA\cos\varepsilon} = \frac{d^2\Phi_e}{d\Omega\, dA\cos\varepsilon}.$$

Radiant excitance M_e
Radiant excitance M_e denotes the radiant flux $d\Phi_{e,H}$ of a light source radiated into the half-space:

$$M_e = \frac{d\Phi_{e,H}}{dA}.$$

Irradiation H_e
Irradiation H_e denotes the proportion of the radiant energy dQ that strikes per time dt a surface element dA.

$$H_e = \int E_e\, dt.$$

Lighting quantities in photometry
Spectral luminous efficiency $V(\lambda)$
Defining the lighting quantities in photometry does not take into account the fact that the eye does not have constant spectral luminous efficiency. The radiation visible to the human eye is in the wavelength range of 380 nm (blue) through 780 nm (red). The eye is at its most sensitive in daylight in the yellow-green range around 555 nm; in weaker light conditions this figure shifts to lower wavelengths. A greater radiant energy is required to achieve the impression of equal brightness for other wavelengths. Spectral luminous efficiency $V(\lambda)$ is defined as the ratio of radiant energy at 555 nm to the radiant energy for the different wavelengths.

Because not all human eyes are identical, a non-dimensional, standardized luminous-efficiency function of the human eye $V(\lambda)$ was defined in DIN 5031-3 [9] for lighting measurements and calculations. This was determined for different wavelength ranges and for daylight and nightlight conditions (Figure 10).

Luminous efficacy of radiation
The absolute spectral efficiency $K(\lambda)$, also called the luminous efficacy of radiation, is the quotient from the physiological quantity luminous flux Φ and the physical radiant flux Φ_e. For daytime vision (eye adapted to the light) the maximum value $K_{m,T}$ of $K(\lambda)$ is obtained at a wavelength of λ = 555 nm. For nighttime vision (eye adapted to the dark) the maximum $K_{m,N}$ is obtained at λ = 505 nm. The following relations are obtained for the absolute spectral efficiency $K(\lambda)$:

Figure 10: Luminous-efficiency function of the human eye
$V(\lambda)$ Day-value curve,
$V'(\lambda)$ Night-value curve.

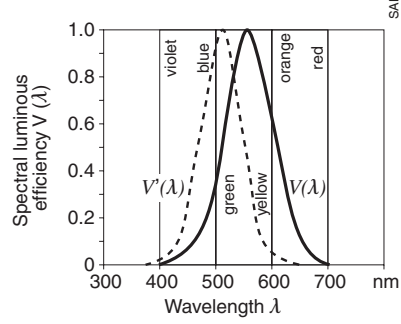


Table 4: Comparison of radiation quantities and photometric quantities

Radiation quantities		Photometric quantities	
Designation	Unit	Designation	Unit
Radiant energy Q_e	Ws	Quantity of light Q	lm s
Radiant flux Φ_e	W	Luminous flux Φ	lm
Radiant intensity I_e	W/sr	Luminous intensity I	cd = lm/sr
Radiance L_e	W/(m^{2}sr)	Luminance L	cd/m^2
Irradiance E_e	W/m^2	Illuminance E	lx = lm/m^2
Radiant excitance M_e	W/m^2	Luminous excitance M	lx
Irradiation H_e	Ws/m^2	Lumination H	lx s

Daytime vision:
$K(\lambda) = K_m\, V(\lambda)$,
$K_{m,T}$ = 683 lm/W.

Nighttime vision
$K'(\lambda) = K_m\, V'(\lambda)$,
$K_{m,N}$ = 1,699 lm/W.

$K(\lambda)$ enables the radiation quantities X_e and the photometric quantities X to be linked (Table 4). The following applies:

$$X = K_m \int X_{e\lambda}\, V(\lambda)\, d\lambda,$$

$$= \int X_{e\lambda}\, K(\lambda)\, d\lambda,$$

where $X_{e\lambda} = \frac{dX_e}{d\lambda}$.

Luminous flux Φ
The luminous flux Φ denotes the weighting of the radiometric radiant flux Φ_e with the wavelength-dependent efficiency curve $K(\lambda)$ of the human eye. The luminous flux Φ determines the light output radiated into the totality of solid angles. All further photometric quantities are linked with the luminous flux.

Quantity of light Q
The quantity of light Q is the photometric equivalent to the radiometric radiant energy Q_e. It is calculated from the integral of the luminous flux Φ over a certain time dt:

$$Q = \int \Phi(t)\, dt.$$

Luminous intensity I
The luminous flux Φ that is radiated into a certain solid angle Ω is defined as the luminous intensity I. It offers a measure of the luminous emittance of a source radiated in a certain direction and is calculated from the radiometric radiation intensity:

$$I = \frac{\Phi}{\Omega}.$$

Illuminance E
In contrast to luminous intensity I, illuminance E denotes the luminous flux of a light source radiated to a certain surface A:

$$E = \frac{\Phi}{A}.$$

Luminance L
Luminance L defines the brightness sensation in the human eye caused by an illuminated (or also self-luminous) surface. It is obtained from the radiometric quantity for the radiant intensity:

$$L = \frac{I}{\Omega}.$$

Luminous excitance M
The proportion of the luminous flux $d\Phi$ that is generated by a defined surface element dA is known as luminous excitance. It is the photometric counterpart to radiometric radiant excitance:

$$M = \frac{d\Phi}{dA}.$$

Lumination H
The lumination H is calculated from the illuminance E_V that strikes the surface dA over a period of time dt.

$$H = \int E_V(t)\, dt.$$

Further terms
The lighting quantities are supplemented by the general terms explained in the following.

Luminous efficiency η
Luminous efficiency η is calculated from the ratio of emitted luminous flux Φ to power input P:

$$\eta = \frac{\Phi}{P}.$$

Luminous efficiency is a measure of the efficacy of converting electric power P into luminous flux Φ. It cannot exceed the maximum value of the luminous efficacy of radiation K_m = 683 lm/W for the wavelength λ = 555 nm.

Solid angle Ω
The solid angle Ω describes the ratio of the penetrated section of the spherical surface (of a sphere concentric to the radiation source) to the square of the sphere radius. The total surface of the sphere is $4\pi r^2$, thus the full solid angle is

$\Omega = 4\pi$ sr (sr = steradian).

Steradian is a non-dimensional quantity for the solid angle.

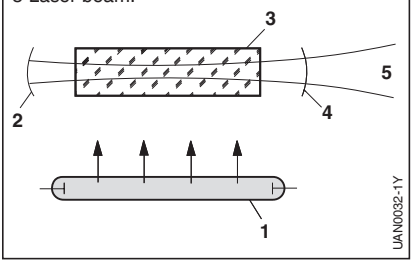
Contrast
The contrast determines the luminance ratio between two neighboring surfaces or the maximum difference in intensity within an illuminated (or self-luminous) surface. The contrast describes the ratio of luminance or the illuminance of a bright area of an image to a dark area of the same image. According to the standard ISO IEC 21118 [10] the contrast must be determined from the values of a black-and-white checkerboard pattern (consisting of sixteen equal squares).

The small-area contrast for alternating black and white lines can also be determined. This is a measure for the specification of an optical lighting system to shown fine details on a screen. Both vertical and horizontal lines are measured for this purpose.

Table 5: Examples of some laser types

Laser type	Wavelength	Applications
He-Ne laser	632 nm	Metrology, holography
CO_2 laser	10.6 µm	Material processing
ND: YAG laser	1,064 nm	Material processing
Semiconductor laser	e.g. 670 nm e.g. 1,300 nm	Measuring technology Telecommunications
Ytterbium fiber laser	e.g. 1,070 nm	Material processing

Laser technology



Compared to other light sources, the laser (Light Amplification by Stimulated Emission of Radiation) has the following characteristic properties:
– Monochromatic radiation, i.e. a limited wavelength range,
– Very high radiation density,
– Low beam expansion,
– Good focusability,
– High time and spatial coherence of radiation.

Functioning principle
A laser contains a laser-active medium that can be gaseous, solid or liquid (Table 5). The supply of energy can place the atoms or the molecules of the active medium in an excited state (Figure 11). This process is called pumping and can take place electrically (by the application of a voltage) or optically (with another light source).

After a certain period of time the excited particles of the active medium relax back into their initial state and in so doing dissipate their energy through the spontaneous emission of a photon (light particle). The energy of the photon is determined by the quantized energy states of the active medium and stipulates the wavelength λ of the laser light:

$$E_P = \frac{hc}{\lambda}.$$

Figure 11: Laser principle
1 Pumping light source,
2 Resonator mirror,
3 Laser-active material,
4 Partly transparent mirror,
5 Laser beam.

h is Planck's quantum of action and c the speed of light in a vacuum. For h and c the following values apply:
$h \approx 6.62606957 \cdot 10^{-34}$ Js
$c \approx 300{,}000{,}000$ m/s

The resonator consists of mirror surfaces at the ends of the active medium and causes the spontaneously emitted photons to be reflected back into the active medium. As they pass through the active medium again they cause new photons of equal wavelength and identical phase position to be emitted. This is called stimulated emission.

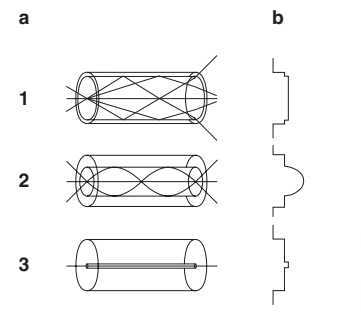
The resonator is responsible for radiation amplification and for the desired beam characteristic. The laser beam emerges at the end of the resonator via a semi-transparent mirror.

Depending on the active medium and the laser type, lasers can be operated with continuous-wave radiation or in pulsed mode with pulse lengths down to below 1 fs (10^{-15} s) [12, 13].

Areas of application
Laser measuring technology permits the noncontact, non-interacting testing of production tolerances of superfinished surfaces (e.g. fuel injectors). Resolutions in the nm range are achieved using interferometric methods.

Lasers facilitate high-precision, flexible and high-speed material processing/machining in production engineering. For example, hole diameters of 30 µm can be achieved with laser drilling.

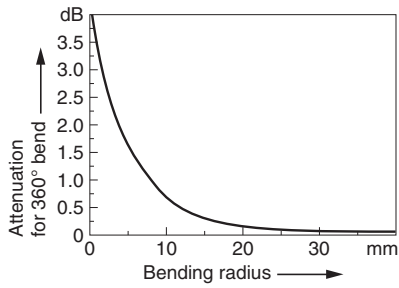
Further laser applications in technology are holography (spatial image information), automatic character recognition (bar-code scanners), information recording (CD scanning, 3D space surveying), material processing/machining, microsurgery, and transmitters for data transmission in optical waveguides.



Specific regulations are to be observed when handling laser products. Laser products are classified according to potential hazards. For details, refer to DIN EN ISO 60825 [11].

Optical fibers/waveguides

Design
Optical fibers/waveguides transmit under controlled conditions electromagnetic waves in the ultraviolet (UV), visible, and infrared (IR) ranges of the spectrum. They are made of quartz, glass, or polymers, usually in the form of fibers or channels created in transparent materials with a core whose refractive index is usually higher than that of the cladding. Thus, light launched into the core is retained in that area by means of refraction or total reflection and routed.



Depending on the refractive index profile, a distinction is made between four types of fiber (Figure 12):
– The step-index fiber, with a sharply-defined boundary between the core and the cladding
– The graded-index fiber, with parabolic refractive index profile in the core
– The monomode fiber with a very small core diameter
– The photonic-crystal fiber with air-filled capillaries arranged periodically around the core. The arrangement corresponds to the step-index or monomode fiber.

Figure 12: Light propagation in optical fibers
a) Fibers schematically represented,
b) Refractive-index profile.
1 Step-index fiber,
2 Graded-index fiber,
3 Monomode fiber.

Step-index and graded-index fibers are multimode fibers, i.e. various oscillation modes of the light waves can be propagated along then at different speeds. The different oscillation modes of the light wave are dependent on the geometry and the material properties of the substrate material. Polymer fibers are always step-index fibers. Monomode fibers are, thanks to their geometry and the material used, designed in such a way that only the fundamental mode of the light wave can be propagated. Depending on the structure configuration, photonic-crystal fibers guide one or more modes.

Figure 13: Attenuation of a 360° bend depending on the bending radius
Source: [14].

Properties
Glass optical fibers have a high degree of transparency in the range from ultraviolet to infrared. Losses occur primarily due to the contamination of the fiber material used in the manufacturing process. Thus, H_2O molecules absorbed from the ambient air generate absorption band in the spectrum of the optical fibers. At 950 nm, 1,240 nm and 1,380 nm the transparency of the optical fibers is reduced by the absorption of the H_2O molecules in the glass fiber. When the spectrally resolved absorption of optical fibers is considered, minima are to be seen at 850 nm, 1,310 nm and 1,550 nm, i.e. attenuation is particularly low for the wavelengths 850 nm, 1,310 nm and 1,550 nm. Synthetic fibers absorb above 850 nm and below 450 nm.

Optical fibers can only absorb light from a restricted angular range Θ. The numerical aperture A_N = sin (Θ/2) (Table 6) serves as the measure for this.

The differences in dispersion and propagation time of the various modes cause an increasing broadening of the light pulses as the length of the fiber increases, and thus restrict the bandwidth. In photonic-crystal fibers, it is possible by means of appropriate microstructuring of the core the influence the dispersion and the efficiency of nonlinear effects to achieve desired results.

Optical fibers can be used within the temperature range of –40 to 135 °C; special versions can even be used up to 800 °C.

Table 6: Characteristic data of optical fibers/waveguides

Fiber type	Diameter		Wavelength	Numerical	Attenuation	Bandwidth
	Core [µm]	Cladding [µm]	[nm]	aperture (A_N)	[db/km]	[MHz · km]
Step-index fiber						
Quartz, glass	50…1,000	70…1,000	250…1,550	0.2…0.87	5…10	10
Polymer	200…>1,000	250…2,000	450…850	0.2…0.6	100…500	<100
Graded-index fiber	50…100	100…500	450…1,550	0.2…0.3	3…5	200…10,000
Monomode fiber	3…10	100…500	850…1,550	0.12…0.21	0.3…1	2,500…10,000
Photonic-crystal fiber	1…35	250…200	300…2,000	0.1…0.8	0.2…2	≤160,000

Areas of application

The main area of application for optical fibers/waveguides is in data transmission. Synthetic fibers are preferred for use in the LAN (Local Area Network) field. Graded-index fibers are the most suitable for medium ranges. Only monomode fibers are used for long-distance data transmission. In fiber-optic networks, erbium-doped glass fibers serve as optical amplifiers. Here, the transported radiation can be boosted by additional optical pumping with a semiconductor source.

Optical fibers/waveguides are used in vehicles in the MOST bus. The required compliance of bending radii means that installation in motor vehicles is critical. If the bending radii are too small, the attenuation is too great (Figure 13, [14]).

Optical fibers are being increasingly used in motor-vehicle lamps and sensors. Fiber-optic sensors generate neither scatter fields nor sparks, and are themselves insensitive to that kind of disturbance. They are currently employed in potentially explosive environments, in medicine, and in high-speed trains (ICE).

Energy transport is at the forefront in the area of material processing with laser beams, in microsurgery, and in lighting engineering.

Thermodynamics

Basic principles

System

Thermodynamic systems are typically divided into three types. What all the systems have in common is that they are delimited from the surroundings by the system boundary within which the system is located.

Isolated system
The system boundary of an isolated system is impermeable to all types of heat Q, work W and mass m (e.g. the medium inside a perfectly insulated Thermos flask).

Closed system
A closed system allows the exchange of heat and work with the surroundings across the system boundary, but not of mass (e.g. a gas in a cylinder sealed by a moving piston).

Open system
Finally, in an open system heat, work and mass can be exchanged across the system boundary with the surroundings (e.g. an open cooking pot).

State and process variables

State variables
In thermodynamics states of systems and (changes to) processes are described by way of state variables such as for example temperature T, pressure p, volume V or mass m. The changes to these variables are called changes of state. The state of a system is described uniquely by means of the state variables. To describe the state of a system which undergoes a change of state from state 1 to state 2, it is therefore not necessary to know the path taken between initial and final states, but solely to know the relevant state variables.

Process and process variables
Generally speaking, the stringing together of changes of state is called a process. In contrast to state variables, the process variables required to describe the process depend on the path between initial and final states. Work and heat are thus process variables, the type and with it also the magnitude of the work input differ e.g. depending on process control.

Table 1: Symbols and units

Quantity		SI unit
A	Cross-sectional area	m^2
a	Thermal diffusivity	m^2/s
c	Specific heat capacity	J/(kg·K)
	c_p Isobaric (constant pressure)	
	c_v Isochoric (constant volume)	
E	Energy	J
e	Specific energy	J/kg
H	Enthalpy	J
h	Specific enthalpy	J/kg
k	Heat-transmission coefficient	$W/(m^2 \cdot K)$
m	Mass	kg
n	Polytropic exponent	–
p	Pressure	$Pa = N/m^2$
Q	Heat	J
$\dot{Q}$	Heat flow dQ/dt	W
R_m	Universal gas constant	J/(mol·K)
	$R_m \approx 8.3145$ J/(mol·K)	
R_i	Specific gas constant	J/(kg·K)
	$R_i = R_m/M$ (M molar mass)	
R_λ	Thermal-conduction resistance	K/W
S	Entropy	J/K
s	Length	m
T	Thermodynamic temperature	K
ΔT	Temperature difference	K
	$\Delta T = T_1 - T_2$	
U	Internal energy	J
u	Specific internal energy	J/kg
V	Volume	m^3
v	Specific volume	m^3/kg
W	Work	J
W_t	Technical work	J
t	Time	s
α	Heat-transfer coefficient	$W/(m^2 \cdot K)$
ε	Emissivity	–
κ	Isentropic exponent	–
λ	Thermal conductivity	W/(m·K)
ρ	Density	kg/m^3
ν	Kinematic viscosity	m^2/s
σ	Stefan-Boltzmann constant	W/m^2K^4
	$\sigma \approx 5.6704 \cdot 10^{-8}$ W/m^2K^4	

When a system runs through a sequence of processes and ends again in the initial state, this is called a cycle. Cycles are important for describing many technical applications (e.g. engines, power plants, power stations, air conditioners).

Intensive and extensive state variables
State variables can be further subdivided into intensive and extensive variables. When an existing system is subdivided into two parts, all the variables whose values are maintained in the two new systems are called intensive variables (e.g. temperature, pressure). Variables whose values change are called extensive variables (e.g. volume).

Often of interest are system properties which do not depend on the absolute value of a system. It can therefore be practicable to divide the extensive variables by the system mass. This results in specific state variables which retain their value when the system is subdivided (e.g. specific volume $v = V/m$ and its reciprocal value, density $\rho = 1/v$).

Forms of energy
As in classic mechanics, the state variables "kinetic energy" and "potential energy" are defined in thermodynamics. When mass m moves at constant speed c, it thus has the kinetic energy

$$E_{kin} = \frac{1}{2} m c^2.$$

A mass m that is under gravity at the acceleration of free fall g and height z has the potential energy

$$E_{pot} = m g z.$$

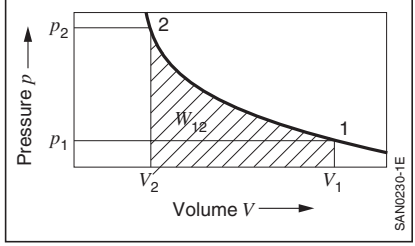
In addition to these forms of energy, a thermodynamic system has a further inherent type of energy, internal energy U. As well as the movement of the system, this type of energy furthermore takes into account changes within the system due for example to a change in temperature. The total energy of a system is then:

$$E_{tot} = U + E_{kin} + E_{pot}\ .$$

Work and heat
Work W is generally defined as the integral of the force F acting at a point of application on the system via the distance covered ds (from s_1 to s_2):

$$W_{12} = \int_{s_1}^{s_2} F\,ds\ .$$

The special case of volume-change work is crucially important in thermodynamics. This is defined as



$$W_{12} = -\int_{V_1}^{V_2} p\,dV.$$

Volume-change work can be shown and read as the area (integral) under the curve in a pV diagram (Figure 1).

In contrast to work, heat Q is a form of energy that occurs in an unordered way. When energy is supplied to a system for example by an electric heater, the change in the system's state of equilibrium is caused by heat, but not by work, which in this example is equal to zero.

The two variables work and heat are counted positively when they are supplied to a system. When work or heat is rejected, they are negative. This equates to a system-egotistical standpoint.

Figure 1: Volume-change work as integral in the pV diagram

Laws of thermodynamics

Zeroth law
Two systems which are each in thermal equilibrium with a third system are also in thermal equilibrium with each other. All the systems thus have the same temperature.

First law
The first law of thermodynamics states that energy cannot be created or destroyed, but only converted from form to another, e.g. heat to work.

For an isolated system, in which there are no flows of mass or energy across the system boundaries, the sum of all the energy changes equals zero.

For a closed system, in which energy but not mass can flow across the system boundaries, the following applies:

$$Q_{12} + W_{12} = \Delta U + \Delta E_{kin} + \Delta E_{pot}.$$

The sum of the change in the internal energy ΔU and the kinetic energy ΔE_{kin}, and the potential energy ΔE_{pot} of the system is, therefore, the sum of the quantity of heat Q_{12} added and the work W_{12} done on the system (in the case of a change from state 1 to state 2).

In many technical applications a medium flows through an open system in a stationary flow process. It is therefore also necessary to consider that the intake and expulsion of the input or output mass is connected with work W_t and the input or output mass has an additional energy content. For a stationary flow process with an input and an output mass flow

$\dot{m}_1 = -\dot{m}_2 = \dot{m}$ the following applies:

$$\dot{Q}_{12} + \dot{W}_{t,12} = \dot{m}\,(\Delta h + \Delta e_{kin} + \Delta e_{pot}),$$

with the new state variable enthalpy:

$$h = u + pv.$$

e denotes the specific variable, i.e.:

$$e = \frac{E}{m}.$$

A perpetuum mobile of the first kind violates the first law of thermodynamics in that it creates “energy from nothing” or presupposes an (impossible) efficiency of more than 100 %.

Second law
Once the retention of the total energy has been described by the first law, the second law of thermodynamics specifies the direction of the energy exchange and the sequences of processes. For example, heat transfer can only take place from a hot body to a cold body, never the other way round. The decisive state variable is entropy. For reversible changes of state the change dS in the entropy S of a system is defined as:

$$dS = \frac{dQ}{T}.$$

In other words, the transferred quantity of heat dQ is divided by the temperature T at the point of heat exchange. If therefore a quantity of heat dQ is isothermally added for example to a system, this results in an increase in the statistical fluctuation of the kinetic energy of the atoms (effectively the addition of heat) and also an increase in its Entropy by the value dS.

For all irreversible changes of state and thus for all real technical processes (accompanied by loss) it follows as a result of energy dissipation that entropy production is positive. In the case of a reversible process, however, no entropy is created. To summarize, it can therefore be stated that the rate of entropy production is never negative and thus:

$$dS \geq 0.$$

A perpetuum mobile of the second type violates the second law of thermodynamics, while it can perfectly comply with the first law. The second main law states that it is not possible to convert heat into work when the ambient temperature stays the same. Nor is it possible to convert a quantity of heat which exists at a temperature level above the surroundings fully into work.

Third law
The third law assigns to the entropy at absolute zero, at which the temperature T = 0 K, a value that is not dependent on pressure, temperature, volume, etc. This is S_0 = 0 J/K.

It also states that absolute zero can be approached by a series of different processes only asymptotically, but never reached.

Table 2: Specific heat capacity c_p at constant pressure for some gases
Values apply to 1 bar and 293.15 K [1].

Gas	c_p [kJ/kg·K]
Nitrogen (N_2)	1.041
Oxygen (O_2)	0.9189
Helium	5.251
Air	1.007
Carbon dioxide	0.8459
Ammonia (NH_3)	2.160

Equations of state

The thermal behavior of a gas is described by way of the correlation of pressure p, temperature T and volume V, i.e. by way of a function $F(p, V, T) = 0$. This function is called the thermal equation of state.

As well as describing the thermal behavior, a further equation, which establishes a correlation between the internal energy U and the thermal state variables, is needed to describe the caloric behavior. The caloric equation of state thus reads $U = U(V, T)$. This correlation is required when for example from the first law the resulting temperature change is to be calculated after a certain quantity of heat has been added.

Ideal gas
The thermal equation of state for an ideal gas reads:

$$pV = mRT \quad \text{or specifically}$$
$$pv = RT,$$

with the (specific) gas constant R ($R = R_m/M$) and the mass m. In addition, the following applies:

$$u = u(T) \text{ and } h = h(T).$$

In other words, the internal energy u and the enthalpy h of an ideal gas only depend on the temperature T. From the differentials of the internal energy and the enthalpy it follows with $(du/dT)_v = c_v$ and $(dh/dT)_p = c_p$:

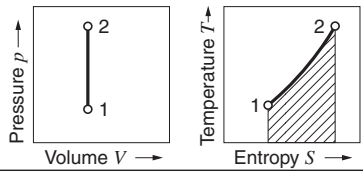
$$u(T) = \int_{T_0}^{T} c_v(T)\,dt + u_0,$$

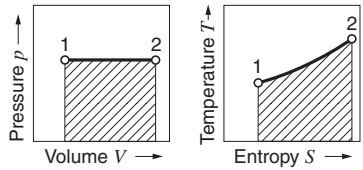
$$h(T) = \int_{T_0}^{T} c_p(T)\,dt + h_0.$$

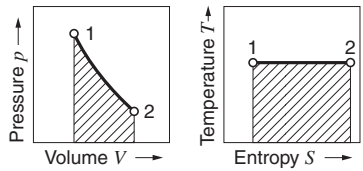
This correlation can be further simplified when c_v and c_p are assumed to be constant, i.e. independent of the temperature. Such a gas is called a perfect gas. Ideal gases are governed by the correlation

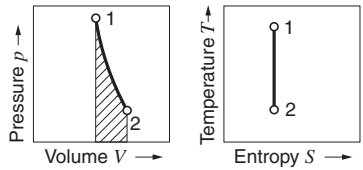
$$c_p - c_v = R.$$

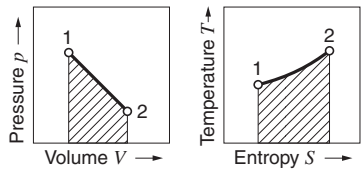
Table 2 shows by way of example values for c_p of some gases.











Real gas

The ideal gas equation demonstrates in certain ranges, e.g. at very high pressures, significant deviations from reality. An equation which better describes this behavior is the van der Waals equation:

$$\left(p + \frac{a}{v^2}\right)(v - b) = R\,T.$$

Here a and b are substance-specific variables, taking into account the influence of internal pressure a/v^2, resulting from molecular attraction, and the specific volume b of the molecules. There are a large number of other real gas equations as well as this equation. For these and further details, refer to the further literature [2], [3], [4].

Table 3: The most important changes of state of ideal gases and their properties

Change of state	Diagram	Equations for W_{12} volume-change work and Q_{12} added heat. (For quantities used, see Table 1).
Isochoric (V = const)		$W_{12} = 0$ $Q_{12} = m\,c_v\,(T_2 - T_1)$
Isobaric (p = const)		$W_{12} = -p\,(V_2 - V_1)$ $Q_{12} = m\,c_p\,(T_2 - T_1)$
Isothermal (T = const)		$W_{12} = -p_1 V_1 \ln \frac{p_1}{p_2}$ $Q_{12} = -W_{12}$
Reversible adiabatic ($dS = 0$)		$W_{12} = \frac{p_1 V_1}{\kappa - 1}\left(\left(\frac{V_1}{V_2}\right)^{\kappa-1} - 1\right)$ $Q_{12} = 0$
Polytropic curve ($p\,v^n$ = const)	 SAN0196-2E	$W_{12} = \frac{p_1 V_1}{n - 1}\left(\left(\frac{V_1}{V_2}\right)^{n-1} - 1\right)$ $Q_{12} = m\,c_v\,\frac{n - \kappa}{n - 1}\,(T_2 - T_1)$

Changes of state

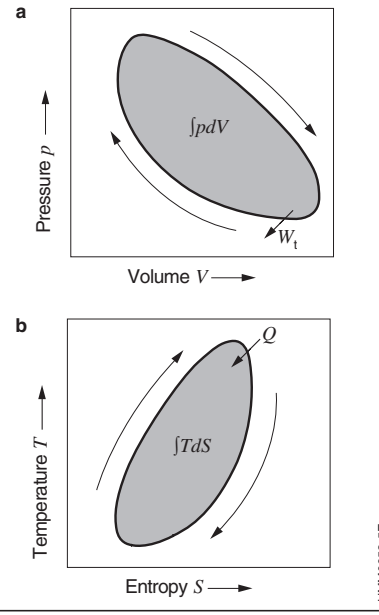
Real changes of state of gases can be can be approached for many technical processes by simplifying, idealized assumptions. The technically most important changes of state include the isothermic (T = const), the isobaric (p = const), the isochoric (V = const), and the reversible adiabatic ($\dot{q}$ = 0 or dS = 0, no heat exchange). In addition to description by these simplified idealized changes of state, which are often realized to a good degree of approximation, it is possible, assuming an ideal gas, to describe many technical processes with greater accuracy by means of a polytropic change of state of the form

$$p\,V^n = \text{const}\,.$$

Depending on the choice of exponent n, different process paths are reproduced, thus the mentioned isothermic (n = 1), isobaric (n = 0), isochoric ($n \rightarrow \infty$), and reversible adiabatic ($n = \kappa$, with the isentropic exponent κ) changes of state. The changes of state, the associated correlations of the variables p, V and T, the associated equations for volume-change work

$$W_{12} = -\int_{V_1}^{V_2} p\,dV$$

and the added or rejected heat Q_{12} are set out in Table 3. Work and heat can further be read from the illustrated pV and TS diagrams as areas.



Cycles and technical applications

Basic principles

A cycle is a sequence of different thermodynamic changes of state (processes) which when completed sees the return of the initial state, i.e. the state variables in the initial and final states are identical. Here, a cycle can take place with a constant, circulating mass flow in a closed system (e.g. in a Stirling engine or a refrigerating machine) or in an open system with media exchange (e.g. in an internal-combustion engine or a gas turbine).

A cycle is typically such that either it is deprived of work (as in a heat engine) or the heat is increased by the addition of work to a higher temperature level (as in a refrigerating machine or a heat pump). These two forms can be subdivided with regard to the successive direction of their changes of state in the pV and TS diagrams into clockwise (engines) and counterclockwise machines (machines). The

Figure 2: Clockwise cycle
a) Depiction in the pV diagram,
b) Depiction in the TS diagram.

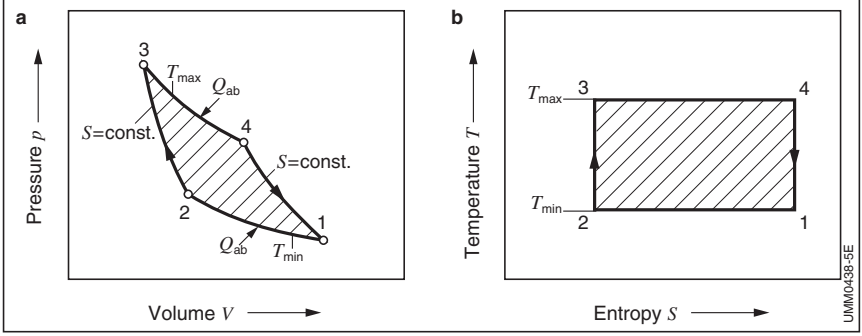
areas enclosed by the cycle represent here the input work in the pV diagram and the added heat in the TS diagram (Figure 2).

Therefore heat is added and work is output net for the situation of a clockwise cycle shown in Figure 2. The efficiency η of such a process is usually represented as the ratio of benefit (work output W_t) and expenditure (heat addition Q_{ad}), in this case therefore:

$$\eta = \frac{|W_t|}{|Q_{ad}|} .$$

For technical applications the real sequences are approached by comparison cycles. Here the entire cycle is subdivided into different reversibly accepted subcycles. The latter can be described by means of simple changes of state (e.g. isentropic, isothermal, isobaric, isochoric). In additional to simple describability, such idealized comparison cycles can be used as reference for comparing real machines as they represent the optimum in the respective process control.

Carnot cycle



The Carnot cycle constitutes the ideal comparison cycle which shows the best possible efficiency of a machine operating between two temperature levels (T_{min} and T_{max}). Heat addition and heat rejection occur in the Carnot cycle isothermally as shown in Figure 3 and thus without dissipation, work is done (compression and expansion) in reversible adiabatic fashion.

For Carnot efficiency the following equation is obtained for an ideal gas according to the above definition and by applying the first law:

$$\eta = \frac{|W_t|}{|Q_{ad}|} = 1 - \frac{T_{min}}{T_{max}} .$$

The Carnot cycle has extra significance because – although in reality it can only be approximately represented at great expense – it describes the describes the maximum amount of utilizable energy (exergy) or non-utilizable energy (anergy) and the maximum possible efficiency can be achieved with it.

Figure 3: Changes of state of the Carnot cycle
a) In the pV diagram, b) In the TS diagram.

Comparison cycles of technical applications

Seiliger cycle

The Seiliger cycle describes the sequences and processes in internal-combustion engines. It also depicts the Diesel cycle (constant-pressure cycle) and the Otto cycle (constant-volume cycle) as boundary cycles. In the Seiliger cycle heat rejection takes place through combustion. This can be taken as isochoric (with a virtually stationary piston and constant volume) or isobaric (with a moving piston and constant in-cylinder pressure). The two forms and mixed forms of these two forms are depicted in the Seiliger cycle. The following five cycles steps are featured and depicted in Figure 4 in the pV and in the TS diagrams:

– Reversible adiabatic compression (1→2),
– Isochoric heat addition (2→3),
– Isobaric heat addition (3→4),
– Reversible adiabatic expansion (4→5),
– Isochoric heat rejection (5→1).

Important characteristics of the Seiliger cycle are the compression ratio $\varepsilon = V_1/V_2$, the pressure-increase ratio $\psi = p_1/p_2$, and the injection ratio $\varphi = V_4/V_3$. For the thermal efficiency of the Seiliger cycle the following expression is obtained for an ideal gas:

$$\eta_{th} = 1 - \varepsilon^{1-\kappa} \frac{\psi\,\varphi^{\kappa} - 1}{\psi - 1 + \kappa\,\psi(\varphi - 1)}.$$

Figure 5 shows the efficiencies that can be achieved of different process controls as a function of compression and pressure-increase ratios. It also shows the values of the boundary cases of constant-volume and constant-pressure cycles. These two

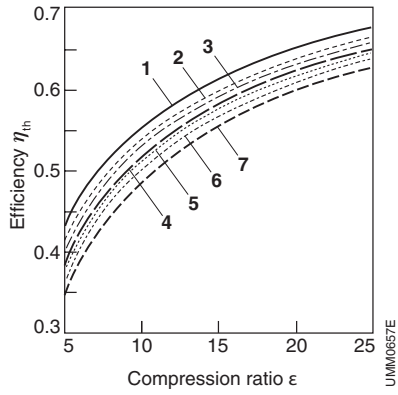

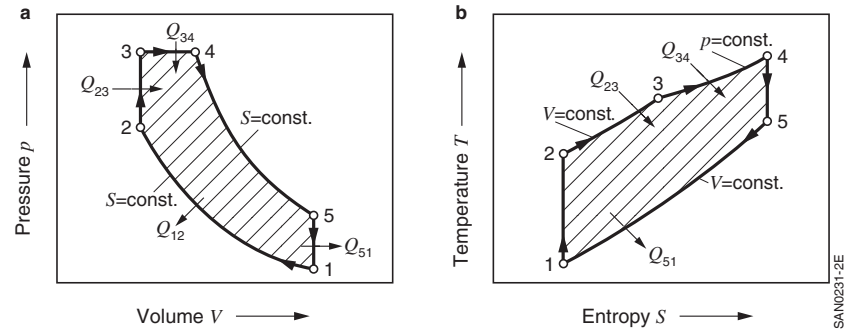

Figure 4: Changes of state of the Seiliger cycle
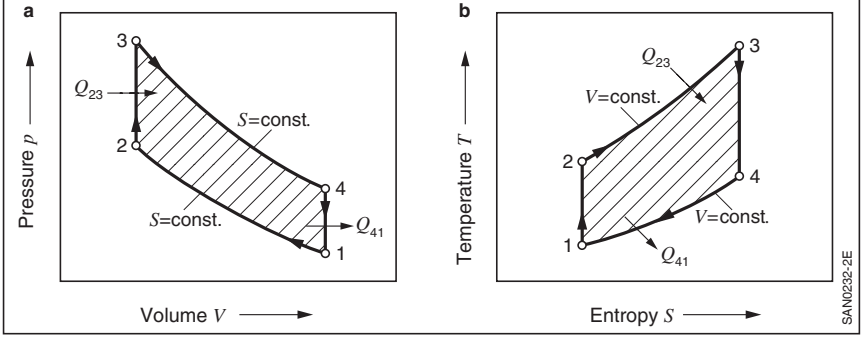
a) In the pV diagram, b) In the TS diagram.

boundary cases are described in further detail in the following.

Otto cycle
The Otto cycle (constant-volume cycle) represents the boundary process of the Seiliger cycle, in which the addition of heat or combustion takes place exclusively isochorically. Compared with the Seiliger cycle, therefore, the cycle step of isobaric heat addition (3→4) is absent. Process control in the pV and TS diagrams is illustrated in Figure 6. The following simplified description is obtained for the efficiency of the constant-volume cycle:

$$\eta_{th} = 1 - \varepsilon^{1-\kappa}.$$

The efficiency increases as the compression ratio ε increases. In gasoline engines the compression ratio is limited by knocking. Naturally aspirated gasoline engines operate at compression ratios of $\varepsilon = 10-12$, the maximum pressures are approximately 60 bar. Turbocharged engines, owing to the knock limit, operate at lower compression ratios, e.g. at $\varepsilon = 9-10$. Peak pressures of up to 120 bar are reached. Direct-injection stratified-charge engines have compression ratios $\varepsilon > 12$; at part load the potential for variable compression ratios is even up to $\varepsilon = 14$.



Diesel cycle
The second boundary process of the Seiliger cycle is the Diesel cycle (constant-pressure cycle). Process control in the pV and TS diagrams is illustrated in Figure 7. In this cycle the addition of heat or combustion takes place isobarically, i.e. the cycle step of isochoric heat addition (2→3) is absent. The efficiency of the constant-pressure cycle is obtained as:

$$\eta_{th} = 1 - \frac{\varphi^{\kappa} - 1}{\varepsilon^{\kappa-1}\kappa\,(\varphi - 1)}.$$

The achieved efficiency is, for the same compression ratio, lower than in the constant-volume cycle ε. However, because diesel engines are typically operated with a higher compression ratio, their efficiency is generally better. The aim of development for diesel engines is therefore to deliver a high peak pressure.

The maximum permissible peak pressures for passenger-car engines are roughly 180 bar, and for commercial-vehicle engines over 220 bar. The compression ratios for the direct-injection processes currently used today are ε =16 – 19. In the case of retarded start of injection, the final compression pressure actually corresponds to the peak pressure, and the diesel cycle resembles the constant-pressure cycle with $\varphi \approx 9$.

Figure 6: Changes of state of the Otto cycle
a) In the pV diagram, b) In the TS diagram.

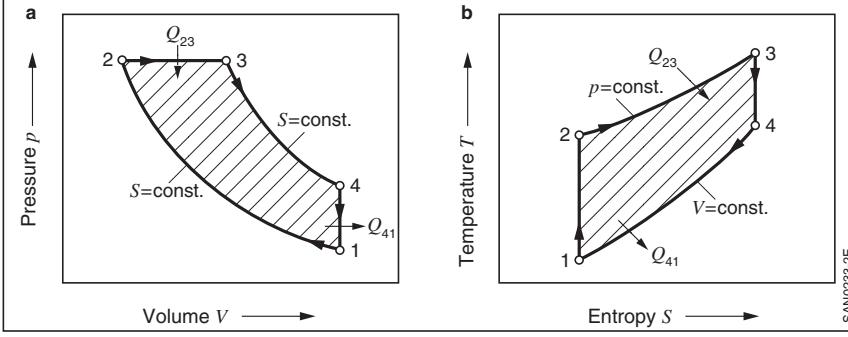
Joule cycle
The Joule cycle (or Brayton cycle) is the comparison cycle for gas turbines. In contrast to internal-combustion engines and their comparison cycles, a gas turbine is subject to continuous flow. The Joule cycle is characterized by the following cycle steps (Figure 8):
– Reversible adiabatic compression (1→2),
– Isobaric heat addition (2→3),
– Reversible adiabatic expansion (3→4),
– Isobaric heat rejection (4→1).

An important characteristic of the Joule cycles is the pressure ratio $\pi = p_1/p_2$. The efficiency is thus:

$$\eta_{th} = 1 - \frac{T_1}{T_2} = 1 - \pi^{\frac{\kappa-1}{\kappa}}.$$

Clausius-Rankine cycle
The Clausius-Rankine cycle is usually used as the comparison cycle for steam turbines. This is a closed cycle in which the working medium undergoes among others two phase changes (evaporation and condensation). The cycle typically contains the following steps (Figure 9):
– Reversible adiabatic pressure increase in the liquid phase (1→2),
– Isobaric heat addition (2→3),
– Isobaric and isothermal evaporation (3→4),
– Isobaric overheating (4→5),
– Reversible adiabatic expansion (5→6),
– Isobaric and isothermal condensation (6→1).

Figure 7: Changes of state of the Diesel cycle
a) In the pV diagram, b) In the TS diagram.



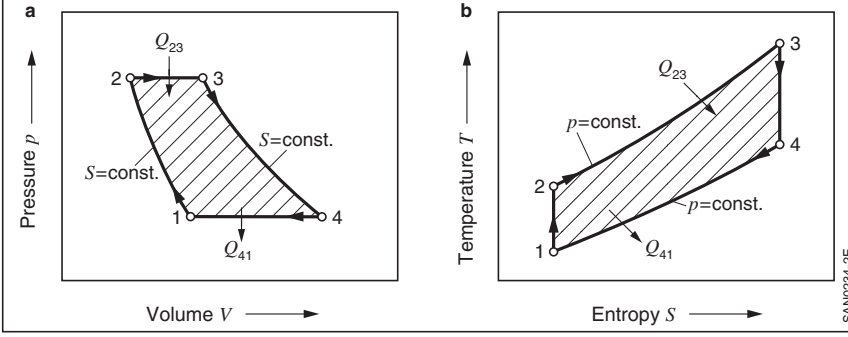


Figure 8: Changes of state of the Joule cycle
a) In the pV diagram, b) In the TS diagram.

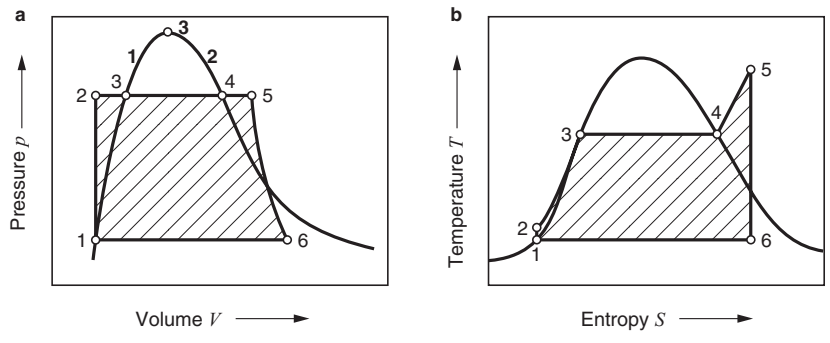
The two curves in Figure 9 relate to the phase boundary lines (saturated-liquid and saturated-vapor lines). The saturated-liquid line represents the range of the just boiling liquid, the saturated-vapor line that of the saturated vapor. Below these two lines is the wet-steam region, i.e., the region in which liquid and gaseous phases exist together. The summit of the curves is called the critical point.

The Clausius-Rankine cycles on account of the phase changes cannot be depicted with an ideal gas; it requires a real-gas description. For the same reason, this produces a depiction which describes benefit and expenditure and thus the thermal efficiency with enthalpies. The thermal efficiency is thus [3]:

$$\eta_{th} = 1 - \frac{h_6 - h_1}{h_5 - h_2}.$$

In automotive applications the Clausius-Rankine cycle is used for example in the field of waste-heat recovery as a comparison cycle. The engine or exhaust-gas waste heat supplies the required heat here for the cycle steps 2 → 5. A turbine or a piston engine for example which makes energy available in mechanical form can be used as the engine for expansion (5 → 6).

Heat transfer



Concept formation
Essentially, heat is transferred in three different ways.

Thermal conduction
In the case of thermal conduction, heat is transferred on the molecular level. Heat is transferred here as a result of an impressed temperature gradient by a solid body or a static medium (liquid or gaseous) without macroscopic matter transport. According to the second law of thermodynamics heat is transferred here in the direction of the lower temperature.

Convective heat transfer
In the case of convective heat transfer, a flow of matter, as exists only in fluid, flowing media (liquids or gases), is required. A further distinction is made between free (caused by natural buoyancy on account of the prevailing temperature gradients) and forced (caused by externally impressed flows) convection.

Thermal radiation
In the case of thermal radiation, energy is transferred in the form of electromagnetic waves. The mechanism of heat transfer from one body to another is not matter- or substance-related and is therefore also possible in a vacuum.

Thermal conduction

Stationary one-dimensional thermal conduction in a simple flat wall

In a homogeneous body with constant cross-sectional area A the heat flow density $\dot{q} = \dot{Q}/A$ in the one-dimensional case is given by:

$$\dot{q} = -\lambda \frac{dT}{dx}.$$

This is the Fourier thermal-conduction equation with the (substance-specific) thermal conductivity λ of the wall. For the case shown in Figure 10 (expansion in the y- and z-directions very high) it follows for a temperature difference $T_1 - T_2$ between the walls:

$$\dot{q} = \frac{\lambda}{d}(T_1 - T_2)$$

and

$$\dot{Q} = \frac{\lambda}{d}(T_1 - T_2)A.$$

By analogy to the science of electricity, the thermal-conduction resistance can be introduced:

$$R_\lambda = \frac{T_1 - T_2}{\dot{Q}} = \frac{d}{\lambda A}.$$

Table 4 shows the values for λ for some materials.

Stationary one-dimensional thermal conduction in a layered flat wall

If the wall is made not of one but of several layered materials of different thicknesses $d_1,\ldots, d_n$ and thermal conductivities $\lambda_1,\ldots, \lambda_n$ (Figure 11), this produces for a temperature difference $T_1 - T_2$ normally for the layering:

$$\dot{q} = \frac{\lambda_R}{d}(T_1 - T_2),$$

with the effective resulting thermal conductivity:

$$\lambda_R = \frac{1}{\frac{d_1}{\lambda_1} + \frac{d_2}{\lambda_2} + \ldots + \frac{d_n}{\lambda_n}}$$

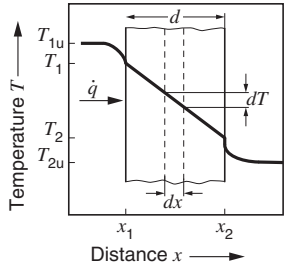
and the thermal resistance:

$$R_{\lambda R} = R_{\lambda 1} + R_{\lambda 2} + \ldots R_{\lambda n}.$$

Table 4: Thermal conductivity λ of some materials at 293.15 K

Material/medium	λ [W/K·m]
Aluminum (Al)	237
Iron (Fe)	81
Copper (Cu)	399
Titanium (Ti)	22
CrNi steel (X12CrNi 18.8)	15
Glass	0.87 – 1.40
Teflon (PTFE)	0.23
Polyvinyl chloride (PVC)	0.15

Figure 10: Stationary one-dimensional thermal conduction through a flat wall



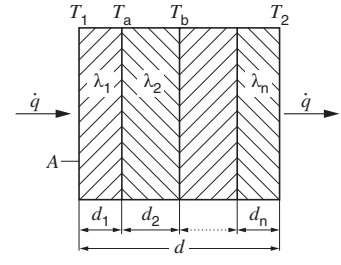


Figure 11: Stationary one-dimensional thermal conduction through a layered, flat wall

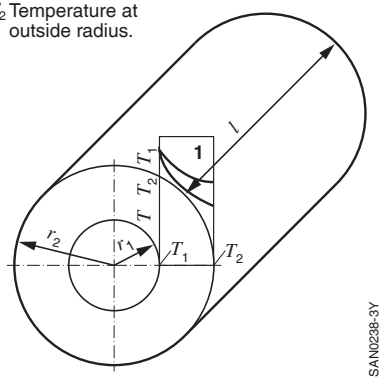
The thermal resistance therefore behaves additively (as in a series connection), with the order of the layers not playing a role.

If the temperature gradient is impressed along the plates (along a length l), it follows that:

$$\dot{q} = \frac{\lambda_p}{l}(T_1 - T_2)$$

with the effective resulting thermal conductivity

$$\lambda_p = \frac{1}{d}(\lambda_1 d_1 + \lambda_2 d_2 + \ldots + \lambda_n d_n)$$



and the thermal-conduction resistance

$$\frac{1}{R_{\lambda p}} = \frac{1}{R_{\lambda 1}} + \frac{1}{R_{\lambda 2}} + \ldots + \frac{1}{R_{\lambda n}}.$$

The reciprocal value of the total thermal resistance is therefore made up additively of the reciprocal values of the individual thermal resistances and behaves as in a parallel connection.

Figure 12: Stationary one-dimensional thermal conduction through a cylindrical tube wall

1 Temperature characteristic over the tube cross-section,
r_1 Inside radius of tube,
r_2 Outside radius of tube,
l Length of tube,
T_1 Temperature at inside radius,
T_2 Temperature at outside radius.

Stationary one-dimensional thermal conduction in a tube wall

Similarly to thermal conduction through a wall, the following is obtained for a tube (of virtually infinite length) of length l in the one-dimensional case (thermal conduction only normally to the tube axis) as shown in Figure 12:

$$\dot{Q} = 2\pi l \lambda \frac{T_1 - T_2}{\ln\left(\frac{r_2}{r_1}\right)},$$

where T_1 is the temperature on the inner side and T_2 the temperature on the outer side.

Because of the different surface areas on the inner and outer sides of the tube the temperature assumes a logarithmic characteristic in the tube wall.

Stationary heat transmission

In many technical applications thermal conduction inside a solid body occurs in combination with a convective heat transfer (see Convective heat transfer). A (convective) heat transfer occurs as well as the thermal conduction, as shown in Figure 10; towards the wall on account of the temperature difference $(T_{1u} - T_1)$ and away from the wall on account of the temperature difference $(T_2 - T_{2u})$. The heat flows must naturally all be of equal magnitude, since heat is not lost in either convective heat transfer or in thermal conduction. The heat flows that occur are governed by:

$$\dot{Q} = \frac{\lambda}{d}(T_1 - T_2)A,$$

$$\dot{Q} = \alpha_{1u}(T_{1u} - T_1)A,$$

$$\dot{Q} = \alpha_{2u}(T_2 - T_{2u})A,$$

with the heat-transfer coefficients α_{1u} and α_{2u}. For such a situation it is possible to create the heat-transmission coefficient k, which is obtained as follows:

$$\frac{1}{k} = \frac{d}{\lambda} + \frac{1}{\alpha_{1u}} + \frac{1}{\alpha_{2u}}.$$

While taking into account the two fluid temperatures T_{1u} and T_{2u}, the following is obtained for the heat flow:

$$\dot{Q} = k(T_{1u} - T_{2u})A.$$

Convective heat transfer
The heat-transfer coefficient α has already been introduced. It is dependent on a variety of influencing variables, such as, for example, temperature, density, geometry, type of flow (laminar or turbulent), and speed. It is determined by the conservation equation (nonlinear partial differential equations) describing the (fluidic) problem for which there are only closed analytical solutions in exceptional cases. Heat-transfer coefficients are therefore often determined on the basis of numerical solutions or directly from experiments. The functional dependencies for the heat-transfer coefficients can be found from these on the basis of dimensional analysis and similarity relationships.

In view of the complexity, reference is made at this point for derivation and further details to the relevant literature (e.g. [1]). The most important dimensionless parameter for heat transfer is the Nusselt number Nu:

$$Nu = \frac{\alpha L}{\lambda}.$$

This numbers contains, in addition to the heat-transfer coefficient α, the thermal conductivity λ of the fluid, and a reference length L, which can be for example a tube diameter or a plate length. It can further be shown that the following functional correlations apply to the averaged, i.e. integrated over the body surface and thus location-independent Nusselt number Nu_∞:
– $Nu_\infty = f(Re, Pr)$ for forced convection,
– $Nu_\infty = f(Gr, Pr)$ for free convection.

The Nusselt number and thus the heat transfer can therefore be described as a function of the dimensionless parameters Reynolds number Re, Prandtl number Pr and Grashof number Gr. These must be calculated in each case as a function of the geometry and the flow (Re and Gr) or as a function of the fluid properties (Pr). The Reynolds number is defined as:

$$Re = \frac{cL}{\nu}.$$

Here c is the flow velocity, L a length characteristic of the application (e.g. tube diameter), and ν the kinematic viscosity of the fluid.

The Prandtl number is a pure substance variable and is given by:

$$Pr = \frac{\nu}{a},$$

with the thermal diffusivity a. For gases Pr = 0.7 can be assumed by approximation for pressures below 10 bar.

To calculate the Grashof number Gr, reference is made to the relevant literature (e.g. [1]).

The correlations for some selected cases with forced convection are set out in the following. The correlations in each case for the averaged values together with their range of application are specified here. The heat-transfer coefficients can be calculated with the Nusselt numbers determined from them and the definition of these.

Flat plate with laminar boundary layer subject to longitudinal flow
Nusselt correlation:

$$Nu_\infty = 0.664\, Re^{\frac{1}{2}} Pr^{\frac{1}{3}}.$$

Characteristic length:
Plate length L.

Range of application:
$Re \le 5 \cdot 10^5$; $0.6 \le Pr \le 2{,}000$.

Flat plate with turbulent boundary layer subject to longitudinal flow
Nusselt correlation:

$$Nu_\infty = 0.037\, Re^{0.8} Pr^{\frac{1}{3}}.$$

Characteristic length:
Plate length L.

Range of application:
$5 \cdot 10^5 \le Re \le 10^7$; $0.6 \le Pr \le 60$.

Turbulent pipe inner flow
Nusselt correlation:

$$Nu_\infty = 0.023\,Re^{0.8}\,Pr^n,$$

with $n = 0.4$ for $T_W > T_F$
and $n = 0.3$ for $T_W < T_F$.

Here, T_W is the wall temperature and T_F the averaged fluid temperature. The Nusselt number must be evaluated for the averaged fluid temperature because this changes during an inner flow from inlet to outlet.

Characteristic length:
Tube diameter D.

Range of application:
$10^4 \le Re$; $0.7 \le Pr \le 120$.

The tube length must be at least ten times the tube diameter.

The above correlation can also be used for tubes with non-circular cross-sections; the equivalent or hydraulic diameter d_h, which is created as follows, is used here:

$$d_h = \frac{4A}{U},$$

with the through-flow cross-sectional area A and the circumference U.

Thermal radiation
Thermal radiation depends only on the type and the temperature of the radiating body. When radiation strikes a body, the following phenomena are observed: Part of the incident radiation is reflected (reflection), part is absorbed (absorption), and part is let through (transmission). Due to the conservation of energy, it follows that the sum of these three energy components is equal to the amount of energy of the incident radiation.

According to the Stefan-Boltzmann law, the heat flow radiated from a body with surface A at temperature T is:

$$\dot{Q} = \varepsilon \sigma A T^4.$$

with the Stefan-Boltzmann constant σ,

$$\sigma \approx 5.67 \cdot 10^{-8} \frac{\mathrm{W}}{\mathrm{m^2K^4}},$$

and the emissivity ε of the body. The emissivity is between 0 (total reflection) and 1 (black-body radiator) and depends among others things on the temperature and the surface condition of the body. Some emissivity values are given by way of example in Table 5.

Electrical engineering

The history of electricity goes back around 3,000 years. For a long time electrical effects were subject to mysterious interpretations. Only in the 19th and 20th centuries were scientists able to describe these effects more accurately through scheduled experimentation and exact measurement. It was recognized that most processes run according to certain laws. The sensible application of these laws resulted in the rapid development of electrical engineering and – for some decades now – electronics. Electrical engineering predominantly comprises areas in which the energy content of electricity plays a role (e.g., in electric motors) while electronic devices are used to measure and control this energy. There are numerous uses for devices which comprise electrical and electronic components. A clear distinction between these two areas is often not possible.

Table 1: Quantities and units
(Additional quantities and units in the text)

Quantity		SI unit
A	Area	m^2
a	Distance	m
B	Magnetic flux density, induction	$T = Wb/m^2 = V\,s/m^2$
C	Electrical capacitance	$F = C/V$
D	Electric flux density, electric displacement	C/m^2
E	Electric field strength	V/m
F	Force	N
f	Frequency	Hz
G	Electrical conductance	$S = 1/\Omega$
G	Antenna gain	dB
H	Magnetic field strength	A/m
I	Electric current	A
J	Magnetic polarization	T
k	Electrochemical equivalent	kg/C (usually: g/C)
L	Inductance	$H = Wb/A = V\,s/A$
l	Length	m
M	Electric polarization	C/m^2
P	Power	$W = V\,A$
P_s	Apparent power	V A
P_q	Reactive power	var = V A
Q	Quantity of electricity, electric charge	$C = A\,s$
q	Cross-sectional area	m^2
R	Electrical resistance	$\Omega = V/A$
r	Radius	m
r	Reflectance factor	–
S	Electromagnetic power density	W/m^2
s	Standing wave ratio	–
T	Temperature	K
t	Time	s
U	Voltage	V
V	Magnetic potential difference	A
W	Work, energy	$J = W\,s$
W_e	Electrical energy	Ws
W_m	Magnetic energy	Ws
w_e	Electrical energy density	Ws/m^3
w_m	Magnetic energy density	Ws/m^3
w	Number of turns	–
Z	Characteristic impedance	Ω
α	Geometric angle	° (degrees)
ε	Dielectric constant	$F/m = C/(V\,m)$
ε_0	Electric field constant $\approx 8.854 \cdot 10^{-12}$ F/m	
ε_r	Relative permittivity	–
λ	Wavelength	m
Θ	Current linkage	A
μ	Permeability	$H/m = V\,s/(A\,m)$
μ_0	Magnetic field constant $\approx 1.257 \cdot 10^{-6}$ H/m	
μ_r	Relative permeability	–
ρ	Resistivity	$\Omega\,m = 10^6\,\Omega\,mm^2/m$
σ	Electrical conductivity (= $1/\rho$)	$1/(\Omega\,m)$ $= 10^{-6}\ m/(\Omega\,mm^2)$
Φ	Magnetic flux	$Wb = V\,s$
φ	Phase displacement angle	° (degrees)
φ (P)	Potential at point P	V
ω	Angular frequency (= $2\,\pi\,f$)	Hz

Basic principles of electricity

Atomic structure

All matter consists of tiny building blocks called atoms (atomos, Greek: indivisible). A copper cube with an edge length of 1 cm contains approximately 10^{23} atoms which are permanently "bound" to each other. According to the findings of atom physics atoms are made up of even smaller particles – electrons, protons, and neutrons. Our solar system, in which the planets (Earth, Jupiter, Mars, etc.) orbit a common nucleus, the Sun, serve as the model for the atomic structure. Materials which are composed of atoms of the same type are called elements.

Today we know that electricity is a property of electrons. These smallest particles orbit the nucleus, consisting of protons and neutrons, at high speed. Depending on the element in question, its atoms contain a different number of electrons on different paths, the electron shells. An electron carries the smallest occurring quantity of electricity; the designation "negative" was coined for this type of electric charge.

The nuclear particles are neutrons and protons. The latter carry the same quantity of electricity as the electrons. But because their electric charge is reversed, they behave like electrons and are positive. These positive protons determine, together with the electrically neutral neutrons, the quantity of electricity.

Because the electrons orbit the nucleus at high speed, they would be thrown from their path by centrifugal force if the two opposing charges in the atom (electrons negative, protons positive) were not mutually attracted. Conversely, bodies with the same electric charge repel each other.

Charge carriers

Free electrons

The movement of these conduction electrons can be guided by electrical forces (voltage) in a certain direction to obtain the electron flow. By supplying energy (electrical, thermal, optical, etc.) it is possible even to release electrons under certain preconditions from the atomic union of a material.

The electrons on the outermost shell of the atoms determine both the electrical and the chemical behavior of a material and establish the bond with neighboring atoms of other or identical elements. These electrons participating in the bonds are called valence electrons. Because only valence electrons participate in electrical processes, the atom model can be further simplified. Accordingly, this model consists of the electrically effective electrons of the outermost shell and a positive kernel, which contains the nucleus and the electrons of the remaining shells. In the copper model each kernel has a valence electron.

Ions

Special measures, e.g., mechanical or chemical effects, can be used to separate or add one or more valence electrons in an atom. This atom is then no longer electrically neutral and is known as an ion. Atoms that lack electrons (negative charge) are positive ions while those that have more electrons than protons are negative ions.

Missing electrons in the atomic union

Finally, a third kind of electric charge carrier takes effect in semiconductors (diodes, transistors). Points in the atomic union with missing electrons (holes) acts as positive charge carriers. Unlike ions, however, the kernels in semiconductor materials (germanium, silicon) are not freely moving.

Charge quantity
The smallest possible charge quantity is the elementary charge; the electron (or the proton) is the carrier of this elementary charge. Each charge quantity is a whole multiple of the elementary charge and the (letter) symbol for the charge quantity is Q.

In contrast to water droplets, it is not the mass of the electrons that is considered here, but only its electrical property, the charge. This has a quantitative character and quantity of electricity is therefore synonymous with electric charge. The unit of charge quantity is the "coulomb" with the symbol C.

Another term for "coulomb" is the "ampere-second" with the symbol "As".

1 C = 1 As; $[Q]$ = C = As.

The amount of the elementary charge is:

$e = 1.602\,176\,634 \cdot 10^{-19}$ As.

This value is obtained from the already established unit "ampere" in accordance with the SI system (see Quantities and units).

For the most part billions of tiny charge carriers (electrons) participate in electrical and electronic processes. It is therefore natural to distill a large number of elementary charges down to a "handy" measure. From the size of elementary charge e: 6.3 trillion elementary charges equal 1 coulomb.

Electrical quantities in an electric circuit

Current
Current intensity
Electric current is the transfer of charge. "Transferred charge quantity" refers to the charge quantity Q or ΔQ that flows through a conductor cross-section A over time t or Δt. The current intensity I is defined as the transferred charge quantity per time unit ([1], [2]):

$$I = \frac{Q}{t}$$

Unit of current intensity:

$[I]$ = A.

Thus for the unit of charge quantity:

$[Q] = [I] \cdot [t]$ = As = C.

A voltage source and a complete circuit are required to generate a current flow (Figure 1). Only negative charges (electrons) are transferred. The current intensity in a complete circuit (without junctions) is the same at all points.

The current flow can be discerned when an electric light bulb lights up. All electrical effects involve the progression of electric charge carriers. Negative and positive charge carriers often participate in the conduction processes in the same device. Normally only the conduction electrons in metals are considered.

Technical current direction
That direction in which positive charge carriers were to move it they were present is defined as the technically positive current direction. The technical current direction is therefore opposite to the direction of electron movement (Figure 1). In the case of the movement of positive ions, the technical current direction and the direction of movement of the charge carriers are identical.

Current density
The current density S is the current intensity I referred to the conductor cross-section A. Figure 2 shows the current density S in the electric conductor.

Current density $S = \frac{I}{A}$.

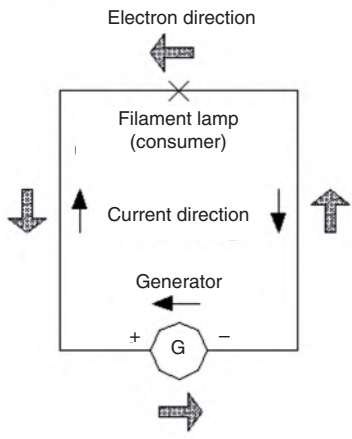
S Current density in A/mm^2,
A Conductor cross-section in mm^2.

Voltage
Voltage is obtained when the positive charge carriers and the negative charge carriers (electrons) which are present in the electrically neutral atoms of all materials are separated from each other. This occurs in voltage generators, e.g., in a flashlight battery. This battery exhibits a surfeit of electrons (negative charge) at the negative terminal and a deficit of electrons (positive charge) at the positive terminal. The negatively charged electrons of a connected conductor are therefore attracted by the positive terminal and repelled by the negative terminal. Because a large number of conduction electrons is available in the conductor, this effect continues and an electron stream flows from the negative terminal to the positive terminal.

The voltage is the cause of the current. The current direction depends on the polarity of the voltage and on the type of charge carriers participating in the current flow. Positive ions in an electrically conductive liquid move for example from the positive terminal (repulsion) to the negative terminal (attraction), i.e., in the opposite direction to the electron stream in a conductor. The positive direction of the technical current is defined by a standard from positive to negative.

Crucial to the occurrence of a voltage are different electric charges at the terminals of the voltage generators. The effect of the voltage corresponds to a force that sets the electric charge carriers (e.g., conduction electrons) in motion. Therefore voltage at the point where it is generated is also called electromotive force. It is recognized that without voltage (cause) there can be no current flow (effect). In contrast, voltage can be present even if there is no current flowing, e.g., between the terminals of a voltage generator.

Figure 1: Electric circuit with generator and light bulb
G Generator (voltage source).



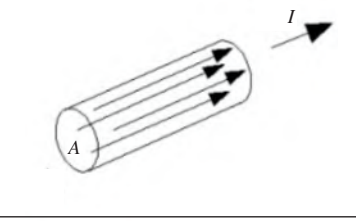


Figure 2: Current density S in an electric conductor
A Cross-sectional area of conductor,
I Electric current.

Unit of measurement
The unit of measurement for voltage, i.e., for a certain charge difference, is the volt and the measurement symbol is V. The symbol (abbreviated form for voltage) is U.

Charge transfer
Voltage is the cause of the movement of charge carriers. A copper wire with a length of 1 m and a cross-section of 1 mm^2 has a volume of 1 cm^3 and contains approximately 10^{23} conduction electrons. At a current intensity of 1.6 A around 10^{19} electrons would flow per second. This constitutes around 1/10,000 of the charge carriers present in the conductor. If now around

10^{19} electrons flow out at the conductor end in one second, the electrons must move further along in the conductor in the same period of time by around 1/10,000 of the total wire length (l = 1 m = 1,000 mm), i.e., by around 0.1 mm. This produces a speed of approximately 0.1 mm/s! At this speed an electron to move through a wire 1 m long needs around 10,000 seconds (approximately three hours!).

Practice shows that a switched-on desk lamp for example lights up instantly when it is connected to the power socket. Voltage as the cause of current must therefore cover the distance (often several meters long) from the power socket through the connecting cable to the lamp at very high speed. Because the electrons are very numerous in the conductor, they "bump" into each other when a voltage is applied. This bump effect (voltage effect) is reproduced at a speed that can approach the speed of light ($3 \cdot 10^8$ m/s).

Resistance

Line resistance

The voltage U can only then set in motion the electrons in a conductor when the circuit is complete. The current intensity here depends on the effective voltage and on the resistance offered to the electric current by the conductor. This "braking effect" varies depending on the material, length, and cross-section of a line. The unit of measurement for resistance is the ohm. The Greek letter Ω is used as the measurement symbol. The symbol is R. Resistance R is all the greater

– the greater the length l of a conductor,
– the smaller the cross-sectional area A,
– the greater the resistivity ρ, i.e., the more poorly the material in question conducts the electron stream under otherwise identical conditions.

For resistance R:

$$R = l/\gamma A,$$

$$R = l\rho/A.$$

R Line resistance in Ω,
l Conductor length in m,
A Conductor cross-section in mm²,
ρ Resistivity in (Ω mm²)/m,
γ Conductivity in m/(Ω mm²).

Resistivity

The resistivity ρ denotes the material. Table 2 specifies for some materials the resistivity ρ and its reciprocal value, the conductivity γ. Different materials must be compared with each other under identical conditions: 1 m length, 1 mm² cross-section, and 20 °C temperature are the conditions for comparing the resistivity of wires.

Conductance

Increasing the cross-section of a conductor reduces its resistance, i.e., it conducts the electron stream better. A low resistance R corresponds to a high conductance G, which is obtained as the reciprocal of the resistance. The unit of measurement for conductance is the siemens.

$$G = \frac{1}{R},$$

G Conductance in S (siemens),
R Resistance in Ω (ohm).

The electric current is conducted well in a circuit with high conductance or low resistance.

Table 2: Resistivity and conductivity of some materials

Material	Resistivity ρ [Ω mm²/m]	Conductivity γ [m/Ω mm²]	Temperature coefficient α [1/K]
Silver	0.0164	61	0.0038
Copper	0.01724	58	0.00393
Aluminum	0.0278	36	0.00403
Iron	0.13	7.7	0.0065
Constantan	0.5	2.0	±0.00001

Example: Which conductance belongs to the resistance value 2 Ω?

$$G = \frac{1}{R} = \frac{1}{2\Omega} = 0.5\ \text{S}.$$

Temperature coefficient of resistors

The resistivity ρ is specified in each case for a temperature or 20 °C. Most materials change their resistance when their temperature is altered.

When metals are heated, the atomic union becomes slightly unsettled by the energy supply. This restricts the mobility of the conduction electrons. The resistance of most metals increases as the temperature rises. Up to a temperature of around 200 °C the resistance change is proportional to the temperature change. In most liquids, gases, and semiconductors the resistance decreases as temperature increases.

The resistance change ΔR per degree temperature change is denoted by the temperature coefficient α. The unit of measurement for temperature differences between two temperature points is °C or K (kelvin) on the celsius or the kelvin scale. Percentages for the temperature coefficient in many cases make it easier to assess the resistance change as a function of the temperature change.

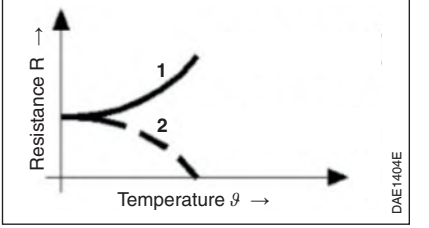
The temperature-dependent resistance change is governed by the following relationship:

$$\Delta R = \alpha R_{20}\, \Delta T$$

ΔR Resistance change in Ω,
ΔT Temperature change in K or C,
α Temperature coefficient in 1/K,
R_{20} Resistance at 20 °C.

Most pure metals have a positive temperature coefficient. Table 2 shows, in addition to the values for the resistivity ρ and the conductivity γ, the temperature coefficient α for some metals.

Figure 3 shows the characteristic curves of thermistors. Materials with a positive temperature coefficient conduct better at low temperatures and are therefore called PTC (positive temperature coefficient) thermistors. Materials with a negative temperature coefficient conduct better at high temperatures and are therefore called NTC (negative temperature coefficient) thermistors.



As well as the ambient temperature, the current intensity can also influence the resistance of a material. "Electric friction" between moving charge carriers and kernels creates in the current-carrying material heat and with it a temperature increase, which increases or decreases the resistance depending on the type of material.

While the resistance of pure metals decreases with decreasing temperature, the resistance of semiconductors increases. In the area surrounding absolute zero (0 K ≈ –273 °C) metals exhibit no resistance whatsoever (superconductivity) and semiconductor materials achieve a infinitely high resistance. In complicated devices temperatures in the vicinity of absolute zero have already been obtained.

Temperature coefficient of measuring resistors

The resistance of measuring resistors are only permitted to change very slightly in response to temperature fluctuations. The change has an affect on the electrical properties of measuring devices which would be influenced by temperature. Very small temperature coefficients for resistor materials are obtained by alloying certain metals, e.g., copper, nickel, and manganese. The temperature coefficient is, depending on the content of alloying constituents, between –0.001 and –0.005 % per K.

Figure 3: Characteristic curves of thermistors
1 PTC thermistor,
2 NTC thermistor.

Temperature coefficient of semiconductors
Virtually all semiconductor materials exhibit a negative temperature coefficient. This ranges between –2 and –5 % per K for germanium and silicon.

Capacitor
Design
Capacitors are components which in principle consist of two opposing, conductive plates (plate capacitor). The two plates are separated by an insulating layer (dielectric). When capacitors are used the effect of the electric field between the two capacitor plates is exploited. When a voltage is applied, charge quantities can be stored with the storage capacity of a capacitor being dependent on the following factors:
– the size and constitution of the plate surface,
– the distance between the plates, and
– the conductivity of the dielectric for the electric field lines.

Capacitance
The possibility of storing electrical energy in an electric field with a capacitor is utilized in varied ways in electric and electronic circuits. A measure of the capacity to absorb electric charges is the capacitance C; this has the unit "farad" (F).

The charge quantity Q absorbed by the capacitor is all the greater the greater its capacitance C and the higher the applied voltage U are as the causal charge difference. The charge quantity Q is calculated from

$$Q = C\,U.$$

The capacitance C can thus be specified as the ratio of the absorbed charge Q to the applied voltage U.

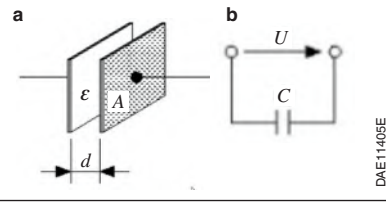
Calculation formula for capacitance
The capacitance C depends on the design of a capacitor, the plate area A, the distance between the plates d, the electrical properties of the dielectric, and the so-called dielectric constant ε as follows.
– Effective plate area A: The greater the plate area, the greater the capacitance. A linear relationship applies → $C \sim A$.
– Distance between the plates d: The smaller the distance between the plates, the greater the capacitance. An inversely proportional relationship applies → $C \sim 1/d$.
– Dielectric constant ε: The greater ε is ("better" dielectric), the greater the capacitance → $C \sim \varepsilon$.

The electric constant ε_0 specifies the permittivity of free space (vacuum between the capacitor plates); it has the constant value

$\varepsilon_0 \approx 8.85$ As/Vm.

The dielectric coefficient ε_r specifies the factor by which the capacitance increases for a certain dielectric in relation to vacuum. It is material-specific and has the unit 1. The dielectric constant ε is obtained as the product of these two quantities.

$\varepsilon = \varepsilon_0\,\varepsilon_r$, with the unit As/Vm or F/m.



The calculation formula for the capacitance of a capacitor can therefore also be specified as follows:

$$C = \varepsilon_0\,\varepsilon_r\,A/d\ .$$

Energy content
The energy content of a charged capacitor (charge Q, voltage U, capacitance C) is:

$$W = \frac{1}{2}QU = \frac{Q^2}{2C} = \frac{1}{2}CU^2\ .$$

Figure 4: Design and graphical symbol of a capacitor
a) Design,
b) Graphical symbol with applied voltage U.

Coil

Design

A current-carrying conductor generates a magnetic field whose magnetic field lines are arranged concentrically around the conductor (see Magnetic field).

In a coil a wire is wound on a coil core in such a way as to produce many parallel conductor loops. As a result, the magnetic field caused by a current is amplified (for details, see "Coil in the alternating-current circuit").

Inductance

The inductance L is a characteristic quantity of coils. It is dependent on the geometric properties of the coils, the number of turns, and the magnetic properties of the material filled by the coil core. For a long coil of length l, cross-sectional area A, and number of turns N:

$$L = \mu_0 \mu_r N^2 A / l.$$

μ_0 is the magnetic constant with the value $4\pi \cdot 10^{-7}$ Vs/Am, μ_r is the material-dependent permeability. For air $\mu_r = 1$.

Energy content

The energy content of the coil carrying current I of inductance L is:

$$W = \frac{1}{2} L I^2.$$

Conductors, nonconductors, semiconductors

The fact that the resistance value R increases as the length increases and the cross-section decreases is common to all materials. The following may be imagined: Aside from the electric charge carriers for the most part a large number of atoms (kernels) is present. In metals the conduction electrons must really "squeeze through" between the kernels. It is true that this "electric friction" is lower in a short piece of wire with a large cross-section than in a long conductor with a small cross-section.

Elements differ in the structure of their atoms. Valence electrons establish the bond with identical or different neighboring atoms. Depending on the material, there is a different number of effective electric charge carriers (e.g., conduction electrons in metals) for a specific volume. The number of effective charge carriers per unit of volume and their mobility between the kernels of the atomic union determine the resistivity ρ of a material.

Conductors

Most metals are good conductors because they have a large number of conduction electrons per unit of volume. The resistivity of metals is therefore low. However, there are significant differences between different metals (see Table 2).

Copper is the preferred choice of conductor due to its low resistivity. Aluminum, nickel, platinum, gold, tantalum, tungsten, silver, mercury, and tin are often used as well. In certain electric motors brushes made of carbonaceous materials are required and in simple microphones sound-pressure changes are converted into resistance changes with the aid of carbon granules. A voltage drop is frequently desirable in electrical engineering and in electronics; the resistor materials are used here to reduce the current intensity. The corresponding components are pooled together under the generic term "resistors". These resistors are – depending on the requirements – made of certain metals, carbon or metal alloys.

Nonconductors

In nonconductors the valence electrons are bound by strong forces within the atomic structure and only very few free charge carriers are available, resulting in high resistivity. These bonds can however be broken by high voltages or by strong heating. Nonconductors are called insulators; these include for example porcelain, glass, rubber, plastics, Teflon, and PVC.

A distinction is made between conductors and nonconductors, depending on the number of effective electric charge carriers.

Semiconductors

There are materials whose conductivity cannot be classified with either conductors or nonconductors. They are, like the components made from them, called semiconductors. These semiconductors (germanium, silicon) are in their very pure state good insulators. The conductivity can be greatly altered by specific measures, e.g., by targeted contamination or temperature increase. The properties of semiconductor materials are used in a variety of applications in diodes and transistors.

Laws

Ohm's law

In an electric circuit current, voltage, and resistance are linked by Ohm's law. This law defines the relationship between voltage U and current I in solid and liquid conductors. Ohm's law states:

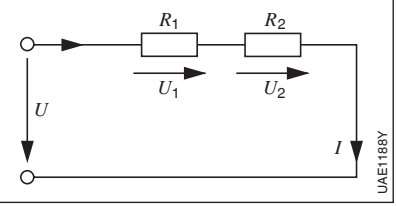
$$U = R I .$$

The proportionality constant R is called ohmic resistance, and is measured in ohms (Ω).

Ohm's law contains the quantities current intensity I, voltage U, and resistance R. One quantity can be calculated when the other two are known. Ohm's law is one of the important basic principles of an electronics engineer.

Kirchhoff's laws

1st Kirchhoff law: current law



The sum of currents (according to their counting direction) flowing into each junction (node) is equal to the sum of currents flowing out of that junction.

2nd Kirchhoff law: voltage law

For each closed loop of a conductor network the sum of the component voltages oriented in the direction of the loop at the individual elements (resistors and sources) is equal to the sum of the component voltages oriented against the direction of the loop.

Figure 5: Series connection of resistors

U Voltage,
I Current,
R Resistance.

Connections of resistors

Series connection of resistors

The series connection of resistors entails the connection of a number of resistors in succession (Figure 5).

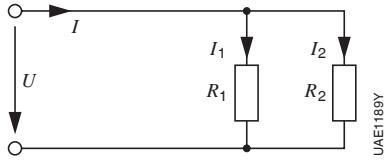
Measurements at different points in a series connection confirm that the current intensity is identical at all points. The following generally applies to series connection:

$I = I_1 = I_2 = I_3 = \ldots$; all currents in A.

In contrast to current measurements, it is not necessary in the case of voltage measurements to break the circuit. For this reason the preferred option for troubleshooting or testing (e.g., in electronic devices and systems) where possible is voltage measurement.

In the example from Figure 5 a specific partial voltage (U_1, U_2) is measured at each resistor. The sum total of these partial voltages is just as high as the total voltage U at the circuit input and the following generally applies:

$U = U_1 + U_2 + U_3 + \ldots$; voltages in V



The total resistance R of this circuit results, also according to Ohm's law, from the total voltage U and the current intensity I as

$R = R_1 + R_2 + R_3 + \ldots$

Parallel connection of resistors

The parallel connection of resistors entails current division (Figure 6). According to the current law (1st Kirchhoff law) the following generally applies:

Figure 6: Parallel connection of resistors
U Voltage,
I Current,
R Resistance.

$I = I_1 + I_2 + I_3 + \ldots$;

$\frac{1}{R_{tot}} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3}$ or

$G_{tot} = G_1 + G_2 + G_3 + \ldots$

The same voltage U is applied at all the resistors.

Example:
Each individual resistor has 100 Ω, the total resistance for three resistors is 33.33 Ω. The values can be calculated by way of two methods, namely via the conductance in S (siemens) or via the resistance in Ω.

$G = \frac{1}{R} = 1/100\ \Omega = 0.01$ S.

$G = G_1 + G_2 + G_3$
$= 0.01$ S $+ 0.01$ S $+ 0.01$ S $= 0.03$ S.

This results in a total resistance of

$R = \frac{1}{G} = 1/0.03$ S $= 33.33\ \Omega$.

The same voltage is effective at each single resistor of a parallel connection. When different resistors are connected in parallel, different single currents also result. According to Ohm's law the current intensity is greatest in the smallest resistor. Conversely, the smallest current flows in the largest resistor. The currents are inversely proportional to the resistors.

Connections of capacitors
Parallel connection of capacitors
Parallel connection of capacitors increases the plate area A (Figure 7b) and total capacitance. The following applies:

$$C_{tot} = C_1 + C_2 + \ldots + C_n.$$

C_{tot} Total capacitance in F.
C_1, C_2 … C_n Individual capacitances in F.

Series connection of capacitors
Series connection of capacitors (Figure 7a) increases the distance between the outer linings. The total capacitance decreases as a result. The following applies:

$$\frac{1}{C_{tot}} = \frac{1}{C_1} + \frac{1}{C_2} + \ldots + \frac{1}{C_n}.$$

Connection of coils
Series connection of coils
Series connection of coils (Figure 8a) entail the adding up of the individual inductances.

$$L_{tot} = L_1 + L_2 + \ldots + L_n.$$

L_{ges} Total inductance in H.
L_1, L_2 … L_n Individual inductances in H.

Parallel connection of coils
The following applies to the parallel connection of coils (Figure 8b):

$$\frac{1}{L_{tot}} = \frac{1}{L_1} + \frac{1}{L_2} + \ldots + \frac{1}{L_n}.$$

Electric power and work

In a resistor through which current passes, the following holds for the energy converted during time t into heat or another form of energy (with ohmic resistance R, voltage U and current I):

$$W = UIt = RI^2 t$$

and thus for power:

$$P = UI = RI^2 = U^2/R.$$

A voltmeter and ammeter can be used to determine the electric power of a device with reference to these mentioned formulas (Figure 9). Figure 10 shows the circuit with a connected wattmeter.

Example
What is the power consumption of an electrical device from a voltage of U = 230 V and I = 0.5 A?

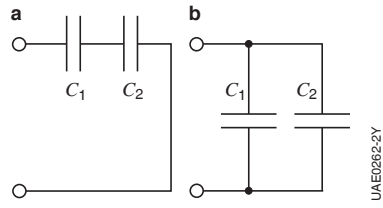
$$P = UI = 230\ \text{V} \cdot 0.5\ \text{A} = 115\ \text{W}$$

The electrical work W is the product of the electric power $U \cdot I$ and the expended time t.

$$W = P\,t.$$

W Electrical work in Ws, Wmin or Wh,
P Power in W,
t Time in s, min or h.

Figure 7: Connection of capacitors
a) Series connection,
b) Parallel connection.



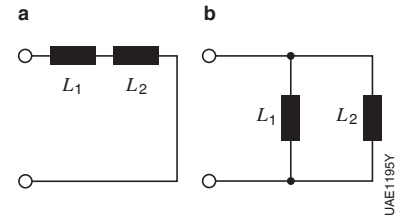


Figure 8: Connection of coils
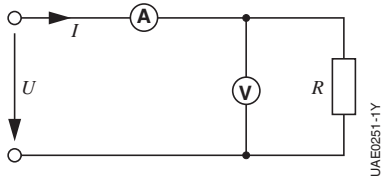
a) Series connection,
b) Parallel connection.

Conversion of measures
Table 3 sets out the conversion factors which are to be applied when converting the different units.

Measurement of electric power
Example
The energy costs can be calculated from the electrical work and the applicable tariff of the energy supply company. The costs for the work and the costs at a tariff of 35 cents/kWh are to be calculated when U = 230 V, I = 5 A and t = 24 h.

Figure 9: Current and voltage measurement
R Load/consumer,
A Ammeter in current path,
V Shunt-connected voltmeter.



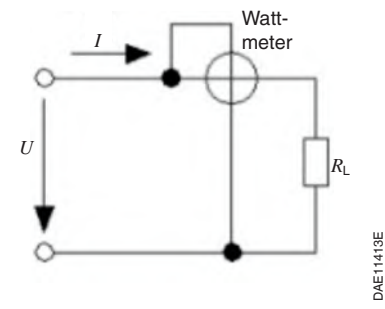


Figure 10: Connection of a wattmeter
U Voltage,
I Current,
R_L Load resistance.

$W = U\,I\,t$
= 230 V · 5 A · 24 h = 27,600 Wh
= 27.6 kWh.

Costs: 27.6 kWh · 35 cents/kWh = 9.66 €.

Example
In combination with a stopwatch the electricity meter also serves as a wattmeter:

$$P = \frac{W}{t}$$

In response to a heating appliance being switched on the meter reading changed from 1432.3 kWh to 1432.6 kWh in 18 minutes. The power of the heating appliance is obtained as follows:

P = 1432.6 kWh – 1432.3 kWh = 0.3 kWh
= 300 Wh = 18,000 Wmin.

$$P = \frac{W}{t} = 18{,}000\ \text{Wmin}/18\ \text{min} = 1000\ \text{W}.$$

The following base quantities are obtained from the International System of Units for direct conversions:

1 Ws = 1 V · 1 A · 1 s = 1 Nm = 1 kg · m^2/s^2.

Table 3: Conversion of units

	Ws	Wmin	Wh	kWh
Ws (watt-seconds)	1	1/60	$2.78 \cdot 10^{-4}$	$2.78 \cdot 10^{-7}$
Wmin (watt-minutes)	60	1	1/60	$1/60 \cdot 10^{-3}$
Wh (watt-hours)	$3.6 \cdot 10^3$	60	1	0.001
kWh (kilowatt-hours)	$3.6 \cdot 10^6$	$60 \cdot 10^3$	10^3	1

Time-dependent current

Charging and discharging a capacitor
A capacitor on direct voltage has two operating states: charging and discharging. When a (discharged) capacitor is connected to a direct-voltage source (Figure 11), it takes on charge, i.e., it is charged. The capacitor voltage rises over time from zero at the outset to approaching the applied direct voltage. A charging current flows which conversely assumes a peak value at the start and then decreases to zero.

The greater the resistance R through which the charging current flows and the greater the capacitance C (absorbable charge quantity), the longer a charging process takes. The product of these two quantities, the time constant τ, is the measure of the duration of the charging process.

$$\tau = R\,C.$$

Charging process

$$I = \frac{U_0}{R} e^{-\frac{t}{\tau}},$$

$$U = U_0 (1 - e^{-\frac{t}{\tau}}).$$

Discharging process

$$I = \frac{U_0}{R} e^{-\frac{t}{\tau}},$$

$$U = U_0\, e^{-\frac{t}{\tau}}.$$

U_0 Charging voltage or voltage at start of discharge,
I Charging or discharging current,
I_0 $I_0 = U_0/R$ Current at start of charge,
R Charging or discharging resistance,
U Capacitor voltage,
τ Time constant.

Charging and discharging currents have opposite directions.

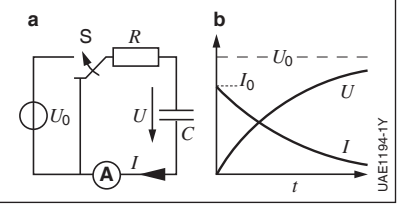
Example 1
The capacitor can charge, C = 1 µF, via the resistance of R = 1 kΩ. Voltage U = 10 V. Charging time t = 2.5 ms. How high is the voltage U?

$\tau = 1\ \text{k}\Omega \cdot 1\ \mu\text{F} = 1$ ms.
$\tau/t =$ 1 ms/2.5 ms = 0.4.

$U = 10\ \text{V} \cdot (1 - e^{-0.4}) = 9.18$ V.

Example 2
The capacitor can charge with capacitance C = 0.15 µF via the resistance of R = 10 kΩ. Voltage U = 10 V. Charging time t = 1 ms. How high is the current I?

$\tau = 10\ \text{k}\Omega \cdot 0.15\ \mu\text{F} = 1.5$ ms.
$t/\tau =$ 1 ms/1.5 ms ≈ 0.667.



$$I = \frac{U_0}{R} e^{-0.667} = 10\ \text{V}/10\ \text{k}\Omega \cdot 0.513 = 0.513\ \text{mA}.$$

After the duration of a time constant of $t = 1\tau$ the capacitor voltage amounts to 63 % of the full charging voltage. After $t = 5\tau$ the capacitor voltage has risen to 99 % of the applied voltage, i.e., almost to the full value of U.

When a charged capacitor is connected to a resistance, it constitutes a voltage source in this circuit; the charges balance themselves out, a drawable discharging current flows, and the capacitor is discharged.

Capacitor in the alternating-current circuit
In the capacitor a current will only then flow when the effective voltage changes, e.g., when a direct voltage is switched on and off. When the capacitor voltage U_C has reached the value of the total voltage U, no further current flows. The capacitive re-

Figure 11: Charging process at capacitor
a) Circuit,
b) Voltage and current curves.
U Voltage,

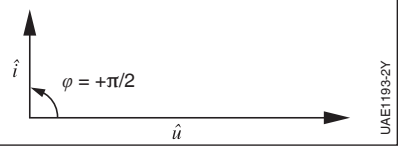
R Resistance,
A Ammeter.

sistance of the charged capacitor appears infinitely high.

In the alternating-current circuit a voltage whose direction changes periodically acts on the capacitor. Charging and discharging therefore alternate likewise in periodic sequence – this consideration should be confined to sinusoidal alternating voltage. The capacitor is charged during the positive half-wave and discharged again via the internal resistance of the voltage generator when the voltage has exceeded its peak value. The current direction is reversed in the process.

For the negative half-wave this process is repeated with the opposite preceding sign. The two capacitor plates alternately carry an electron surfeit and an electron deficit. A certain current intensity can be determined with a measuring device. The capacitor works as a resistor in the case of alternating voltage. The capacitor current (due to charging and discharging) then reaches its highest value when the greatest voltage change is present. Transferred to the sinusoidal alternating voltage, this means high current intensity at voltage zero. Current and voltage are in phase quadrature (Figure 12), the capacitor current leads the voltage at every instant by 1/4 period (1 period = 360°). Because current and voltage do not take effect at the same time, in contrast to ohmic resistance there is no thermal output in the capacitor. The capacitor's AC resistance is called capacitive reactance X_C.



For an ideal capacitor the phase displacement angle φ between voltage and current is –90°. Because of the finite dielectric resistance, occurring surface currents and dielectric losses through polarity reversal in the case of alternating voltage, this angle is however not quite –90° for the real capacitor. This deviation is described by the loss factor or a reciprocal value, the capacitor Q factor. A capacitor separated from its voltage source will discharge slowly via its dielectric.

At a constant voltage the current intensity is all the greater the higher the frequency of the applied alternating voltage (with more charge reversals in a certain time) and the higher the capacitance C (because more electrons participate in the charge reversals). The current-determining capacitive reactance X_C is accordingly inversely proportional to the frequency f and the capacitance C. For sinusoidal alternating voltage the angular frequency $\omega = 2\pi f$ must be used.

$$X_C = 1/(2\pi f C) = 1/\omega C.$$

X_C Capacitive reactance in Ω,
f Frequency in Hz,
C Capacitance in F.

Charging and discharging a coil

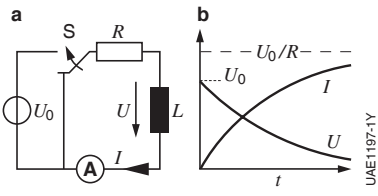
Switching on the coil

When the time characteristic of the making current of a coil is measured, a similar picture is obtained as for the time characteristic of the making voltage at a capacitance.

The cause of the delayed current rise is the inductance L of the coil. During switch-on the build-up of the coil's magnetic field starts. This field build-up is counteracted by the coil's self-induction voltage. Crucial to the charging process is the time constant $\tau = L/R$. Figure 13 shows the voltage and current characteristics.

$$U = U_0\, e^{-\frac{t}{\tau}}.$$

$$I = \frac{U_0}{R}\,(1 - e^{-\frac{t}{\tau}}).$$



Switching off the coil
When an inductor is switched off in the direct-current circuit, the induction voltage is directed in such a way as to counteract the field decay. It is all the higher the faster the field decay (due to the change of current). When circuits with inductors are opened, high induction voltages are obtained due to the small time constant $\tau = L/R$ (R approaches infinity, τ thus approaches zero) because the rapidity of the current change during switch-off is particularly high. The induction voltage therefore drops from its peak value at the start of the breaking process in the time characteristic of an e function with the time constant $\tau = L/R$ to zero. The current during the breaking process also follows the same characteristic.

$$I = I_0\, e^{-\frac{t}{\tau}}.$$

$$U = I_0\, R\, e^{-\frac{t}{\tau}}.$$

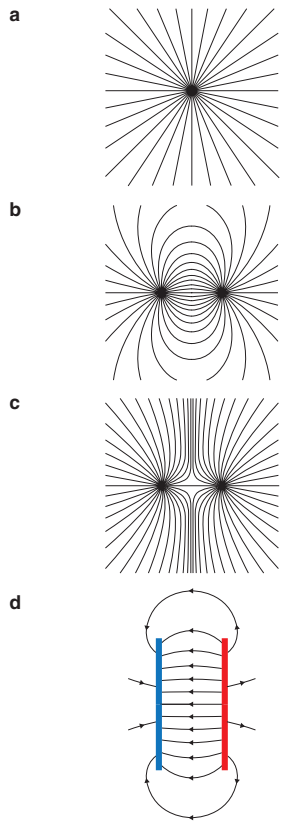
Coil in the alternating-current circuit
Inductive reactance
The coil current cannot follow rapid voltage changes because the inductance has a current-delaying effect. When the direct voltage is switched on, no current flows in the first moment. In the switch-off moment the voltage U reverts sharply to the value zero while the current intensity only decays with a delay. The coil current lags behind the voltage.

In the case of sinusoidal alternating voltage the inductance causes a time difference between identical phases of current and voltage. The current reaches for example the positive crest value in each case 1/4 period later than the voltage; the crest values of the coil voltage U_L include in each case the current intensity zero. The phase displacement between current and voltage is 90° if the coil losses (e.g., winding resistance) are disregarded (Figure 14). The curve shape of the two quantities remains unchanged here.

In coils the current delayed by the inductance cannot reach its full value because the crest values of the sinusoidal alternating voltage in contrast to direct voltage only occur as instantaneous values. The current intensity therefore complies with the applied alternating voltage and with the self-induction voltage generated in the coil. This influence of the inductance is summarized in the inductive reactance X_L. High frequencies result in rapid field changes in the coil and thus high self-induction voltages. The inductive reactance is therefore proportional to the inductance L and the frequency f.



$$X_L = 2\pi f L = \omega L$$

Figure 14: Phasor diagram, coil
$\hat{u}$ Voltage amplitude,
$\hat{\imath}$ Current amplitude.

The factor 2π takes into account, as with the capacitive reactance, the time sinusoidal characteristic of current and voltage. Because current intensity and voltage are effective at different times and in different directions, no heat is obtained in the loss-free (ideal) coil. This fact explains the designation “reactance”.

Electric field

Features

The force acting on a static electric charge is ascribed to the effect of an electric field. Figure 15 shows some field patterns by way of example. An electrostatic field can be defined by the following quantities.

Electric potential φ(P) and voltage U

The electric potential φ(P) at point P is a measure of the work required per charge to move the charge Q from a reference point to point P:

$$\varphi(\mathrm{P}) = \frac{W(\mathrm{P})}{Q} .$$

The voltage U is the potential difference (using the same reference point) between two points P_1 and P_2:

$$U = \varphi(\mathrm{P}_1) - \varphi(\mathrm{P}_2) .$$

Electric field strength E

The electric field strength E at point P depends on the location and its surrounding charges. It defines the maximum slope of the potential gradient at point P. The following applies to the field strength at a distance a from a positive point charge Q_1: It is directed away from the charge Q_1 and has the value

$$E = \frac{Q_1}{4\pi\varepsilon_0 a^2} .$$

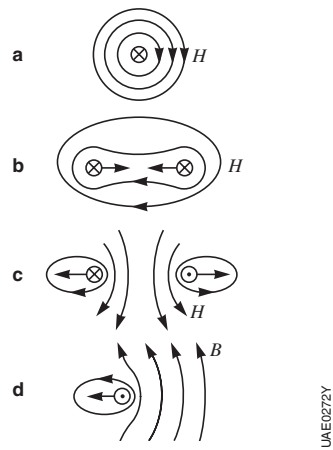
Acting on a positive charge Q_2 at point P is a force in the direction of the electric field strength of the value

$$F = Q_2 E .$$

Electric field and matter

In a material which can be polarized (dielectric), an electric field generates electric dipoles (positive and negative charges $\pm Q$ at a distance a; Qa is called the dipole moment). The dipole moment per unit volume is called the polarization M. The displacement density D indicates the density of the electric displacement flux, The following applies:

$$D = \varepsilon E = \varepsilon_0 \varepsilon_\mathrm{r} E = \varepsilon_0 E + M .$$



$\varepsilon = \varepsilon_0 \varepsilon_r$ is the dielectric constant of the material, ε_0 the electric field constant (dielectric constant of vacuum), ε_r the permittivity (relative dielectric constant). For air, $\varepsilon_r = 1$.

The quantity

$$w_e = \frac{1}{2} E D$$

is the electrical energy density. When multiplied by the volume, it produces the electrical energy W_e.

Figure 16: Current-carrying conductors and the associated magnetic lines of force

b) Parallel conductors, current flow in the same direction (conductors attract each other),
c) Parallel conductors, current flow in opposite directions (conductors repel each other),
d) A magnetic field of flux density B exerts a force on the current-carrying conductor (direction of force is determined using the right-hand rule).

Magnetic field

Features
Moving charges are associated with a magnetic field, i.e., electric current generates a magnetic field in the space surrounding it. Its manifestations match the manifestations of natural magnetic fields, e.g., the field of a permanent magnet or the Earth's magnetic field. In the same way as for electric fields, field lines were introduced to facilitate the depiction of magnetic fields (Figure 16). The direction in which the current flows (⊗ current flow into the page, ⊙ current flow out of the page) in the case of positive currents and the direction of the magnetic field strength form a right-handed screw. Whereas, however, in an electric field the electric field lines start out radially from the positively charged electrode and end at the negatively charged electrode, the magnetic field lines are always self-contained, i.e., they exhibit neither a start nor an end.

Another significant difference between an electric field and a magnetic field is that a magnetic field always has a pole character. Therefore it is not possible to realize a separate north or south pole. The field lines are always directed from the north to the south pole of the magnetic field and never touch.

Magnetic field quantities
A series of magnetic field quantities is required to calculate magnetic circuits.

Ampere-turns
In practice the magnetic fields of conductor loops and particularly of coils, which can be considered as the series connection of many conductor loops, are significant. These coils are as important as components in electrical engineering and electronics as resistors and capacitors. The connection between the current and the number of coil turns as the cause of the generated magnetic field is registered by the current linkage Θ (Figure 17).

$\Theta = NI$,

Θ Ampere-turns in A (magnetic potential),
N Number of turns on coil,
I Current in A.

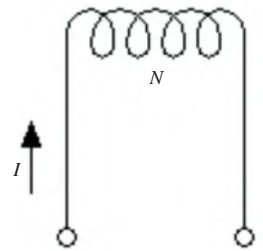
Magnetic field strength
The magnetic field strength H assigns as a vector quantity to each point in space a strength and direction of the magnetic field generated by the magnetic potential (Figure 18).

$H = \Theta / l$,
$H = NI / l$

H Magnetic field strength in A/m,
l Mean field-line length in m,
N Number of turns.

Magnetic flux and flux density
The magnetic flux Φ is the measure of the sum total of magnetic field lines (Figure 19).

Figure 17: Magnetomotive force
I Current,
N Number of turns.



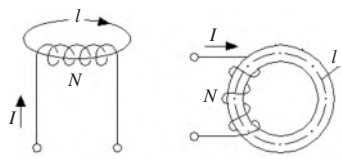


Figure 18: Magnetic field strength
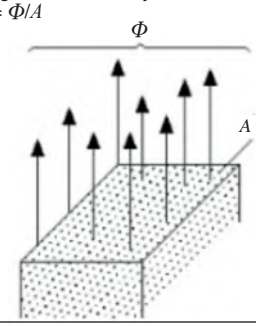
I Current,
N Number of turns,
l Mean field-line length.

Another important field quantity is the flux density or magnetic induction B.

$B = \Phi / A$,
B Magnetic flux density in tesla
1 T = 1 tesla = 1 Vs/m^2,
Φ Magnetic flux in Weber (Vs)
1 Wb = 1 weber = 1 Vs,
A Area in m^2.



Magnetism and magnetic field
Magnets refer to bodies with the property of exerting a force on certain materials, e.g., iron, in its environment; a magnet attracts iron. This magnetic effect is intensified at the two ends of the magnet poles.

The ampere-turns Θ (current linkage or magnetomotive force) constitutes a measure of the magnetic effect of a current-carrying coil. Here the ampere-turns is all the greater the higher the current I and the number of turns N on the coil.

With complete magnetic circuits without considerable stray fields (ring coils, coils with a complete iron core, if necessary also with an air gap) the mean field-line length is obtained from the mean path length. It must be noted that for different materials or different cross-sections the following relationship applies:

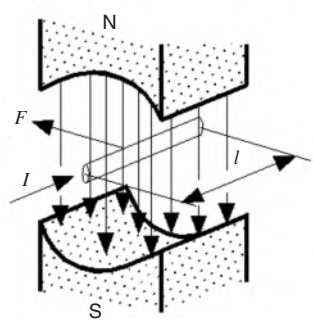
$\Theta = I_1 N_1 + I_2 N_2 + \ldots$

Figure 19: Magnetic flux and magnetic flux density (induction)
Φ Magnetic flux,
A Area,
B Magnetic flux density.
$B = \Phi / A$

The magnetic field of a current-carrying coil can be amplified by a multiple when a ferromagnetic material – e.g., in the form of an iron core – is introduced into the coil cavity. This influence is taken into account in the magnetic flux density B, whereby the causative field strength H is multiplied by a factor, the so-called permeability μ.

$$B = \mu H.$$

Here the permeability μ is made up of two components:
- the magnetic field constant $\mu_0 \approx 1.256 \cdot 10^{-6}$ Vs/Am (the value for vacuum), and
- the relative permeability μ_r, which as a pure numerical factor specifies by how much the magnetic flux density is increased by a specific material in the coil cavity as against vacuum.



With $\mu = \mu_0 \mu_r$, therefore, the magnetic flux density is obtained

$$B = \mu_0 \mu_r H \approx 1.256 \cdot 10^{-6} \text{ Vs/Am } \mu_r H.$$

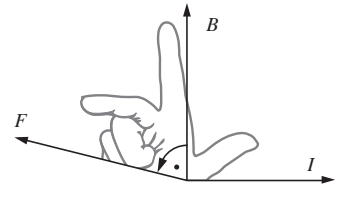
With the magnetic field strength H in A/m and μ_0 in Vs/Am the unit Vs/m^2 is obtained for the magnetic flux density B and is denoted by tesla (T).

With B in Vs/m^2 and A in m^2 the unit Vs is obtained for Φ and is abbreviated to weber (Wb).

Figure 20: Current-carrying conductor in a magnetic field
I Current,
F Force on the conductor,
l Conductor length in magnetic field.

Forces on current-carrying conductors in the magnetic field

Magnetic fields exert forces on each other. Unlike poles attract, like poles repel. These effects can be substantiated with permanent magnets (e.g., magnetic bar and magnetic needle). Even the current-carrying conductor with its magnetic field is exposed to forces by other magnetic fields (Figure 20). The current-carrying conductor amplifies the right part of the permanent-magnet field (same field-line direction). To the left of the conductor the permanent-magnet field is weakened (opposite field-line direction).



The current-carrying conductor thus experiences a force in the permanent magnet's magnetic field. The force F is obtained as

$$F = B I l z \sin\alpha.$$

F Force on the conductor in N (newton),
B Magnetic flux density in T (tesla),
l Effective conductor length in m (meter),
α Angle between l and B, in Figure 20 $\sin\alpha = \sin 90° = 1$.
z Number of conductors (number of turns),
I Current intensity in A (ampere).

The direction of the force can be determined by applying the right-hand rule (Figure 21). The thumb points in the direction of the positive current flow (cause), the index finger points in the direction of the magnetic field (relaying), and finally the middle finger specifies the direction of force (effect).

Figure 21: Right-hand rule
I Current,
B Magnetic flux density,
F Force.

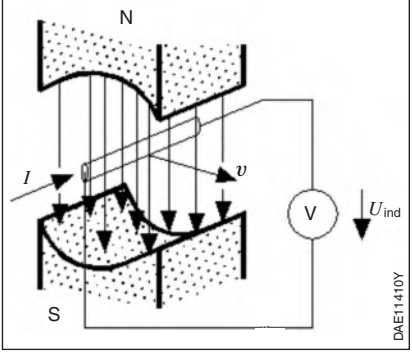
Electrodynamic principle

Induction

Whereas in a motor electrical energy is converted into mechanical energy, with a generator mechanical energy can be converted into electrical energy. If namely a conductor is moved in a magnetic field in such a way that it intersects field lines, a voltage is induced in it while it is moving (Figure 22). The level of the induced voltage U_{ind} depends here on the magnitude of the magnetic flux density B, the rate of motion v of the conductor loops, and thus on the change of area dA in the time unit dt as well as on the number of turns z. The following applies:

$$U_{ind} = -z\,B\,dA/dt.$$

Self-induction



When the current intensity and thus the magnetic field change in a conductor or in a coil, an induction voltage is also generated in the conductor or coil itself. The magnitude of this self-induction voltage depends just like the magnitude of the induction voltage (of the rest or the motion) on the extent and rapidity of the magnet-field change.

The property of a coil of generating a certain self-induction voltage U_{ind} for a certain current change dI per time unit dt is known as inductance L. Its unit is obtained from the generated voltage (in volts) per current change (in A/s) as V/(A/s) = Vs/A, abbreviated as henry (H). The following applies:

$$U_{ind} = -L\,(dI/dt).$$

In all cases the level of the generated induction voltage depends on the extent to which the strength of the magnetic field (B or Φ) and the rapidity with which the strength of the magnetic field changes.

Figure 22: Induction of motion
I Current,
v Speed of the conductor in the magnetic field perpendicular to the field lines,
U_{ind} Induced voltage.

Magnetic field and matter

Magnetic polarization

In matter, induction B theoretically consists of two components. One component comes from the applied field ($\mu_0 H$), and the other from the matter (J):

$$B = \mu_0 H + J.$$

J is the magnetic polarization and describes that component of flux density contributed by the matter. In physical terms, J corresponds to one magnetic dipole moment per unit volume and is generally a function of field strength H. For many materials $J >> \mu_0 H$ and is proportional to H. Thus:

$$B = \mu_r \mu_0 H$$

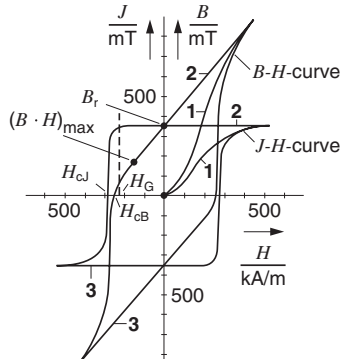
with relative permeability μ_r; in free space it has the value $\mu_r = 1$.

Magnetic energy density

The quantity

$$w_m = \frac{1}{2} B H$$

is called magnetic energy density. When multiplied by the volume, it produces the magnetic energy W_m.



Classification of materials
Materials are divided into three groups according to their relative permeability values.

Diamagnetic materials
μ_r is independent of magnetic field strength and smaller than 1; the values are within the range:
$(1-10^{-5}) < \mu_r < (1-10^{-11})$
(e.g., Ag, Au, Cd, Cu, Hg, Pb, Zn, water, organic materials, gases).

Paramagnetic materials
μ_r is independent of magnetic field strength and greater than 1; the values are within the range
$(1+10^{-8}) < \mu_r < (1+10^{-4})$
(e.g., O_2, Al, Pt, Ti).

Ferromagnetic materials
The magnetic polarization in these materials is very high, and its change as a function of the field strength H is nonlinear; it is also dependent on hysteresis. Nevertheless, if, as is usual in electrical engineering, the relationship $B=\mu_r\mu_0 H$ is chosen, then μ_r is a function of H and exhibits hysteresis; the values for μ_r are within the range
$10^2 < \mu_r < 5\cdot 10^5$
(e.g., Fe, Co, Ni, ferrites).

Figure 23: Hysteresis loop (e.g., hard ferrite)
1 Rise path,
2, 3 Demagnetization curves.
H Magnetic field strength,
B Magnetic flux density,
J Magnetic polarization,
B_r Remanence,
H_{cB}, H_{cJ} Coercive field strength,
H_G Limiting field strength.

Hysteresis loop
The hysteresis loop (Figure 23), which illustrates the relationship between B and H as well as J and H, is explained as follows: If the material is in the unmagnetized state ($B=J=0$, $H=0$) when a magnetic field H is applied, the magnetization follows the rise path (1). From a specific, material-dependent field strength, all magnetic dipoles are aligned and J reaches the value of saturation polarization J_s (material-dependent) which can no longer be increased. If H is now reduced, J decreases along section (2) of the curve and at $H=0$ intersects the B or J axis at the remanence point B_r or J_r (in which case $B_r=J_r$). The flux density and polarization drop to zero only on application of an opposing field whose field strength is H_{cB} or H_{cJ}; this field strength is called the coercive field strength.

As the field strength of the opposing field is further increased, saturation polarization is reached in the opposite direction. If the field strength is again reduced and the field reversed, curve (3), which is symmetrical to curve section (2), is traversed.

The most important characteristic values of a ferromagnetic material are usually tabulated:
- saturation polarization J_s,
- remanence B_r (residual induction for $H=0$),
- coercive field strength H_{cB} (demagnetizing field strength where B becomes equal to 0) and
- coercive field strength H_{cJ} (demagnetizing field strength where J becomes equal to 0, of significance only for permanent magnets),
- limiting field strength H_G (a permanent magnet remains stable up to this field strength),
- maximum small-signal permeability μ_{max} (maximum slope of the rise path; significant only for soft magnetic materials),
- hysteresis loss (energy converted into heat per volume during one remagnetizing cycle, corresponds to the area of the B–H hysteresis loop; significant only for soft magnetic materials).

Ferromagnetic materials
Ferromagnetic materials are divided into soft and permanent magnetic materials. What must be emphasized is the immense range of eight powers of ten covered by the coercive field strength.

Permanent-magnet materials
Permanent-magnet materials have high coercive field strengths; the values lie within the range

$$H_{cJ} > 1 \frac{kA}{m}$$

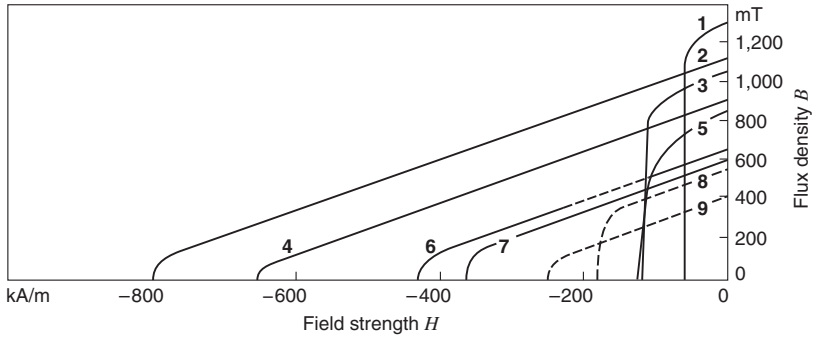
Thus high demagnetizing fields H may occur without the material losing its magnetic polarization. The magnetic state and operating range of a permanent magnet lie within the second quadrant of the hysteresis loop, on the demagnetization curve.

In practice, the operating point of a permanent magnet never coincides with the remanence point, because magnetic polarization of the permanent magnet in its interior always causes a magnetic field, the demagnetizing field, which shifts the operating point into the second quadrant.

The point on the demagnetization curve at which the product BH reaches its maximum value $(BH)_{max}$ is a measure of the maximum attainable air-gap energy. In addition to remanence and coercive field strength, this value is important for characterizing permanent magnets.

AlNiCo, ferrite, FeNdB (REFe), and SeCo magnets are currently the most important types of permanent magnets in terms of industrial applications; their demagnetization curves (Figure 24) exhibit characteristics typical of the individual magnet types.

Soft magnetic materials
Soft magnetic materials have a low coercive field strength



$$H_{cJ} < 1 \frac{kA}{m},$$

i.e., a narrow hysteresis loop. The flux density assumes high values (large μ_r values) for low field strengths so that, in customary applications $J >> \mu_0 H$, i.e., in practice no distinction need be made between $B(H)$- and $J(H)$ curves.

Due to their high induction at low field strengths, soft magnetic materials are used as conductors of magnetic flux. As they exhibit low remagnetization losses (hysteresis loss), materials with low coercive field strengths are particularly well-suited for applications in alternating magnetic fields.

The characteristics of soft magnetic materials depend essentially on their pretreatment. Machining increases the coercive field strength, i.e., the hysteresis loop becomes broader. The coercive field strength can be subsequently reduced to its initial value through material-specific annealing at high temperatures (magnetic

Figure 24: Demagnetization curves for various permanent-magnet materials

final annealing). The magnetization curves, i.e., the B-H relationships, are set out in Figure 25 for several important soft magnetic materials.

Remagnetization losses
In Table 4 P1 and P1.5 represent the remagnetization loss for inductions of 1 and 1.5 tesla respectively, in a 50 Hz field at 20 °C. These losses are composed of hysteresis losses and eddy-current losses. The eddy-current losses are caused by electric fields which are induced (law of induction) in the magnetically soft components of the magnetic circuit as a result of changes in flux during alternating-field magnetization. Eddy-current losses can be kept low by applying the following measures to reduce electric conductivity:

– lamination of the core,
– use of alloyed materials (e.g., silicon iron),
– use of insulated powder particles (powdered cores) in the higher frequency range,
– use of ceramic materials (ferrites).

M 800 – 50 A	0.5	3.6	8.1	1.77

Electromagnetic fields

Electrical engineering deals with electromagnetic fields and their effects. These fields are associated with electric charges (in each case an integral multiple of the electric elementary charge). Physics does not indicate whether the fields are the cause or the effect. Static charges produce an electric field, whereas moving charges give rise to a magnetic field as well. The association of electric and magnetic fields with static and moving charges is described by Maxwell's equations [3].

The presence of these fields is evidenced by the effects of their forces on other electric charges. The force on a point charge Q in an electric field is called Coulomb force. It causes a repulsion between charges of the same name. For two point charges Q_1 and Q_2 in free space at a distance a, it is:

$$F = \frac{Q_1 Q_2}{4\pi\varepsilon_0 a^2} .$$

$\varepsilon_0 \approx 8.854 \cdot 10^{-12}$ F/m is the electric field constant, also called the dielectric constant of free space.

The force acting on a moving charge in a magnetic field is expressed by the Lorentz force. This is responsible for two parallel conductors which carry rectified currents I_1 and I_2 being mutually attracting. Over a length l in free space at conductor distance a the force of attraction between the two conductors is:

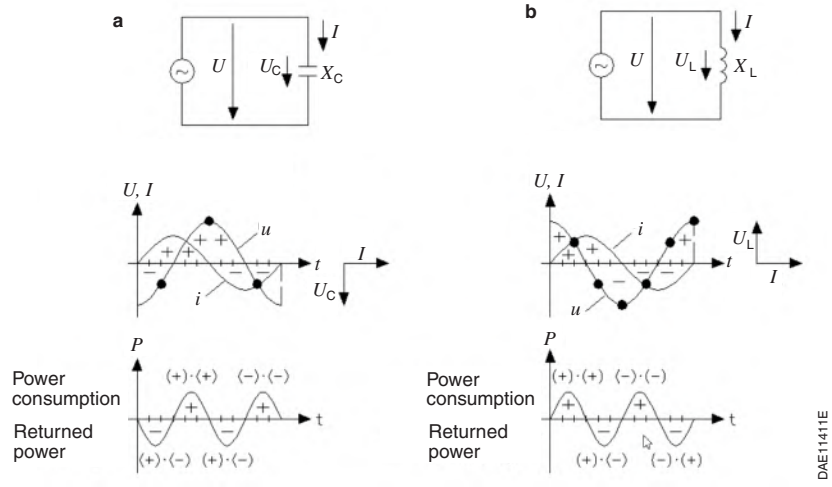
$$F = \frac{\mu_0 I_1 I_2 l}{2\pi a} .$$

$\mu_0 \approx 1.257 \cdot 10^{-6}$ H/m stands for the magnetic field constant, also called the permittivity of free space.

Power in the alternating-current circuit

Features

Resistors, capacitors, and coils are important components in electrical engineering and electronics. Especially in electronic circuits they can be found in the most varied combinations and circuit variants. But also many electrical devices exhibit as consumers (e.g., motors and fluorescent lamps) behavior that can be emulated with an equivalent circuit of resistors, capacitors, and coils.



The behavior of these components and their interaction are of significance particularly in the case of operation on sinusoidal alternating voltage. If an ohmic resistance is connected to a sinusoidal voltage, current and voltage are constantly in phase. For a capacitor the current leads the voltage by 90°, while for a coil the current lags behind the voltage by 90°.

The occurring phase displacements can be depicted in both line and phasor diagrams. However, the phase diagrams for voltages, currents, resistances, and power are particularly important to describing the interaction of active resistances and reactances. In this connection a right-angled triangle appears in each phasor diagram so that mathematical relationships can be derived using Pythagoras' theorem. But the trigonometric functions sine, cosine, and tangent can also be used to describe the mathematical relationships in phasor diagrams and thus in alternating-current circuits.

There are three different types of power in an alternating-current circuit: Active power P in watts, apparent power S in va (volt-ampere), and reactive power Q in var (volt-ampere-reactive).

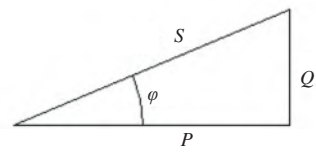
Figure 26: Comparison of capacitive and inductive reactive power

Capacitor and coil are taken as ideal, resulting in phase quadrature of current and voltage.
a) Current, voltage, and power diagram for capacitive reactive power,
b) Current, voltage, and power diagram for inductive reactive power.

Active power
The ohmic resistance in a heater consumes in alternating current pure active power because current I and voltage U are in phase. Multiplying the instantaneous values of voltage and current produces the instantaneous values of power $P = U\,I$.

Example:
An electric heating plate is connected to U = 230 V and a current of I = 3 A flows. How high is the active power?

$P = UI$ = 230 V · 3 A = 690 W



Reactive power
Owing to the phase displacement between voltage and current u and i do not always have the same preceding sign (Figure 26). For the power an area is obtained which is situated precisely halfway each in the positive and negative regions. "Positive" power is the power drawn by the consumer from the voltage source.

The values U and I are multiplied and produce the reactive power $Q = U\,I \sin\alpha$ or $Q = S \sin\alpha$.

Apparent power
An apparent power S is created when effective resistances (R) and reactances (X_L or X_C) are interconnected. Multiplying for such a circuit the measured voltage U by the measured current I produces the apparent power S.

The apparent power does not permit any conclusion as to how big the share of the actually drawn and "consumed" power is.

Figure 27: Active, apparent, and reactive power in power triangle
P Active power,
Q Reactive power,
S Apparent power.

Active and reactive power can be added to the apparent power in the phasor diagram (Figure 27).

For a sinusoidal characteristic $S = UI$. The phase displacement φ of current and voltage can be calculated

$P = UI\cos\varphi$
$P = S\cos\varphi$
$Q = UI\sin\varphi$

S Apparent power in VA,
P Active power in W,
Q Reactive power in var,
U Voltage (effective value),
I Current (effective value),
cos φ Power factor,
sin φ Reactive-power factor.

Reactive-power compensation
The energy supplier companies make it compulsory for their customers to achieve a power factor of around cos φ = 0.9 in their systems. If this value is undershot, the phase angle is reduced by individual or group compensation. By connecting an appropriate capacitor in parallel, it is possible to free the incoming cable in part or in whole of reactive current. In this way, the reactive currents or reactive power in the incoming cable cancel each other out and these can be output with active current or active power.

Wave propagation

Waveguide

At higher frequencies forward and return conductors of an electric connection section are combined and called a waveguide or in short a line. Common structures are the parallel-wire line, the twisted two-wire line (twisted pair), the coaxial line, the strip line, and the microstrip line.

At higher frequencies the current is no longer distributed evenly over the line cross-section. In the individual wire the current is increasingly displaced to the edge as the frequency increases (skin effect). In lines there is an additional displacement of current to the other conductor in each case (proximity effect). In particular the ohmic loss resistance and thus the damping of the line are thereby increased.

A line has the characteristic impedance Z if it is terminated with this resistance Z and then demonstrates the same impedance Z as the input resistance. In the lines used in motor vehicles (TEM or L lines) the characteristic impedance Z is directly connected with the capacitance C per length l and the inductance L per length l:

$$Z = \sqrt{\frac{L}{C}} .$$

Table 5 shows characteristic impedances for some selected line types.

Even the amplitudes of the electric and magnetic fields along the line are linked via the characteristic impedance:

$$Z = \frac{\hat{E}}{\hat{H}} .$$

A line of characteristic impedance Z which is terminated with resistance R demonstrates at its end the reflectance factor

$$r = \frac{R - Z}{R + Z} .$$

The square of the absolute value of the reflectance factor indicates what fraction of the power is sent back at the end of the line.

$$P_r = |r|^2 P_0 .$$

Passed on to the terminating resistor, however, the power becomes

$$P_t = (1 - |r|^2) P_0 .$$

When $R = Z$ applies, adaptation occurs and the reflectance factor r is zero. In this case, no power is reflected, the full power being passed on to the terminating resistor R.

At higher frequencies and with longer lines, voltage and current along the line are no longer constant. At a fixed instant both vary along the line. Here there can be points over the length of the line at which the amplitude of the voltage fluctuations is at maximum, while at other points only minimum voltage amplitudes occur. The ratio of maximum to minimum amplitude on a line is called the standing wave ratio s.

$$s = \frac{U_{max}}{U_{min}} .$$

If a line is supplied at one end only with a sinusoidal time function, while terminated at the other end with a resistor, it is possible to calculate the standing wave ratio from the reflectance factor.

$$s = \frac{1 + |r|}{1 - |r|} .$$

Table 5: Characteristic impedances for some selected line types

Parallel conductors (twin conductors) in air	$Z = \sqrt{\frac{\mu_0}{\varepsilon_0}} \frac{1}{\pi} \ln \frac{a + \sqrt{a^2 - 4r^2}}{2r}$	a r	Distance between conductors [m] Conductor radius [m]
Concentric line (coaxial line)	$Z = \sqrt{\frac{\mu_r \mu_0}{\varepsilon_r \varepsilon_0}} \frac{1}{2\pi} \ln \frac{r_2}{r_1}$	r_2 r_1	Inside radius of outer tube [m] Radius of center tube [m]
Conductor to ground in air	$Z = \sqrt{\frac{\mu_0}{\varepsilon_0}} \frac{1}{2\pi} \ln \frac{a + \sqrt{a^2 - r^2}}{r}$	a r	Distance from conductor to ground [m] Conductor radius [m]

During adaptation s = 1 and at all points on the line the voltage amplitude is the same.

Couplers and matching transformers
Couplers are used in conjunction with matching transformers to forward an electromagnetic wave from one waveguide to another. Matching transformers reduce the reflectance factor during the transition from one characteristic impedance to another or couple a symmetrical waveguide (e.g. a parallel-wire line) with an asymmetrical one (e.g. a coaxial line).

Couplers and matching transformers are usually reciprocal, coupling just as well in one direction as in the other.

Wave propagation in free space
Even free space is a waveguide, with the characteristic impedance of free space (field characteristic impedance Z_0):

$$Z_0 = \sqrt{\frac{\mu_0}{\varepsilon_0}} \approx 377\ \Omega.$$

Far away from antenna structures the direction of the electric field, the direction of the magnetic field and the direction of propagation of the electromagnetic wave in free space are vertically on top of one another, and the electric field strength is linked with the magnetic field strength via the characteristic impedance Z_0. The electromagnetic power density S emitted by a transmitter is established via the amplitudes of the electric field strength $\hat{E}$ and the magnetic field strength $\hat{H}$. In free space, far away from the transmitter, the electromagnetic power density decreases with the inverse square of the distance from the transmitter:

$$S = \frac{1}{2}\hat{E}\,\hat{H},$$

$$S(r) = S(r_0)\,\frac{r_0^2}{r^2}.$$

Electric and magnetic field strengths, on the other hand, decrease only inversely with the distance from the transmitter:

$$\hat{E}(r) = \hat{E}(r_0)\,\frac{r_0}{r},$$

$$\hat{H}(r) = \hat{H}(r_0)\,\frac{r_0}{r}.$$

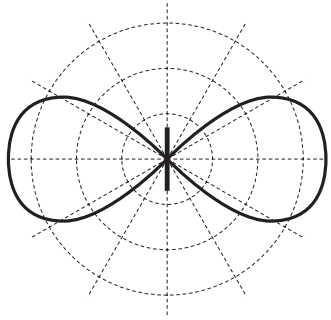
For some applications in motor vehicles the receiver is situated so near to the transmitter that near-field conditions prevail. Radio remote controls, for example, generate via a current-carrying coil magnetic fields whose field strength in the near field is inversely proportional to the cube of the distance from the transmitter.

Antennas
A coupler from a waveguide to free space is called an antenna. Antennas too are usually reciprocal; they can therefore act equally as transmitting and receiving antennas.

An electromagnetic wave in free space consists of time-variant electric and magnetic fields. These have one spatial direction – far away from transmitting antennas the field directions of these two fields are vertical to the direction of propagation of the wave. The direction of the corresponding electric field determines the polarization direction of the electromagnetic wave. Most antennas are designed in such a way that they can transmit and receive only one single direction of the electric (sometimes also the magnetic) field strength. They therefore transmit only linearly polarized waves and receive only one particular polarization of the wave.

A distinction is made between narrow-band antennas (dipole antennas, as used for example for GPS, GSM, Bluetooth, WLAN or even VHF) and wide-band antennas, which are used as transmitting and receiving antennas in EMC measurements in motor vehicles. An example of a narrow-band antenna is the half-wave dipole, a rod or wire of length l = 0.96 $\lambda/2$ (λ: wavelength in free space). The optimum length becomes shorter for thicker rods, or if necessary also through connection with additional capacitances. In conjunction with an extended metal surface the dipole length is shortened by half to one $\lambda/4$-dipole.

An example of a wide-band antenna is the logarithmically periodic antenna. Here, several half-wave dipoles are of different lengths are arranged along a twin line. No antenna transmits in transmitting mode uniformly in all directions. Likewise, no antenna receives in receiving mode all directions equally well. This directionality is described by the directional diagram (also known as the antenna directional characteristic). Figure 28 shows the directional diagram of a half-wave dipole in a vertical section through the dipole antenna. What is depicted is the radiated power density against the angle.



Often what is of interest is not the entire directional diagram, but only its maximum value in the preferred direction. The directivity indicates by how much the radiated power per surface area S_{max} of the antenna in transmitting mode is greater in the preferred direction than for a reference antenna which does not prefer a direction:

$$D_0 = \frac{S_{max}}{S_0}.$$

The directivity in relation to the antenna gain G is given as a dB value:

$$G = 10 \log D_0.$$

Figure 28: Directional diagram of a half-wave dipole
(Vertical section through the dipole antenna, power density against the angle).

The antenna losses are usually also included in the antenna gain such that G is smaller than in the ideal case. The same directivity and the same antenna gain also apply in receiving mode. There they indicate by how much the antenna power input is greater than for the reference antenna.

In the EMC standards calculations are made not with the antenna gain but with the antenna factor AF:

$$AF = 20 \log \frac{E}{U}.$$

The antenna factor indicates what voltage amplitude U (in V) drops at the input resistance of the measuring device connected to the antenna when an electric field of amplitude E (in V/m) is received. The same antenna factor also applies to transmitting mode and links the voltage amplitude U (in V) at the input of the transmitting antenna with the amplitude E (in V/m) of the electric field of the emitted wave.

Antenna gain and antenna factor can be converted into one another:

$$AF = 10 \log \left(\frac{4\pi Z_0}{\lambda^2 R_L} \right) - G$$

where
R_L Input resistance of measuring device and of antenna input (in Ω, usually 50 Ω), Z_0 Field characteristic impedance of free space (equal to 377 Ω), λ Wavelength (in m).

Electric effects in metallic conductors

Contact potential between conductors
Contact potential occurs in conductors, and is analogous to the triboelectricity or voltaic emf in insulators (e.g., glass, hard rubber). If two dissimilar metals at the same temperature are joined to make metal-to-metal contact with one another and are then separated, a contact potential is present between them. This is caused by the different work functions of the electrons. The magnitude of contact potential depends on the element positions in the thermoelectric series (Table 6). If more than two conductors are so joined, the resulting contact potential is the sum of the individual contact potential values.

Thermoelectricity and thermocouples
Seebeck effect
A voltage occurs between the two ends of a conductor if these exhibit different temperatures. As the temperature increases the electron density in the conductor decreases on account of the increasing kinetic energy of the electrons: The electrons in the "hot" zone have a greater kinetic energy and move on average towards the "cold" zone. In all, there is then a higher electron density in the "cold" zone than in the "hot" zone and hence a negative potential. In semiconductor physics this can be expressed by different Fermi levels and a resulting potential difference (thermoelectromotive force U_T). In all, the thermoelectromotive force U_T between the ends is obtained with the temperature difference ΔT according to the following equation:

$$U_T = \alpha \Delta T,$$

where
α: Seebeck coefficient in µV/K,
Δt: Temperature difference in K.

The Seebeck coefficient α is approximately temperature-independent and is determined by the material. The Seebeck coefficient α can be used to determine the thermoelectromotive force U_T in µV for the respective material for a given temperature difference in kelvin; frequently the second conductor is made of platinum – therefore the Seebeck coefficient α for platinum in Table 7 equals zero. Occasionally the k factor is used instead of α.

Technically, this effect cannot be used with a homogeneous material. Since the two measuring points are brought to the same temperature for the voltage tap via the measuring device, two equal voltages would be connected in series in the opposite direction. Consequently, no voltage would be tapped between the two mea-

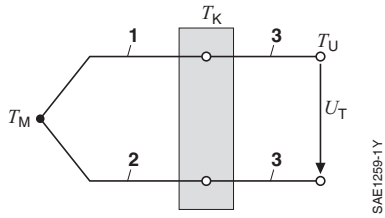
suring points. This changes when different materials are used (Figure 29). The actual thermocouple consists in Figure 21 of two conductors made of materials 1 and 2. Since the connections are in some cases too short, they are extended at a coupling point. This coupling point at the temperature T_K. If necessary, a further extension is required – this is depicted in Figure 29 with material 3. This can involve, for example, conductor tracks of copper. Finally, the thermoelectromotive force U_T can be tapped. The electronic circuit here is at the ambient temperature T_U.

The series connection of the different elements in Figure 29 produces the following relationship:



$$U_T = \alpha_3 (T_U - T_K) + \alpha_1 (T_K - T_M) + \alpha_2 (T_M - T_K) + \alpha_3 (T_K - T_U),$$

$$U_T = (\alpha_1 - \alpha_2) (T_K - T_M).$$

To match the material pairing of a thermocouple corresponding extensions of the same material can be used as compensating lines.

The advantage of thermocouples is their small size, enabling them to be used in areas with very small dimensions – for example, thermocouples can be stuck to the surface for flow measurements in a wind tunnel. The thermoelectromotive forces are indeed very low; however, the internal resistance of the thermocouples is low such that disturbances have little bearing on the output signal. Thermocouples can be used to good effect up to temperatures in excess of 2,000 °C. On the down side, however, thermocouples are subject to low long-term stability.

Peltier effect
The reciprocal of the Seebeck effect is the Peltier effect, in which a temperature difference is created by electrical energy (e.g., as a heat pump). A current flow through the contact points of two different conductors results in heat energy Q being absorbed at one contact and picked off at the other. Depending on the current direction, heat can thus be supplied or dissipated at a contact. The heat transfer ΔQ per time unit Δt is governed by the following equation:

$$\frac{\Delta Q}{\Delta t} = \Pi I \text{ (in V A)},$$

where
Π: Peltier coefficient (in V),
I: Current intensity (in A),
Δt: Time interval (in s).

The relationship between the Peltier coefficient Π, the temperature T and the thermoelectromotive force U_T is as follows:

$$\Pi = U_T T .$$

To utilize the Peltier effect, bismuth telluride (Bi_2Te_3) or even silicon-germanium (SiGe) for example is used; these are either n- or p-doped so as to obtain zones with different Fermi levels. The maximum voltage per thermocouple (i.e., per n- and p-doped zone) is 0.12 V so that a Peltier element with 127 thermocouples requires a supply voltage of approximately 15 V.

It must be noted when operating a Peltier element that the cooling capacity does indeed increase with increasing current I, but this results on account of the electric (ohmic) power loss $P = RI^2$ in self-heating, which counteracts the cooling capacity. Consequently, determining the operating point with maximum efficiency is governed by the following: The ratio between current intensity and maximum current intensity must be chosen in the same way as that between the temperature difference and the maximum achievable temperature difference.

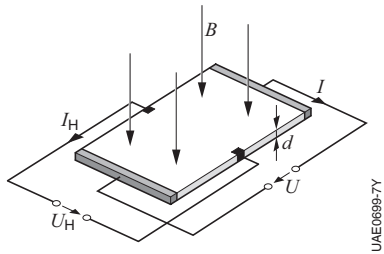
Galvanomagnetic and thermomagnetic effects

Such effects are understood to be changes caused by a magnetic field in the flow of electricity or heat within a conductor. There are twelve different recognized effects which fall into this category, the most well-known of which are the Hall, Ettingshausen, Righi-Leduc, and Nernst effects.

Hall effect

The Hall effect is of particular significance in technical applications. If a current I is sent through a suitable conductor and simultaneously a magnetic field or a magnetic flux density B is applied perpendicular to this current, a voltage is produced which is perpendicular to both the flow of current and the magnetic field. This voltage is called the Hall voltage U_H (Figure 30):

$$U_H = \frac{R_H I B}{d},$$



where

R_H Hall constant (in m^3/As),
I Supply current (in A),
B Magnetic flux density (in Vs/m^2),
d Thickness of conductor (in m).

In the case of Hall-effect sensors made of doped materials such as silicon – i.e., n- or p-type silicon – the majorities determine the sign and the direction of the Hall voltage U_H.

Figure 30: Hall-effect sensor element

B Flux density,
I Supply current,
U Supply voltage,
I_H Hall current,
U_H Hall voltage,
d Thickness of conductor.

The Hall constant R_H is relevant to use: Highest values in the range of 10^{-4} m^3/As are achieved for indium arsenide (InAs); for silicon, the values are among other things dependent on the doping and are much lower. When the current I is known, it is possible to infer the magnetic flux density B or the magnetic field. The advantage here is the strong linear dependence of the Hall voltage on the magnetic field or the magnetic flux density; the disadvantage is as a rule the not insignificant offset on account of inhomogeneities (crystal defects, particularly on the surface) and geometry influences.

In ferromagnetic materials, the Hall voltage is a function of magnetization, where hysteresis effects can also occur.

Hall-effect sensors are frequently used for rotational-speed recording, in which the alternation of tooth and gap of a rotating soft-magnetic sensor wheel is detected. Other applications in automobiles include the detection of end points or the potential-free (i.e., contactless) measurement of electric currents via the magnetic field generated by the current.

Magnetoresistive effects

Anisotropic magnetoresistive effect

Sensors based on the anisotropic magnetoresistive effect (AMR effect) change the electrical resistance R on account of an applied magnetic field H; in contrast to conventional Hall-effect sensors and also magnetoresistors, AMR sensors react to magnetic fields in the layer plane (here xy plane in Figure 31).

AMR sensor elements essentially consist of a thin strip roughly only 20 to 50 nm thick of highly permeable permalloy ($Ni_{81}Fe_{19}$ alloy), which exhibits strong shape anisotropy (Figure 31). This is expressed by a much greater length l than width b; this defines an "easy axis", which determines the orientation of magnetization M without an external magnetic field H in the xy plane in Figure 31. A magnetic field H in the direction of the "hard axis", in Figure 31 in the y direction) rotates M out of this position, which results in a relative change of the electrical resistance R by max. 3 %.

R depends on the angle Θ_{JM} between the current density J and the magnetization M: If J and M are parallel (i.e., $\Theta_{JM}=0$), the

maximum electrical resistance $R_{||}$ results; if J and M are perpendicular to each other ($\Theta_{JM}=90°$), the minimum value $R_{\perp}$ is obtained. The term $\sin\Theta_{JM}$ can be expressed for small angles Θ_{JM} by the ratio of the applied magnetic field H_y in the hard direction and the anisotropy field strength H_K, where H_K depends on the geometry of the AMR layer – more precisely on the ratio of width b to thickness d. The following relationship applies to R (Figure 31b, [6]):

$$R(\Theta_{JM}) = R_{||} - \Delta R_{max}(\sin\Theta_{JM})^2.$$

The following applies to small Θ_{JM}:

$$\sin\Theta_{JM} \approx \frac{H_y}{H_K}.$$

$R_{||}$: Resistance for $\Theta_{JM} = 0°$;
$R_{\perp}$: Resistance for $\Theta_{JM} = 90°$;
$\Delta R_{max} = R_{||} - R_{\perp}$: Maximum achievable absolute resistance change.

Quantum physics provides a physical explanation of this effect: Changes in the electric conductivity are obtained depending on the spin orientation.

The anisotropy field strength H_K plays an important role for the sensitivity $S = dR/dH$; the wider the AMR layer, the steeper the characteristic curve and hence the sensitivity S.

It follows from Figure 31b that for small magnetic fields H_y the sensitivity S is very low; the operating point should therefore be brought into a zone with linear behavior. Above all two methods are known for this purpose: Linearization with an additional (constant) magnetic field H_{y0} (in the direction of the hard axis in Figure 31a), which shifts the characteristic curve in Figure 32 to the left into the steep zone; or the frequently used barber-pole structure in Figure 33. Here the current-density vector J is rotated through approximately 45° to obtain a linear characteristic curve for small magnetic fields H_y.

1 Characteristic curve with additional magnetic field H_{y0} (measured with $H_{y0} = 980$ A/m),
2 Characteristic curve without linearization.
H Magnetic field,
R Resistance.

However, it is to be noted according to Figure 34 that the orientation of the easy axis may not be changed since "rotating the domains around an axis" through 180° leads to a mirroring of the characteristic curve with regard to $H_y = 0$ ("butterfly curve"). This is as a rule effected by an additional constant magnetic field in the "easy direction" (here: x-direction), but which reduces the sensitivity and also the absolute resistance and hence also the absolute resistance change since the maximum relative change of R is always approximately 3 %. Rotating the domains around an axis results in a change of the characteristic curve during linearization with a constant magnetic field H_{y0}.

The use of AMR sensors is favored by the higher magnetic-field sensitivity obtained than with silicon Hall-effect sensors. On the down side, AMR sensors are not compatible with semiconductor processes and must therefore be designed separately. Because of the mirror-symmetric characteristic curve around zero AMR angle sensors can only resolve an angular range of 180°.

Figure 35 shows a typical circuit of four AMR elements with barber-pole structure; because of the opposing orientation of the highly conductive strips in two AMR elements respectively a piecewise linear characteristic curve is achieved, as can be seen by reference to Figure 35b.

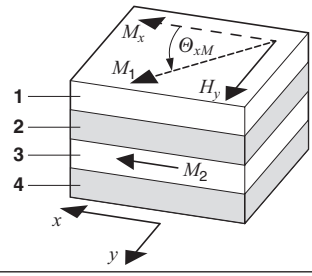
Giant magnetoresistive effect

In the case of the giant magnetoresistive effect (GMR effect) the electrical resistance R changes with the orientation of the magnetization M of two closely neighboring ferromagnetic layers (Figure 36, e.g., iron or cobalt) which are separated by a very thin non-magnetic intermediate layer (e.g., chrome). As with the AMR effect, only applied magnetic fields in the layer plane are relevant with regard to the GMR effect. The spin-dependent scattering of the electrons in one of the magnetic layers brings about, with a parallel orientation of the magnetization M (i.e., ferromagnetic coupling), the minimum electrical resistance R_{min} in the two layers; with an antiparallel orientation of the two magnetizations M (thus antiferromagnetic coupling) the maximum value R_{max} is the result. Relative resistance changes of approximately 6 % are obtained when a number of layer sequences are used.

Figure 36: Characteristic curve and basic design of a GMR sensor element
a) Basic design,
b) Characteristic curve.
M Magnetization,
I Current,
R Resistance,
H Magnetic field.



The current I flows in GMR sensors preferably in the layer plane of the magnetization M (CIP-GMR, Current-in-plane-GMR). However, a current flow perpendicular to the layer plane (CPP-GMR, Current-perpendicular-to-plane-GMR) is also possible. Figure 36b shows the bell shape of R (similar to the AMR effect) as a function of an applied magnetic field H.

The important aspect here is the minimal thickness of the electrically conductive and non-magnetic intermediate layer (chrome in Figure 36 or "spacer" in Figure 37; copper is also used), which is in the region of below one nanometer.

GMR sensor elements are frequently used as spin valves in order to generate a sufficient and at least piecewise linear signal in the case of small magnetic fields H. The basic design is shown in Figure 37: Here the magnetization M_2 of a ferromagnetic layer is retained (in the "pinned layer" with antiferromagnetic coupling) so that only the ("rotatable") magnetization M_1 of the soft-magnetic layer follows an external magnetic field H_y; M_x in Figure 37 corresponds to the orientation of M_1 without an external magnetic field H_y. The resulting characteristic curve is shown in Figure 38; this characteristic curve shows for small magnetic fields H_y an at least piecewise linear shape – however hysteresis oc-

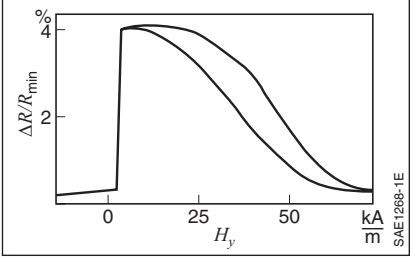
curs with higher magnetic fields H_y. The maximum relative change of R for GMR spin-valve sensors is in the range of approximately 4%.

GMR sensor elements are frequently designed in a Wheatstone bridge circuit – i.e., as a full bridge.

The advantages of GMR sensors in comparison with AMR sensors lie in their higher sensitivity S (= dR/dH) and smaller space requirement, i.e., more signal per surface area. Furthermore, a higher resolution can be achieved on account of the smaller GMR sensor elements. All this permits the use of smaller magnets for angle sensors and smaller gear wheels for example for rpm sensors.



In addition, angle sensors with a measurement range of 360° are possible with GMR sensors, while only 180° can be achieved with AMR sensors. The reason for this is that with GMR sensors the orientation of the pinned magnetization can be arranged differently for the individual GMR sensor elements.

Tunnel magnetoresistive effect

In the case of the tunnel magnetoresistive effect (TMR effect), as with the GMR effect, the electrical resistance R changes with the orientation of the magnetization M of two closely neighboring ferromagnetic layers. However, with TMR sensors, the current I does not, as with customary CIP-GMR sensors, flow parallel (compare here Figure 36), but instead flows due to the tunnel effect, perpendicularly to the electrically insulating and non-magnetic intermediate layer. As with the AMR and GMR effects, only applied magnetic fields in the layer plane are relevant with regard to the TMR effect.

Much smaller and even more sensitive sensors compared with GMR and AMR sensors can be designed with TMR technology; this is due to the much higher electrical resistance R for comparative relative resistance changes. The electrical power demand is reduced here in accordance with $P = U^2/R$.

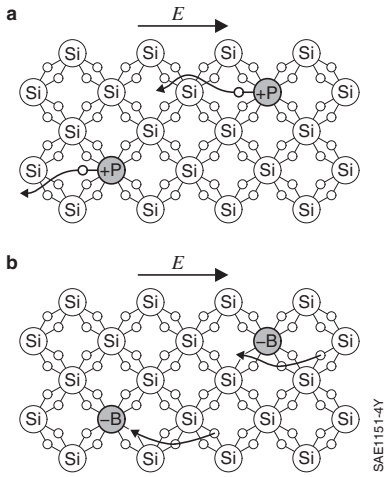
Electronics



Basic principles of semiconductor technology

Electric conductivity in solid bodies

An individual material's capacity for conducting electricity is determined by the number and mobility of the free charge carriers which it contains. The disparities in the electric conductivities displayed by various solid bodies at room temperature extend through a range defined by 10 to the 24th power. Accordingly, materials are divided into three electrical groups.

Conductors (metals)
All solid bodies contain approximately 10^{22} atoms per cubic centimeter; they are held together by electrical forces. In metals, the number of free, i.e. non-attached, charge carriers is extremely high (one to two free electrons per atom). The free carriers are characterized by moderate mobility. The electrical conductivity of metals (e.g. silver, copper, aluminum) is high. In good conductors, this amount to approx. 10^6 S/cm.

Figure 1: Doped silicon
a) *n*-doped silicon,
b) *p*-doped silicon.
o Electron, Si Silicon, P Phosphorus, B Boron, *E* Electric field.
The curved arrows indicate the direction of motion of the electrons when electric field *E* is applied.

Non-conductors (insulators)
The number of free charge carriers in insulators (ex. aluminum oxide, Teflon, fused quartz) is practically zero. Accordingly, the electric conductivity is negligible. The conductivity of good insulators is approximately 10^{-18} S/cm.

Semiconductors
The amount of electrical conductivity in semiconductors (ex. germanium, silicon, gallium arsenide) is between that of metals and insulators. It is – unlike the conductivity of metals and insulators – greatly dependent on the following factors:
– the pressure affects the mobility of charge carriers,
– the temperature influences the number and mobility of charge carriers,
– the action of light also influences the number of charge carriers,
– the presence of additives also determines among others the number and type of charge carriers.

Because they are dependent on the above factors, semiconductors are also suitable for use as pressure, temperature and light sensors.

Doping of semiconductors

Doping, i.e. the controlled addition of electrically active foreign substances to the base material, makes it possible to define and localize the semiconductor's conductivity. This procedure forms the basis of semiconductor devices. The producible and also adjustable electric conductivity of silicon that can be reproduced by doping is 10^4 to 10^{-2} S/cm.

Electric conductivity of semiconductors
The following discussion focuses on the silicon-based semiconductor. In its solid state, silicon assumes the form of a crystal lattice with four equidistant contiguous atoms. Each silicon atom has four outer electrons, with two shared electrons form-

ing the bond with the contiguous atoms. In this ideal state, silicon has no free charge carriers; thus it is not conductive. The situation changes dramatically with the addition of appropriate additives and the application of energy.

Doping will be explained here by reference to a clear model presentation. However, it is important to bear in mind that not all effects can be explained by reference to this model [2].

n Doping

As only four electrons are required for bonding in a silicon lattice (Figure 1a), the introduction of foreign atoms with five outer electrons (e.g. phosphorus) results in the presence of free electrons. Thus, each additional phosphorus atom will provide a free, negatively charged electron, where a single positively charged phosphorus nucleus remains. The silicon is transformed into an n conductor (n-type silicon), since there is an excess of negative charges (electrons). In response to an externally applied voltage, an electric field E is generated, which gives the mobile charge carriers a preferred direction for movement (Figure 1).

p Doping

The introduction of foreign atoms with three outer electrons (e.g. boron) produces electron holes which result from the fact that the boron atom has one electron less for complete bonding in the silicon lattice (Figure 1b). This hole indicates a missing electron. Holes remain in motion within the silicon; they are filled by electrons that leave behind their own hole. In an electric field, they travel in the opposite direction of the electrons. The holes exhibit the properties of a free positive charge carrier. Thus, every additional boron atom provides a free, positively charged electron hole (positive hole). The silicon is transformed into a p conductor and is called a p-type silicon.

Intrinsic conduction

Heat and light also generate free mobile charge carriers in undoped silicon; the resulting electron-hole pairs produce intrinsic conductivity in the semiconductor material. This conductivity is generally modest in comparison with that achieved by doping. Increases in temperature induce an exponential rise in the number of electron-hole pairs, ultimately obviating the electrical differences between the p and n regions produced by doping. This phenomenon defines the maximum operating temperature to which semiconductor devices may be subjected: This is for germanium 90 to 100 °C, for silicon 150 to 200 °C, and for gallium arsenide 300 to 350 °C.

A small number of opposite-polarity charge carriers is always present in both n-type and p-type semiconductors. These minority charges exert a considerable influence on the operating characteristics of virtually all semiconductor devices.

pn junction in the semiconductor

The area of transition between a p-type zone and an n-type zone within the same semiconductor crystal is referred to as the pn junction. The properties of this area exercise a major influence on the operating properties of most semiconductor devices.

pn junction without external voltage

The p-type zone has numerous holes, and the n-type zone has only very few; there is a very large number of electrons in the n-type zone, while in the p-type zone there is an extremely small number. Each type of mobile charge carrier tends to move across the concentration gradient, diffusing into the other zone (Figure 2b).

The diffusion of holes into the n-type zone gives the p-type zone in the pn junction area a negative charge, since the negatively charged core atoms (i.e. boron atoms) remain stationary. Electron depletion results in the n-type region being positively charged, since here this is an excess of stationary, positively charged atomic residues (e.g. phosphorus). The result is an electrical potential between the p- and n-type zones (diffusion potential U_D). This potential opposes the respective migration tendencies of the charge carriers. This ultimately brings the exchange of holes and electrons to a halt. The potential current U_D created on account of diffusion cannot be directly measured from the outside and in silicon is typically just 0.6 V.

A poorly conducting zone deficient in mobile charge carriers is thus produced at the *pn* junction: This zone is called the space-charge region or depletion layer. This zone has an electric field whose strength is also dependent on the externally applied voltage.

pn junction with external voltage
Now the conditions at a diode will be explained because a *pn* junction corresponds to the structure of a diode; here the anode is situated at the *p*-doped silicon, while the cathode is situated at the *n*-doped zone.

The application of voltage U in the reverse direction (negative pole at the *p*-type zone and positive pole at the *n*-type zone) extends the space-charge region (Figure 2c). Consequently, the flow of current I is blocked except for a minimal residual current (reverse current) which stems from the minority charge carriers. The voltage U then drops within the space-charge region; this region is therefore subject to a high electric field strength.

Breakdown voltage is the level of reverse-direction voltage beyond which a minimal increase in voltage will suffice to produce a sharp rise in reverse current (Figure 3). This effect can be explained as follows: Electrons which reach the space-charge region are greatly accelerated on account of the high field strength. In this way, they can for their part generate free charge carriers as a result of impacts; this is also known as collision ionization. This brings about a dramatic rise in current and results in avalanche breakdown. In addition to avalanche breakdown, there is also Zener breakdown, which is based on the tunnel effect. The breakdown of a *pn* junction can destroy it and for this reason is often not wanted. In many cases, however, breakdown is wanted. Avalanche breakdown and Zener breakdown only occur when the diode is operated in the reverse direction.

The application of a voltage U in the forward direction (positive pole at the *p*-type zone and negative pole at the *n*-type zone) reduces the space-charge region (Figure 2d). Charge carriers permeate the *pn* junction, resulting in a large flow of current in the forward direction (Figure 3), as the space-charge region no longer has a significant resistance. Only the bulk resistance, i.e. the ohmic resistance of the doped layers, is effective. The current I increases exponentially as a function of U. It is, however, important to be aware of "thermal breakdown", at which point the semiconductor can be destroyed on account of the high level of heat. This can occur, for example, if the diode is operated in the forward direction with an unacceptably high current.

Discrete semiconductor devices

The properties of the *pn* junction and the combination of several *pn* junctions in a single semiconductor-crystal chip provide the basis for a steadily increasing array of inexpensive, reliable, rugged, compact semiconductor devices. A single *pn* junction forms a diode, two *pn* junctions are used for transistors. The planar technique makes it possible to combine numerous operating elements on a single chip to form the important component group known as integrated semiconductor circuits. Semiconductor chips measure no more than several square millimeters and are usually installed in standardized housings (metal, ceramic or plastic).

Diodes

A diode is a semiconductor device incorporating a single *pn* junction. Its specific properties are determined by the distribution pattern of the dopant in the crystal. Diodes which conduct currents in excess of 1 A in the forward direction are frequently referred to as power diodes.

Rectifier diode

The rectifier diode acts as a form of current valve; it is, therefore, ideally suited to rectifying alternating current. The forward current can be approximately 10^7 times higher than the current in the reverse direction (reverse current, Figure 3). As the temperature rises, the power of this current increases significantly.

Diodes can also be used as polarity-reversal protection diodes in order to prevent a current flow in the event of an incorrect voltage connection. It is also customary to use them as free-wheeling diodes.

Rectifier diode for high reverse voltage

In the case of a rectifier, the voltage drops over the space-charge region. Because this region is generally only a few micrometers in size, the high reverse currents produce a high electric field strength and the free electrons can accelerate greatly. Accelerated electrons can cause the semiconductor to be destroyed (avalanche breakdown). To prevent this, it has proved useful to integrate an intrinsic layer between the *p*- and *n*-layers because this layer only contains few free electrons and thereby reduces the danger of a breakdown.

Switching diode

A switching diode is generally employed for rapid switching between high and low impedances. More rapid switching response can be achieved by diffusing gold into the material; this promotes the recombination of electrons and holes. During switching the space-charge region must be recharged accordingly; during switching-on from the blocking to the conducting state the initially charge-free space-charge region is filled with charges, which results in the forward recovery time. Accordingly, when the diode passes into the blocking state the (excess) charge carriers located in the space-charge region must be removed – the time needed for this is called the backward recovery time. For bipolar transistors the saturation (U_{CE} < 0.2 V) is therefore critical when rapid switching is required. The storage charge or the maximum reverse current is often also specified here.

A distinction is made in the losses between forward power losses (forward voltage times current) and switching power losses; at lower frequencies up to a few 100 Hz the forward power losses dominate while at higher frequencies the switching power losses increasingly play role.

Power diodes

When compared with switching diodes, power diodes are designed for higher currents (> 1 A) and high reverse voltages (up to over 1 kV). These demands arise from the conditions in power electronics where high current intensities and high (reverse)voltages can occur with low forward power losses being desired. Power diodes therefore frequently have – similarly to rectifier diodes for high reverse voltages – a lightly doped "middle layer" between the *p*- and *n*-doped regions – i.e. a pin structure: *p*-doped, undoped or intrinsic, *n*-doped. The space-charge region can further expand in the lightly doped region and thus a higher (reverse) voltage

can be achieved without the dopings having to be reduced in the p and n regions.

Aside from pure silicon diodes, Schottky diodes based on silicon carbide (SiC) are also used here; these diodes exhibit a forward voltage of 0.8 V and a maximum reverse voltage of barely 2 kV. Furthermore, SiC diodes can also be operated at higher temperatures (up to 200 °C).

Free-wheeling diodes
High voltages can occur during the rapid switching of currents by inductance since the induced voltage is proportional to dI/dt. Frequently free-wheeling, or flyback, diodes are used to prevent damage to components such as power transistors (e.g. MOSFET or IGBT). In this case the current flow is not abruptly interrupted, but can continue to flow via the free-wheeling diodes so that high induced voltages are avoided.

Zener diode
A Zener diode is a semiconductor diode which, once a specific initial level of reverse voltage is reached, responds to further increases of reverse voltage with a sharp rise in current flow. This phenomenon is a result of a Zener and/or avalanche breakdown. Zener diodes are designed for continuous operation in this breakdown range. These are frequently used to provide a constant voltage or reference voltage.

Variable-capacitance diode (varactor)
The space-charge region at the pn junction functions as a capacitor; the dielectric element is represented by the semiconductor material in which no charge carriers are present. Increasing the applied voltage extends the depletion layer and reduces the capacitance, while reducing the voltage increases the capacitance.

Schottky barrier diode (Schottky diode)
A Schottky diode contains a metal-to-semiconductor junction. As the electrons move more freely from the n-type silicon into the metal layer than in the opposite direction, an electron-depleted layer is created in the semiconductor material; this is the Schottky barrier layer. Charges are carried exclusively by the electrons, a factor which results in extremely rapid switching, as the minority carriers do not perform any charge storage function (charge-carrier surplus in the space-charge region is reduced). The forward voltage and thus the voltage drop is at approximately 0.3 V smaller in Schottky diodes than in silicon diodes (approximately 0.6 V). Because of the rapid switching and the comparably low losses, Schottky diodes are used in high-frequency circuits down into the microwave range.

Solar cell
The photovoltaic effect is applied to convert light energy directly into electrical energy. Solar cells, consisting largely of semiconductor materials, are the basic elements of photovoltaic technology. Exposure to light can cause the formation of free charge carriers (electron-hole pairs) in the semiconductor. If the semiconductor incorporates a pn junction, the free charge carriers separate in its electric field before proceeding to the metal contacts on the semiconductor's surface. Depending on the semiconductor material used, a DC voltage (photovoltage) ranging from 0.5 to 1.2 V is generated between the contacts. This occurs only when the light quanta have at least the energy required to create an electron-hole pair; the energy is proportional to the frequency and inversely proportional to the wavelength of the light. The theoretical efficiency of crystalline silicon solar cells is approximately 30 %.

Photodiode
The photovoltaic effect is utilized in a photodiode. The pn junction is operated in the reverse direction. Incident light creates additional free electrons and holes. These increase the reverse current (photovoltaic current) in direct proportion to the intensity of the light. The photodiode is thus, in principle, very similar to the solar cell.

Light-emitting diode
A light-emitting diode or LED is an electroluminescent lamp. which consists of a semiconductor element with pn junction. The charge carriers (free electrons and holes) recombine during operation in forward direction. The amount of energy

released in this process is converted into electromagnetic radiation energy.

Depending on the choice of semiconductor and its doping, the LED emits in a limited spectral range. Frequently used semiconductor materials are: gallium arsenide (infrared), gallium arsenide phosphide (red to yellow), gallium phosphide (green), and indium gallium nitride (blue). In order to generate white light, either a combination of three LEDs with the primary colors Red, Green and Blue is used, or a fluorescent dye is excited with a blue or ultraviolet-emitting LED. The maximum luminous efficiency of present-day LEDs is over 300 lm/W – the maximum possible value is approximately 350 lm/W, where only the spectrum that can be detected by the human eye is taken into account here (photometric quantity "luminous flux" in lumens or abbreviated as "lm").

OLED

OLED stands for "Organic Light-Emitting Diode". An OLED is a very thin, two-dimensional light source which emits soft and for the most part non-dazzling light – sharp cast shadows do not occur. OLEDs are in a good approximation Lambertian emitters, i.e. they always appear with uniform brightness regardless of the viewing angle. The small geometric dimensions are also to be noted; thus, OLEDs are less than 2 mm thick – including glass substrate and encapsulation. A further particularity is the flexibility of the extremely flat design, which creates further possible applications in addition to the light properties with high color rendering.

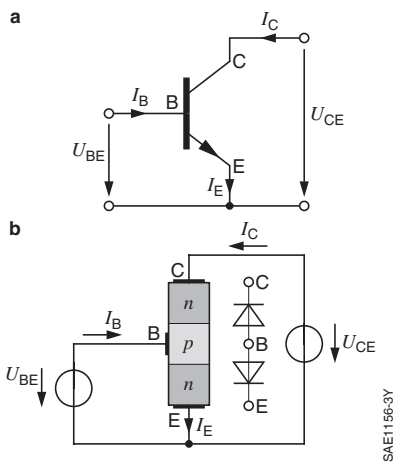
OLEDs - as non-dazzling large-area emitters with a broad spectrum - are particularly suitable for interior applications in automobiles. Constant-current operation suggests itself as the form of activation, enabling light changes on account of aging, temperature or even by production tolerances to be minimized. OLEDs can be dimmed for example by pulse-width modulation.

During the manufacture of OLEDs a number of thin organic semiconductor layers are placed in succession on the conductive substrate (formation of a stack); these layers can form polymeric substances or "small-molecule materials" as an amorphous layer.

Further conductive and transparent electrodes, which cover the organic layers on both sides, are then used. Oxides such as indium tin oxide (ITO) are used as the material for these electrodes; on account of the non-ideal conductivity there is a voltage drop in the active layers from the outside inwards, which results in a corresponding reduction of the radiation intensity from the outside inwards. A remedy can be provided by an auxiliary structure made of more conductive material. However, the homogeneity of the radiation intensity can be improved by the multi-layer design (stacking).

The maximum luminous efficiency for OLEDs is today approximately 100 lm/W – i.e. still significantly below that of LEDs. However, the service life must also be noted; this decreases with higher operating current – and consequently higher light output.

Laser LED



New lighting systems increasingly use laser LEDs – semiconductor-based laser light sources. These are small spotlights with very high luminance (a factor of approximately 4 compared with LEDs). It is to be noted here that the initially generated blue laser beam ($\lambda \approx 450$ nm) does not leave the headlamp, but is converted with the aid of luminescent materials (ceramic high-power materials) into visible white light with a color temperature of around 5,500 K. A light cone with a very high range (up to 600 m) can then be achieved with very small optical lenses. This makes possible small headlamps with high light output. The performance of a laser LED is decisively influenced by the properties of these luminescent materials and their optical properties. Hybrid light concepts are frequently used at present so that LEDs and laser LEDs are used for the driving lights and for the high-beam lights respectively.

Bipolar transistors

Two contiguous *pn* junctions produce the transistor effect, a feature employed in the design of components used to amplify electrical signals and to assume switching duties. Bipolar transistors consist of three zones of varying conductivity, the configuration being either *pnp* or *npn*. The zones (and their terminals) are called emitter E, base B, and collector C (Figure 4).

There are different transistor classifications, depending on the fields of application: small-signal transistors (power dissipation up to 1 watt), power transistors, switching transistors, low-frequency transistors, high-frequency transistors, microwave transistors, and phototransistors. They are termed bipolar because charge carriers of both polarities (holes and electrons) are involved in the transistor effect.

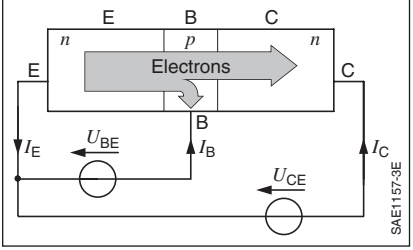
I_C Collector current,
I_E Emitter current.



Operation of a bipolar transistor

The operation of a bipolar transistor is explained here using an *npn* transistor as the example (Figure 5). The *pnp* transistor is obtained similarly by switching the *n*- and *p*-doped zones. The base-emitter junction is forward-biased; this is shown in Figure 4b as a diode between base B and emitter E. In this way, with sufficient voltage U_{BE}, electrons are injected into the base zone and base current flows.

The base-collector junction is reverse-biased; this is shown in Figure 4b as a diode between base B and collector C. This creates a space-charge region at the *pn* junction between base and collector with a high electric field.

Because of the reverse-biased diode between the base and the emitter, a high current consisting of electrons flows from the emitter to the base. Here, however, only a small fraction can recombine with the (much fewer) holes and flow as base current I_B out of the base terminal; what must be borne in mind is that the technical current direction – i.e. the direction of motion of the positive charge carriers – is specified in Figure 4. The much greater amount of electrons injected into the base diffuses through the base zone to the base-collector junction and then flows as collector current I_C to the collector (Figure 5). Because the base-collector diode

Figure 5: Operation of an *npn* transistor
E Emitter,

U_{BE} Base-emitter voltage,
U_{CE} Collector-emitter voltage,
I_B Base current,
I_C Collector current,
I_E Emitter current.

is operated in the reverse direction and a space-charge region is predominant, virtually all (approximately 99 %) of the electrons flowing from the emitter are "drawn off" through the strong electric field in the space-charge region from the collector. In this case, a linear connection applies approximately between the collector current I_C and the base current I_B:

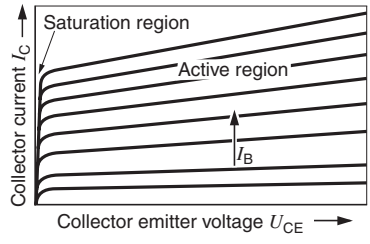
$$I_C = B\, I_B$$

where B is the current gain, which is generally between 100 and 800. In the bipolar transistor, the following relation for the emitter current I_E also applies (cf. Figure 4 and Figure 5):

$$I_E = I_B + I_C\,.$$

Assuming that I_B on account of the current gain B is much smaller than I_C, it then follows:

$$I_E \approx I_C\,.$$



The very thin (and relatively low-doped) base represents a barrier that can be adjusted by means of the base-emitter voltage U_{BE} from the charge-carrier flow from the emitter to the collector. With a small change of U_{BE} and the base current I_B, it is possible to control a greater change of the collector current I_C and the collector-emitter voltage U_{CE}. Small changes in the base current I_B thus bring about large changes in the emitter-collector current I_C. The *npn* transistor is a bipolar, current-controlled semiconductor amplifier. In all, there is a power amplification.

The output characteristic curve for an *npn* transistor is shown in Figure 6. From the saturation voltage of approximately 0.2 V for U_{CE}, the collector current I_C is virtually only dependent on the base current I_B as the parameter; this region is termed the "active region": U_{CE} here has virtually no influence on I_C and the following applies:

$$I_C = B\, I_B.$$

The region below the saturation voltage is called the "saturation region". In this region, I_C increases sharply with U_{CE}.

Figure 6: Output characteristic curve of an *npn* transistor
U_{CE} Collector-emitter voltage,
I_C Collector current,
I_B Base current as parameter of characteristic curve.

Darlington transistor

The Darlington arrangement of two bipolar transistors is often used to achieve a higher current amplification; the interconnection of the two transistors is also called a Darlington transistor (Figure 7). Transistor T_1 (as emitter follower) switches transistor T_2 so that in total a very high current amplification β (up to 50,000) is achieved as the product of the two current amplifications of the two transistors T_1 and T_2: $\beta = \beta_1 \cdot \beta_2$ ($\approx I_{C2}/I_{B1}$). Compared with power bipolar transistors ($\beta \approx 5\ldots10$), the current amplification is much higher and consequently the control current is much lower.

Darlington transistors are used when a voltage (which is not to be subjected to load) connects as high a load as possible (i.e. current). On account of the phase displacement between the input (control current I_{B1} to the base of T_1) and the output (collector current I_{C2} in T_2), the Darlington transistor is only suitable for relatively low frequencies – this circuit is therefore not used in high-frequency circuits. The main reason for this is the time required for the switching of T_2 through the removal of the excess charges in the base of T_2 via resistance R; if R is selected as too small, the total current amplification β is reduced.

Another drawback is the voltage at the input of 1.2…1.4 V, which is twice as high compared with simple bipolar transistors. The forward voltage U_{CE2} at T_2 increases by U_{BE2} to approximately 0.9 V (compared with the saturation voltage of 0.2 V for simple bipolar transistors – here U_{CE1}) or approximately 2 V for power types. As a result the losses are increased (proportionally $U_{CE2} \cdot I_{C2}$).

Diode D_3 is a free-wheeling diode for inductive loads in order to avoid high voltages between the emitter and collector of T_2.

IGBT

The insulated-gate bipolar transistor (IGBT) is an important switching element in the middle power range for currents up to 3 kA and voltages up to 3 kV. The IGBT is characterized by relatively low switching power losses and high efficiency.

The IGBT combines the advantages of a MOSFET (T_1 in Figure 8, see Field-effect transistors) with low-power, voltage-controlled activation and of a power bipolar transistor T_2 with a relatively low forward voltage at the output: In Figure 8 voltage U_{GE} is used at the MOS transistor T_1 to switch on the *pnp* bipolar transistor T_2, which then directs the output current I_C with relatively low forward voltage U_{CE}; the saturation voltage U_{CESAT} is in the range of 2…3 V.

Due to the curved decay of the current during switch-off on account of the light doping, the switching frequency is limited – as a rule 20 kHz to max. 100 kHz for smaller power levels.

Field-effect transistors

In a field-effect transistor (FET), control of the current flow in a conductive path is essentially exercised by an electric field. The field, in turn, is generated by a voltage applied at a gate (Figure 9). Field-effect transistors differ from their bipolar counterparts in that they utilize only a single type of charge carrier (either electrons or holes), giving rise to the alternate designation "unipolar transistors". These are subdivided into the following categorizations: junction-gate field-effect transistors (junction FET, JFET) and insulated-gate field-effect transistors, particularly MOS field-effect transistors (MOSFET or MOS transistors).

MOS field-effect transistors are well suited for application in high-integration circuits. Power field-effect transistors represent a genuine alternative to bipolar power transistors in many applications.

The advantages of a bipolar transistor and of a field-effect transistor are utilized in power electronics in "insulated-gate bipolar transistors" (IGBT), which exhibit a low volume resistance (for small losses) and comparatively low triggering power.

Operation of a junction FET
The operation of a junction-gate field-effect transistor is explained by reference to the n channel type (Figure 9). The terminals of a field-effect transistor are referred to as gate (G), source (S) and drain (D).

Positive direct voltage U_{DS} is applied at the ends of an n-type crystal. Electrons flow through the channel from the source to the drain. The width of the channel is defined by two laterally diffused p-type zones and by the negative gate-source voltage U_{GS} applied at them. The voltage U_{GS} between the control electrode (gate G) and the source terminal thus controls the current I_D between the source and the drain.

Only charge carriers of one polarity are required for field-effect transistor operation. The power necessary for controlling the current is virtually nil. Thus, the junction FET is a unipolar, voltage-controlled component. Increasing U_{GS} causes the space-charge regions to extend further into the channels, thereby constricting the channel and thus the current path (see dashed lines in Figure 9). If the voltage U_{GS} at the gate is zero, the channel between the two p-type zones is not constricted and the current I_D from the drain to the source is at its maximum.

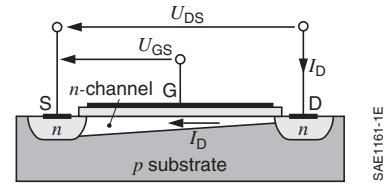
U_{GS} Gate-source voltage,
I_D Drain current.



The transfer characteristic curve – i.e. I_D as a function of U_{GS} – then looks exactly the same as the characteristic curve of a self-conducting n-channel MOSFET as shown in Figure 11c.

Operation of an MOS transistor
The operation of an MOS transistor (metal-oxide semiconductor) is explained by reference to the self-blocking n-channel MOSFET (enhancement type) (Figure 10). If no voltage is applied to the gate, then no current will flow between the source and the drain: the pn junctions remain in blocking mode. The application of a positive voltage at the gate causes, on account of the electrostatic induction in the p-type zone below this gate, the holes to be displaced toward the interior of the crystal and electrons – which are always present in p-type silicon as minority charge carriers – to be pulled to the surface. A narrow n-type layer, an n channel, forms below the surface. Current can now flow between the two n-type zones (source and drain). This current consists exclusively of electrons. As the gate voltage acts through an insulating oxide layer, no stationary current flows through the gate; no power is required for the control function. It is required merely to activate and deactivate electrical power in order to recharge the gate capacity. In summary, the MOS transistor is a unipolar, voltage-controlled component.

In the case of the self-conducting n-channel MOSFET (depletion type, Figure 11a), the gate-source voltage U_{GS}

Figure 10: *n*-channel MOSFET, cross-section
S Source, G Gate, D Drain.
U_{DS} Drain-source voltage,
U_{GS} Gate-source voltage,
I_D Drain current.

is between the here negative threshold voltage U_T and zero volts (Figure 11c). At U_{GS} = 0 V, the self-conducting n-channel MOSFET has a channel below the gates for the current flow. Figure 11c shows I_D as a function of U_{GS}, where the circuit is operated in the active region with sufficient and constant U_{DS}. The transfer characteristic curve is a parabola. In contrast, the self-blocking n-channel MOSFET (Figure 11b) conducts only from the positive threshold voltage U_T^* > 0 V here (see Figure 11c). The self-blocking MOSFET is much more common that the self-conducting MOSFET.

The output characteristic curve of a self-blocking n-channel MOSFET is shown in Figure 12. The region below the knee-point voltage U_K, i.e. for $U_{DS} < U_K$ is referred to, on account of the linear characteristic curve, as the linear or ohmic region; here the MOSFET behaves like an ohmic resistance. Above the knee-point voltage U_K, i.e. for $U_{DS} > U_K$, the output current I_D is virtually uninfluenced by the drain-source voltage U_{DS}; this region is known as the cut-off region. The amount of I_D is dependent only on the gate-source voltage U_{GS}. The formula is:

$$I_D = 0.5\, K\, (U_{GS} - U_T)^2$$

where K is the proportionality number (dependent among others on technological quantities) and U_T the threshold voltage from which the transistor conducts, i.e. a channel forms (see Figure 11c).

PMOS, NMOS, CMOS transistors

As well as the n-channel MOSFET (NMOS transistor), mixing the doping produces the PMOS transistor. As the electrons in the NMOS transistor are more mobile, it operates more rapidly than the PMOS device, although the latter was the first to become available due to the fact that it is physically easier to manufacture.

It is also possible to employ complementary MOS technology to pair PMOS and NMOS transistors in a single silicon chip; the resulting devices are called complementary MOS transistors (CMOS transistors, Figure 13). The specific advantages of the CMOS transistor are extremely low power dissipation, a high degree of immunity to interference, relative insensitivity to varying supply voltages, and suitability for analog signal processing and high-integration applications [2].

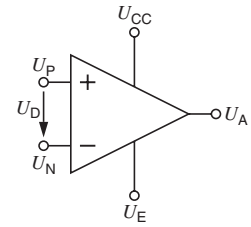
BCD hybrid technology
Integrated structures for power-electronics applications are becoming increasingly important. Such structures are realized by combining bipolar and MOS components on a single silicon chip, thereby utilizing the advantages of both technologies. BCD hybrid technology is a significant manufacturing process in automotive electronics and also facilitates the manufacture of MOS power components (DMOS). This technology is a combination of bipolar, CMOS and DMOS technologies [2].

Operational amplifiers
Areas of application of operational amplifiers
The name "operational amplifier" (OPA) comes from analog computing technology and denotes an (almost) ideal amplifier. Because of its properties, it was used particularly in analog computers to solve nonlinear differential equations, i.e. as a summator, integrator and differentiator. The rapid development of digital electronics saw analog computers being increasingly driven from the market with the result that today analog computers do not play a role at all.

By integrating them in microelectronic circuits, it is today possible to offer such operational amplifiers at a very economical price on the market so that many amplifier applications can be put into effect. To achieve the desired properties, operational amplifiers in their integrated form contain some (depending on the requirement 10 to 250) transistors, the number of which however is only of subordinate importance with regard to integration.

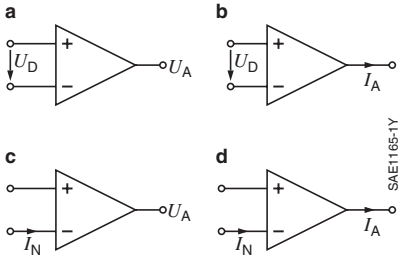
Figure 13: CMOS inverter composed from PMOS and NMOS technology



Starting out from a "normal" operational amplifier with voltage input and voltage output (VV operational amplifier), first the behavior of an ideal operational amplifier will be described and its use demonstrated. Then the real – i.e. actual – properties will be examined in more detail and its effect to be realized on the circuit analyzed.

Basic principles
The ideal standard operational amplifier is an amplifier with two inputs and (normally) one output (Figure 14). The inputs are the non-inverting input and the inverting input. The differential voltage U_D is amplified and then made available at the output as the output voltage U_A. The following formula applies:

$$U_A = A_D\, U_D.$$



A_D is the open-loop gain. The operational amplifier is connected to a positive supply voltage and to a negative supply voltage with regard to the frame potential. In the case of a unipolar supply, the negative supply voltage can be applied to the frame potential. The supply voltages are not usually indicated in many circuit diagrams. They are however very much needed in order to guarantee the energy supply to the operational amplifier.

U_D Differential voltage between the two input potentials U_P and U_N where $U_D = U_P - U_N$,
U_A Output voltage,
U_{CC} positive supply voltage,
U_E negative supply voltage.

The following variants of the operational amplifier are common (Figure 15):
– "Normal" operational amplifier (VV operational amplifier) with voltage inputs and voltage output.
– Transconductance amplifier (VC operational amplifier) with voltage inputs and current output.
– Transimpedance amplifier (CV operational amplifier) with current inputs and voltage output.
– Current amplifier (CC operational amplifier) with current inputs and current output.

Figure 15: Operational-amplifier types (diagram)
a) Normal operational amplifier (VV) with voltage input and voltage output.
b) Transconductance amplifier (VC) with voltage input and current output.
c) Transimpedance amplifier (CV) with current input and voltage output.
d) Current amplifier (CC) with current input and current output.

As a rule, the VV operational amplifier is used; this will now be explained in more detail in the following. Because the circuit arrangement is of crucial importance to the function of an operational amplifier, this will be addressed in more detail first. The distinction between positive feedback and negative feedback is important here. Furthermore, an ideal operational amplifier will be assumed when deriving the correlations.

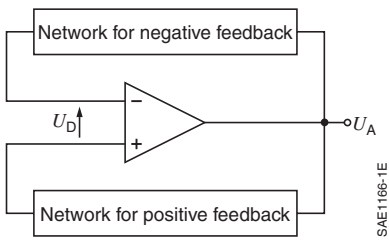
Circuit arrangement: negative and positive feedback

Negative feedback counteracts the cause. In the operational amplifier, a connection is required from the output to the inverting input for this purpose (Figure 16). This connection can be implemented by a network. The cause of a change in the output voltage U_A is always a change in the differential voltage U_D at the input; negative feedback therefore always acts in such a way that the voltage U_D becomes small and ideally zero.

Positive feedback, in contrast to negative feedback, supports the cause of the change at the output. U_A is thus amplified by positive feedback, i.e. U_D increases as U_A changes and is therefore always not equal to zero. In this way, the output voltage U_A can assume only two stationary values, namely the maximum value or the minimum value.

From a control-engineering standpoint, a negative feedback results from the operational amplifier and the feedback as shown in Figure 17. Taking a high gain A_D into consideration, it follows:

Figure 16: Negative and positive feedback
U_D Differential voltage,
U_A Output voltage.



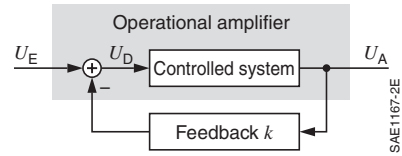


Figure 17: Negative feedback
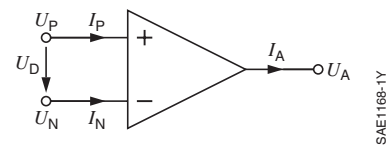
U_E Input voltage as setpoint value,
U_A Output voltage,
U_D Differential voltage is obtained at the summing point $\oplus$ $U_D = U_E - k\,U_A$.
Controlled system with gain A_D,
Feedback with gain k.

$U_A = A_D U_D = A_D (U_E - k U_A)$

and for the total gain

$$A = \frac{U_A}{U_E} = \frac{A_D}{1 + k A_D} \approx \frac{1}{k} .$$



It thus becomes clear that, in spite of a very high open-loop gain A_D on the part of the operational amplifier, with the aid of negative feedback a finite gain A can be set with the negative-feedback network. This is explained below in greater detail using examples.

Ideal and real operational amplifier
First, the properties of an ideal operational amplifier as shown in Figure 18 will be summarized. For further information, see [1].
- Common-mode input resistance between, in each case, one input and ground, where: $r_{GL_P} = U_P/I_P$; $r_{GL_N} = U_N/I_N$. Generally speaking, r_{GL} can be ignored.
- Differential input resistance between the two inputs; here: $r_D = (U_P - U_N)/I_P$. r_D is increased by negative feedback.
- Output resistance, differential quantity $r_A = dU_A/dI_A$. r_A is decreased by negative feedback.
- Offset voltage U_{OS}: Characteristic quantity for describing the fact that even in the event of a short circuit between the two inputs (i.e. $U_D = 0$) the output voltage U_A is not equal to zero.
- Common-mode rejection ratio (CMRR): This quantity describes the change in the output voltage U_A if the two input voltages U_P and U_N change simultaneously (in the case of periodic input signals co-phasally), i.e. U_D remains constant.
- Power-supply rejection ratio (PSRR): Change in the output voltage U_A on account of a change in the supply voltages.

The essential idealizations are:
- The open-loop gain A_D approaches infinity; in the case of negative feedback the following applies: $U_D = 0$.
- The input currents I_N and I_P each approach zero.
- If I_N and I_P each approach zero, it follows that the common-mode and differential input resistances approach infinity.
- The offset voltage U_{OS} approaches zero.
- The output resistance R_A approaches zero.
- The common-mode rejection ratio (CMRR) approaches infinity, i.e. in the case of an equal and co-phasal change in the voltages U_P and U_N, U_A remains unchanged.
- The power-supply rejection ratio (PSRR) approaches infinity, i.e. in the case of a change in the supply voltage, U_A does not change.
- The behavior is not dependent on the frequency.

In reality, the above-mentioned idealizations do not apply entirely:
- The open-loop gain A_D is in the range of 10^4 to 10^7.
- The input currents I_N and I_P are in the range of 10 pA to 2 µA.
- The common-mode input resistance is in the range of 10^6 to 10^{12} Ω, the differential input resistance at up to 10^{12} Ω.
- The output resistance R_A is in the range of 50 Ω to 2 kΩ.
- The common-mode rejection ratio (CMRR) is in the range of 60 to 140 dB.
- The power-supply rejection ratio (PSRR) is in the range of 60 to 100 dB.
- The behavior is dependent on the frequency (low-pass behavior).

Basic circuits
The external circuit arrangement of an operational amplifier determines the behavior of the entire circuit. Here, negative feedback plays the dominant role, since it enables the gain to be set exactly through the choice of resistances. The function shall now be explained by reference to several examples.

Inverting amplifier
The basic circuit for an inverting amplifier is shown in Figure 19. The name can be attributed to the negative gain, i.e. in the case of a periodic input voltage, the output voltage U_A is always in phase opposition to the input voltage U_1. In the following, it is important that, on account of the negative feedback and the high open-loop gain A_D, the differential voltage U_D at the input be constantly zero, since the non-inverting and inverting inputs are kept at the same potential. Since, on account of the negative feedback, the differential voltage U_D is regulated to zero, this is referred to as a "virtual short circuit". "Virtual ground" is also referred to here, as the inverting input is actively kept at zero (i.e. at frame potential). In addition, the input currents are ignored, in particular $I_N = 0$ is set. The following applies:

$$I_{R1} = \frac{U_1}{R_1} \text{ and } I_{R2} = -\frac{U_A}{R_2}.$$

Where $I_{R1} = I_{R2}$ it then follows:

$$U_A = -\frac{R_2}{R_1} U_1 .$$

The output voltage U_A is thus directly dependent on the input voltage U_1 and on the choice of resistances R_2 and R_1.

Non-inverting amplifier
The non-inverting amplifier can be handled along similar lines to the inverting amplifier (Figure 20). Due to negative feedback, $U_D = 0$. Where $I_{R1} = I_{R2}$, it is possible in accordance with the voltage divider – consisting of R_1 and R_2 – to calculate the voltage.

$$U_1 = \frac{R_1}{R_1 + R_2} U_A .$$

This means that

$$U_A = \frac{R_1 + R_2}{R_1} U_1 = \left(1 + \frac{R_2}{R_1}\right) U_1 .$$

The output voltage U_A is here also directly dependent on the input voltage U_1 and the choice of resistances R_2 and R_1; however, here the gain U_A/U_1 has at least the value one; U_A and U_1 are in phase.

A special case of the non-inverting amplifier is the isolation amplifier or impedance transformer. If R_1 assumes an infinitely high value (open loop) and R_2 is set equal to zero (short circuit) (Figure 21), then the gain is equal to one (i.e. $U_A = U_1$).

The advantage of this circuit is the property to the effect that the input-voltage source U_1 is not loaded with the internal resistance R_E, as the input current I_P is approximately equal to zero. This results in a negligible voltage drop over R_E and because $U_D = 0$, the input voltage U_1 is available at the output of the operational amplifier as U_A. This is important particularly for conditioning sensor signals, as here the sensor output voltage may not be loaded in many cases, i.e. any current flow from the sensor element can reduce the tappable voltage significantly.

Subtracting amplifier

The subtracting amplifier (Figure 22) can be considered as a common variant of the two previously mentioned circuits. On account of the superposition theorem (superposition principle), the relationship between the output voltage U_A and the input voltages U_1 and U_2 can be derived.

$$U_A = \frac{R_2}{R_1}(U_2 - U_1) .$$

Instrument amplifier

Particularly in sensor systems, differential voltages must often be picked off at bridge circuits and amplified without the sensor voltage or the bridge voltage being subjected to an unacceptably high load. This can be implemented by means of a high-resistance voltage tap. An instrument amplifier, which outputs the difference between two potentials U_2 and U_1 as amplified output voltage U_A, can be used for this purpose. The instrument amplifier can be subdivided into two parts: the pre-amplifier and a subtracting amplifier (Figure 22) with further amplification. Figure 23 shows the basic input circuit for the pre-amplification of an instrument amplifier.

According to the rule of negative feedback, the potential difference between the inverting and non-inverting inputs is equal to zero. In each case, the current I can flow through the resistors R and R', as the input currents I_{N1} and I_{N2} can be ignored. The following applies:

$$I = \frac{U_1 - U_2}{R'} = \frac{U_{A1} - U_{A2}}{2R + R'}, \text{ thus}$$

$$U_{A1} - U_{A2} = (U_1 - U_2)\left(\frac{2R}{R'} + 1\right).$$

Figure 21: Impedance transformer or isolation amplifier

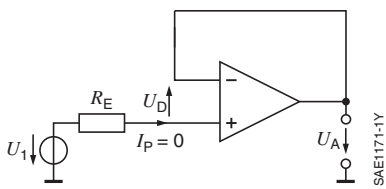
I_P Input current.



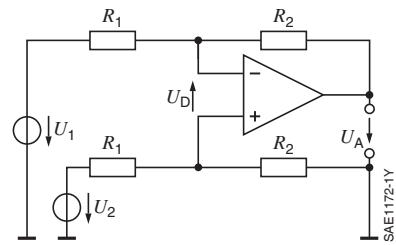


Figure 22: Subtracting amplifier

U_1, U_2 Input voltages,
U_D Differential voltage,
U_A Output voltage,
R_1, R_2 Network resistances.

In this way, the amplified difference between the two voltages U_1 and U_2 is obtained as the potential difference U_D between the two outputs of the two operational amplifiers. In order to output this voltage U_D as an output voltage referred to ground U_A, a subtracting amplifier can be connected in series (Figure 22), where U_{A1} instead of U_1 and U_{A2} instead of U_2 are supplied.

Important characteristic data
For many applications, the operational amplifiers must demonstrate properties which partly contradict each other. There are a large number of operational amplifiers, which are optimized for different fields of application. Basically, the data for specific operating points or operating ranges are specified.

Temperature range
In the field of consumer electronics, a temperature range of between 0 °C and 70 °C is customary. For the extended industrial field, a temperature range of between –20 °C and +70 °C is often specified; this range is required above all for devices which are used outside buildings. For military applications, a temperature range of –55 °C to +125 °C is specified. These demands do not, however, cover all the requirements for use in motor vehicles; for example, even higher temperatures occur in the engine compartment or in brake systems.

Offset voltage
The characteristic quantity for describing the fact that, even in the event of a short circuit between the two inputs (i.e. for $U_D = 0$), the output voltage U_A is not equal to zero is termed the offset voltage U_{OS}. This thus acts like a voltage applied from an external source U_D and is added to this. The offset voltage U_{OS} can, for example, be determined by the fact that at the input that voltage which sets the output voltage U_A equal to zero is determined (Figure 24). The offset voltage U_{OS} stems, among other things, from asymmetries in the internal circuit arrangement of the two inputs and is typically in the range of a few µV to a few mV.

However, as well as the value of the offset voltage U_{OS}, the temperature effect and long-term stability are also highly important. Some operational amplifiers offer the possibility of compensating the offset voltage by means of an external circuit arrangement – provided this is not already effected by internal circuit-engineering measures. It is important in this connection that the input voltage can also drift on account of the temperature effect; thus soldered junctions can represent thermocouples with a voltage of a magnitude of 10 to 100 µV/K.

Input resistances and currents
On account of the, as a rule, very low input currents I_N and I_P, very high input resistances, which are sometimes in the high megaohm range, are accordingly obtained. A distinction is made here between the common-mode input resistance (resistance between an input in each case and ground) and the differential input resistance between the two inputs.

The inputs of customary operational amplifiers form transistors; either bipolar transistors in which the base in each case is activated or MOS field-effect transistors in which the gate is recharged. The small input currents are explained in this way. When bipolar transistors are used, these are base currents and are in the range of μA. When MOSFET are used, the corresponding gate currents are obtained which are required to recharge the associated gate capacity. The latter are proportional to the operating frequency and are usually in the range of pA.

The input bias current can cause an input-voltage error in high-resistance circuits. This can be compensated for by connecting identical impedances to the two inputs, as then in each case the same voltage drops and the differential voltage U_D remains unaffected. Like the offset voltage, the input current can also drift over the temperature and the time.

Output resistance
The output of the operational amplifier can be described by a series connection of an ideal voltage source and a resistance; the latter is then the output resistance R_A. This resistance limits the output current. In general, operational amplifiers can drive output currents of 20 mA; there are also types with an output current of up to 10 A.

Slew rate
The slew rate (SR) denotes the maximum possible change in the output voltage U_A per period of time, i.e. the maximum value for dU_A/dt. The values for the slew rate for conventional operational amplifiers are in the range of less than 1 V/μs to more than 1 V/ns.

Noise
Noise can be described by specifying the noise-voltage density or the noise-current density. Usually the noise-voltage density U_R' is given in nV/$\sqrt{\text{Hz}}$.

The effective value of the noise voltage U_R (this also applies to the noise current) is obtained from the respective key figure multiplied by the root of the bandwidth B being considered:

$$U_R = U_R' \sqrt{B} \ .$$

For an amplifier circuit, the total effective noise-voltage density is obtained as the root of the sum of the squares of the effective values.

$$U'_{R,tot} = \sqrt{(U_{R,1})^2 + \text{to } (U_{R,m})^2} \ .$$

m here denotes the number of noise terms.

The noise is determined predominantly at the input of the operational amplifier. If JFET or MOSFET are used, low current but comparatively high voltage noise is obtained. The behavior is reversed in operational amplifiers which are based on bipolar transistors (see [1] and [4]).

Push-pull drivers

Operational amplifiers usually exhibit a maximum output current of approximately 20 mA. If a larger current is needed for example to activate power components or actuators (e.g. DC electric motors), this can be achieved with a driver stage – stages of this kind are also know as push-pull circuits, push-pull stages, or push-pull drivers. It is important in this connection that in some cases a large current I_{load} flows through the load (ohmic resistance R_{load}, Figure 25) in both directions. This is made possible by the use of two power transistors (in Figure 25 T_1 as *npn* and T_2 as *pnp* transistor); MOSFETs can also be used instead of bipolar transistors.

Because of the negative feedback the output voltage U_{OUT} is always equal to U_{IN} (Figure 26) and consequently for an ohmic load the output current I_{load} follows the input voltage U_{IN}.

The two transistors T_1 and T_2 in Figure 25 are activated in such a way that they never conduct simultaneously (push-pull operation) because this could lead to a short-circuit of the supply voltages $+U_V$ and $-U_V$. Since when the current I_{LOAD} is reversed through the load resistance R_{LOAD} first one transistor and then immediately afterwards the other transistor must conduct, this results in the voltage U_{OPV_out} in the circuit according to Figure 25 jumping abruptly from for example –0.7 V to +0.7 V, as shown in Figure 26. This can give rise to problems in applications with high dynamic response.

Push-pull circuits are frequently also used in driver circuits for IGBTs (insulated-gate bipolar transistors); a positive voltage (frequently +15 V) and a negative voltage (frequently –15 V) are made available here for the activation of IGBTs. The driver output stage is as a rule supplied with a metallically separated voltage via an insulated DC/DC converter. In addition, the driver circuit takes on various protective functions such as overcurrent detection or even interlocking logic.

Monolithic integrated circuits

Monolithic integration
In monolithic integrated circuits (IC), components are assembled on a single piece of monocrystalline silicon (substrate). Semiconductor processes are used for creating layers (e.g. epitaxy), removing layers and changing material properties (e.g. doping). This technology enables complex circuits to be housed in the smallest of spaces.

Planar technology is based on the oxidation of silicon wafers, which is a relatively simple process, and the speed at which the dopants penetrate into silicon, which is exponentially greater than the speed at which they enter the oxide. Doping only occurs at locations where openings are present in the oxide layer. The specific design requirements of an individual integrated circuit determine the precise geometric configuration, which is applied to the wafer in a photolithographic process. All processing procedures (oxidizing, etching, doping, and depositing) progress consecutively from the surface plane (planar).

Planar technology makes it possible to manufacture all circuit components (e.g. resistors, capacitors, diodes, transistors) and the associated conductor strips on a single silicon chip in a unified manufacturing process. Monolithic integrated circuits are built from semiconductor components.

This integration generally comprises a subsystem within the electronic circuit and increasingly comprises the entire system (a system on a chip).

Because of the ever-increasing component density (integration density), the third dimension, i.e. the plane vertical to the surface, is also increasingly being utilized in the design. In this way, particularly in the field of power electronics, advantages such as lower resistances, smaller losses and thus also higher current densities can be achieved.

Integration level
The integration level is a measure of the number of function elements per chip. The following technologies relate to the level of integration (and chip surface):

- SSI (Small Scale Integration) with up to several hundred function elements per chip and a mean chip surface area of 1 mm^2. But the chip surface area can be very much larger in circuits with high power outputs (e.g. smart power transistors).
- MSI (Medium Scale Integration) with a several hundred to 10,000 function elements per chip and a mean chip surface area of 8 mm^2.
- LSI (Large Scale Integration) with up to 100,000 function elements per chip and a mean chip surface area of 20 mm^2.
- VLSI (Very Large Scale Integration) with up to 1 million function elements per chip and a mean chip surface area of 30 mm^2.
- ULSI (Ultra Large Scale Integration) with over 1 million function elements per chip (flash memory today contains up to 20 billion transistors per chip), a surface area of up to 300 mm^2 and the smallest structure sizes of less than 30 nm.

Computer-aided simulation and design methods (CAE and CAD) are essential elements in the manufacture of integrated circuits. Entire function modules are used in VLSI and ULSI, otherwise the time expenditure and failure risk would make development impossible. In addition, simulation programs are used to detect any defects made.

Basic principles of electrical machines

Energy conversion

Electric machines are electro-magneto-mechanical energy converters in motor and generator operation. The supplied electrical energy W_{el}

$$W_{el} = W_m + W_v$$

is converted into magnetic energy W_m and lost energy W_v where

$$W_m = \int_0^{t_0} u_l i_l dt \quad \text{and} \quad W_v = \int_0^{t_0} i_l^2 R\, dt.$$

Where $u_l = d\Psi/dt$ the magnetic energy follows by means of integration

$$W_m = \int_0^{\Psi_0} i_l(\delta, \Psi)\, d\Psi.$$

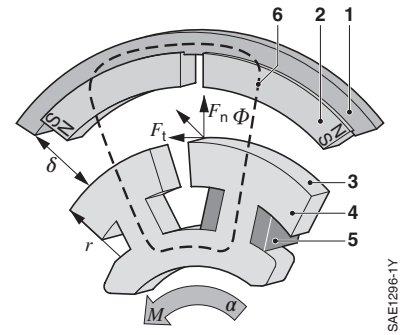
Here δ is the air gap in the magnetic circuit, Ψ the magnetic flux interlinked with all the turns of a winding, and Ψ_0 the maximum occurring interlinked magnetic flux. In Figure 1 for example the energy W_m is accumulated in the space $V = A_z \delta$ above the tooth surface permeated by the flux Φ. Through discharging of the magnetic energy to a space coordinate Ω the magnetic force F_m follows

$$F_m = \frac{\partial W}{\partial \Omega}$$

in the direction of the space coordinate as a force on the boundary layer for the generation of motion. If, for example, the magnetic energy is discharged to a circumferential coordinate, this results in a magnetic force in the circumferential direction which through multiplication by radius r causes the torque $M = F_m r$. If the magnetomechanical energy conversion is effected through discharging of the magnetic energy to an angular coordinate α, torque M follows:

$$M = \frac{\partial W}{\partial \alpha}.$$

The section of a permanent-magnet motor is shown in Figure 1. The stator consists of the magnetic yoke and the permanent magnet. The rotor is formed by the rotor-tooth surface A_z, the rotor tooth, and the winding, which is permeated by the magnetic flux and causes a torque-producing reluctance force (tangential force F_t) at the tooth surface. The normal force F_n acting on the tooth surface counterbalances together with the normal force of the opposite tooth on the shaft.



With regard to forces, a distinction is made between the following:
– magnetic force which acts on a boundary layer consisting of air and iron,
– Lorentz force on moving charge carriers in the magnetic field.

Application examples for the first case are commutator machines and switched reluctance motors. Application examples for the second case are commutator machines with ironless rotors and commutator disk-rotor machines.

For further references, see [1] and [2].

Systematics of rotating electric machines

The energization of the windings of electric machines determines their properties. A distinction is made between self-commutated (position-commutated, field-commutated) and externally commutated (line-commutated, frequency-commutated) motors.

The first group includes DC motors in which cyclic activation of the winding phases in the rotor is effected on a self-regulated basis via the mechanical (or electronic) commutator. Magnetic excitation is effected either with an electromagnet (DC and AC operation of the motor possible) or by means of permanent magnets (only DC operation of the motor possible).

In externally commutated motors (e.g. asynchronous motor) the phases are switched by the supply system or the control electronics. Table 1 shows a systematization of electric motors with regard to their commutation performance. DIN 42027 [3] sets out motor systematics with regard to power supply.

Definitions of geometric quantities

Figure 2 depicts a 4-pole (number of pole pairs $p = 2$) machine cross-section. The quantities are named in part by DIN EN 60027-4 [4]. This standard gives names and letter symbols for quantities and units.

A pole pair consists in each case of a north pole and a south pole. The magnetic flux that is set emerges from the north pole through the rotor via the air gap into the south pole.

Table 1: Systematics of electric motors

Self-commutated machines			Externally commutated motors	
Mechanical commutator		Electronic commutator	Load-dependent rotational speed	Frequency-dependent rotational speed
AC motors	DC motors	Electronically commutated motors (EC motors)	Asynchronous motors	Synchronous motors
Commutator motors, universal motors	Series-wound, shunt-wound motors	Block-, sinusoidally commutated motors	Rotating-field motors, cage motors	Rotating-field motors

Direct-current machines

In direct-current machines motor operation is frequently preferred to generator operation. These are used for example as drives for electric fuel pumps, fans, starters, windshield wipers, and power-window units. Figure 3a shows a two-pole motor and Figure 3b a four-pole motor. In higher-pole motors a number of shorter magnetic circuits are generated which facilitate greater utilization of the magnet volume. The motors consist of the magnetic yoke, the poles, copper segment, inlet brush, winding phase, and outlet brush, through which the armature current I_A passes which in turn is split into the branch-circuit currents I_Z.

Figure 3: DC machines

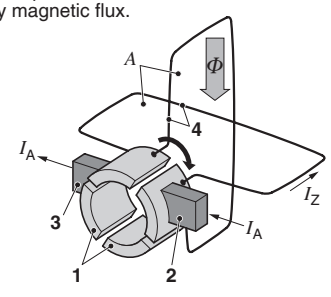
1 Magnetic yoke, 2 Pole,
3 Copper segment, 4 Inlet brush,
5 Winding phase, 6 Outlet brush.
I_A Armature current, I_Z Branch-circuit current.
NZ Neutral zone.

Direct-current machines with excitation by electromagnets are classified according to their winding behavior. In a series-wound motor the armature and excitation windings are connected in series. In a shunt-wound motor the armature and excitation windings are connected in parallel. The terminal markings of direct-current machines comply with DIN EN 60034 Part 8 [5] and DIN EN 60617 Part 6 [6].

Commutator voltage

Figure 3 is simplified down to the equivalent motor circuit diagram Figure 4, consisting of commutator and two phases reduced to one turn. The equivalent electric circuit diagram Figure 5 is derived from this. Figures 5a and 5b show motor operation, Figures 5c and 5d show generator operation. The voltage relationships that are obtained can be taken from Table 2.



The induced voltage U_L is according to Faraday's law

$$U_L = \frac{d\Psi(I,\delta)}{dt}. \qquad (1)$$

With the total differential (differentiation of a function according to all its independent variables) of the interlinked, current- and air-gap-dependent magnetic flux Ψ

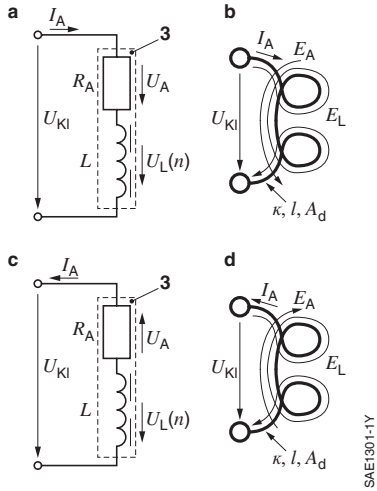
$$d\Psi = \frac{\partial\Psi(I,\delta)}{\partial I}\, dI + \frac{\partial\Psi(I,\delta)}{\partial\delta}\, d\delta \qquad (2)$$

Figure 4: Equivalent motor circuit diagram
1 Copper segment, 2 Inlet brush,
3 Outlet brush, 4 Winding phase.
I_A Armature current, I_Z Branch-circuit current.
Φ Magnetic flux,
A Area permeated by magnetic flux.

the induced voltage follows again

$$U_L = \frac{\partial \Psi(I,\delta)}{\partial I}\,\frac{dI}{dt} + \frac{\partial \Psi(I,\delta)}{\partial \delta}\,\frac{d\delta}{dt}, \qquad (3)$$

where the first term becomes zero due to DC energization. This leaves the second term of Faraday's law, which is further developed with the number of turns N, the flux Φ, the flux density B, and the area A:



$$U_L = N\frac{\partial \Phi}{\partial \delta}\,\frac{d\delta}{dt} = NB\frac{dA}{dt}. \qquad (4)$$

Table 2: Voltage relationships

Motor operation	Generator operation
$U_{Kl} = U_A + U_L$	$U_{Kl} = U_A - U_L$
$U_{Kl} = E_A l + E_L l$	$U_{Kl} = E_A l - E_L l$
$U_{Kl} = (E_A + E_L)\, l$	$U_{Kl} = (E_A - E_L)\, l$

Figure 5: Equivalent electric circuit diagram for motor and generator operation

κ Specific electric conductivity.

With the replacement of the differential function by a differential function using the period T and taking into account that for the arrangement in Figure 4 with $k = 4$ segments for commutation only $T/4 = T/k$ time remains, the induced voltage follows again

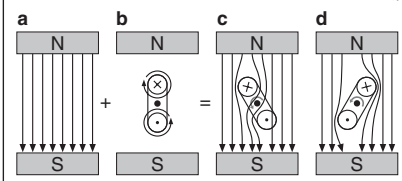
$$U_L = NB\,\frac{A}{\frac{T}{k}} = NBAfk \qquad (5)$$

as a function of the rotational frequency f [s^{-1}]. An extension with 60 and conversion with $c_1 = k \cdot 60$ leads to

$$U_L = \Psi n k \cdot 60 = L I n c_1 = \Psi n c_1 \,(n \text{ in } \text{min}^{-1})$$

and thus to the rotational-speed-proportional induced voltage with which the mesh equation of Figure 5

$$U_{Kl} = R_A I_A \pm \Psi n c_1 \qquad (6)$$



is fulfilled. Here "+" applies to motor operation and "–" to generator operation. n specifies the revolutions per minute.

Commutation

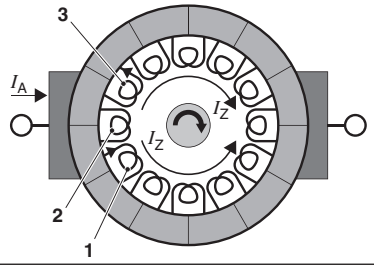
Only the commutator facilitates rotation of the armature and serves to reverse the direction of the current in a winding phase ("commutate" means to change quantities, to transpose with each other, to change the direction of electric current). Commutation is therefore the reversal of the current direction.

Figure 6: Superposition of fields during commutation

a) Undisturbed stator field distribution,
b) Undisturbed armature field distribution,
c) Superposition of field distribution from a and b,
d) Reversal of current direction while maintaining the direction of armature rotation.

The undisturbed stator field distribution is shown in Figure 6a. The undisturbed armature field distribution is drawn in Figure 6b. The two cases are superposed in Figure 6c. This generates a resulting force which allows the armature to rotate to the left. The current direction is reversed by a commutator in Figure 6d while maintaining the direction of armature rotation.

The rotor from Figure 3a is shown enlarged in Figure 7. The armature current I_A is split in each case into branch-circuit currents I_Z. The branch-circuit currents flows into the winding phases of the north and south poles. Beneath the pole faces the current direction in the winding phases is therefore always the same. The current direction changes in each case only in the winding phase to be commutated. The commutation of a winding phase at the inlet brush is given as an example of a commutation. The coils to be commutated are in the neutral zone (NZ). With an accepted right-hand rotation of the rotor the winding phase runs underneath the inlet brush (Figure 7, position 1). Its present current direction is marked with an arrow. In due course the winding phase is short-ed-circuited by the inlet brush (Figure 7, position 2). In position 3 the energization direction of the branch-circuit current was reversed (commutation), which is marked by an arrow.



The time process of commutation within the commutation period T_C can be seen in Figure 8. The start of commutation is marked with t_{CB} and the end of commutation with t_{CE}. The ideal case is complete commutation following the shape of curve 1. Here the effect of the inductive voltages is canceled out by the commutating pole (see following section). The voltage induced by the commutating field is equal to the reactance voltage. Curve shape 2 is called under-commutation. The coil current I decreases from $+I_Z$ only slowly and reaches the current level $-I_Z$ only shortly before the time t_{CE}. The cause of this is an excessively underdimensioned induced commutating-pole voltage.

The opposite to this is curve shape 3, which describes an over-commutation. This is achieved by an excessively high induced commutating-pole voltage.

Basically, the abrupt current change loads the contact system consisting of brush and segment.

The designations have been taken from DIN 1304, Part 7 [7].

Field distribution

The main field that penetrates the rotor without hindrance when no current is present has a symmetrical distribution (Figure 10a). Likewise, there is a symmetrical flux division when current is applied to only the rotor (Figure 10b). If both fields are superpositioned, the neutral zone is deflected by the angle β (Figure 10c). This magnetically neutral zone thus no longer corresponds to the geometrically neutral zone (position of the commutator brushes). In the geometrically neutral zone, this creates a magnetic field through which a voltage is induced during the commutation process in the coil to be commutated, creating brush sparking (break sparks) between the brush and the running commutator lamina. To prevent this, another voltage is induced during commutation in the coil concerned where the amplitude and direction cancel out the effect of the originally induced voltage.

This is achieved by means of the commutating winding (Figure 9). The commutating winding is connected in series to the rotor winding. It uses rotor retroaction to counteract a shift in the magnetically neutral zone. In the case of motors with-

out commutating windings, the brushes have to be shifted into the magnetically neutral zone.

The main field distortion that occurs in the area of the pole shoe leads to a reduction in the available pole surface, combined with an increase in the magnetic resistance. This is why larger machines are given a compensation winding that is integrated in the pole shoes (Figure 9). The compensation winding is connected in series with the rotor winding and its dimensions are such that it compensates for the rotor quadrature-axis field.

Effect of the commutating and compensation winding

The sequence of images in Figure 11 describes the effect of both windings. The field distributions in the air gap are shown. The pole arrangement with winding and the neutral zone can be seen in Figure 11a. The distribution of the excitation field $B_E(x)$ below the pole shoe as well as the pole pitch τ_P are shown in Figure 11b. Figure 11c shows the rotor quadrature-axis field distribution $B_R(x)$. The superposition of both field distributions can be seen in Figure 11d. The compensation induction $B_K(x)$ (Figure 11e) as well as the superposition that took place with Figure 11d are shown in Figure 11f. If the commutating induction $B_W(x)$ in Figure 11g is superposed with the field distribution of Figure 11f, this results in the desired field distribution according to Figure 11h.

Torque and power

The power input (+) or output (–) by the motor at the terminal is

$$P_{el} = P_{th} \pm P_{em} = I_A^2 R_A \pm U_L I_A, \qquad (7)$$

where P_{em} corresponds to the internal power and P_{th} to the thermal power, R_A is the armature resistance, and I_A the armature current. The internal mechanical motor torque M corresponds to

$$M = \frac{P_{em}}{\omega} = \frac{c_1 \Psi n I_A}{2\pi f} = \frac{c_1}{2\pi 60} \Psi I_A. \qquad (8)$$

For operation at constant rotational speed and mechanical load torque M_{mech} the following applies

$$M = M_{mech}.$$

Shunt-wound machine

A feature of the shunt-wound machine is that the rotor winding is connected parallel to the exciter winding. The following terminal markings (Figure 12) as set out in DIN EN 60034-8 [5] apply to the shunt-wound machine:

– A indicates the armature winding,
– B the commutating winding,
– C the compensation winding, and
– E the shunt field winding.

By transposing equation (6) in accordance with the rotational speed n the speed/current equation follows

$$n(I_A) = -\frac{R_A}{c_1 \Psi} I_A + \frac{U_{KI}}{c_1 \Psi} \qquad (9)$$

as a line equation with a negative slope and axis intercepts

$$n_0(I_A = 0) = \frac{U_{KI}}{c_1 \Psi};\ I_{An}(n = 0) = \frac{U_{KI}}{R_A}. \qquad (10)$$

Here n_0 is the idle speed and I_{An} the starting current. Through the conversion of equation (8) in accordance with the current and insertion in equation (9) the speed/torque equation follows as a line equation

$$n(M) = -\frac{R_A c_2}{{c_1}^2 \Psi^2} M + \frac{U_{KI}}{c_1 \Psi},\ c_2 = 2\pi \cdot 60 \qquad (11)$$

The axis intercepts are given with

$$M(n = n_0) = 0,\ M_{An}(n = 0) = \frac{U_{KI}}{R_A} \frac{c_1}{c_2} \Psi \qquad (12)$$

In Figure 13 the speed is shown against the armature current and the motor torque with four quadrants. Here, motor operation differs from generator operation in each case through the direction of rotation and torque. The speed points of the machine can follow by changing the terminal voltage U_{KI} according to equation (9), which brings about a parallel shift of the straight line in Figure 13. A change of the excitation current separate from the armature current permits according to equation (9) a change of the flux Ψ and thus also a speed change. This measure is called field weakening.

The straight-line slope of equation (9) is changed by a series connection of armature resistance R_A with a series resistance R_V in the armature circuit (Figure 14a). Speed curves with the series resistance as the parameter can be seen in Figure 14b.

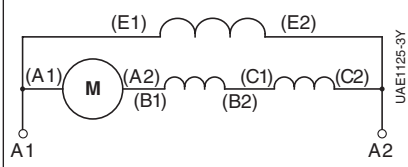

Figure 13: Four-quadrant operation of the shunt-wound machine

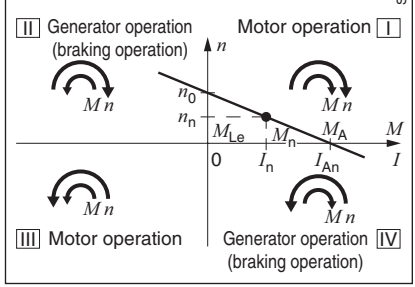

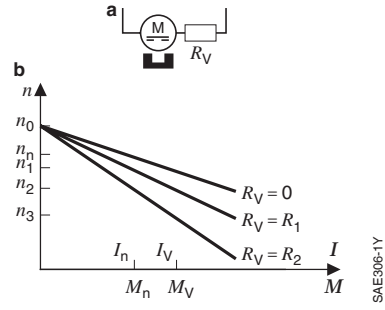

Figure 14: Speed points by means of armature series resistance

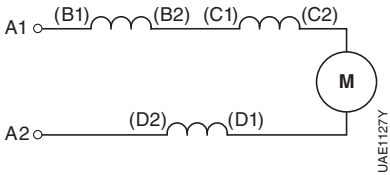
a) Series connection of armature resistance and series resistance,
b) Speed curves with the series resistance as parameter.

Series-wound machine

In the case of the series-wound machine, the commutating, compensation, exciter, and rotor winding are connected in series (Figure 15). D designates the exciter winding of the series-wound machine. To determine the operating characteristics, the ohmic resistances of the windings are added up to form the resistance R_A. The relationship $\Psi = L I$ and equation (8) inserted in equation (9), the speed/torque equation follows the series-wound machine:



$$n(M) = \frac{1}{c_1 L}\left(U_{Kl}\sqrt{\frac{c_1 L}{c_2 M}} - R_A\right). \qquad (13)$$

Because of the torque in the denominator the motor achieves reaches high speeds at low load an may never be operated completely without base load. Owing to the absence of external excitation the series-wound commutator machine can only function as a motor. The speed/torque characteristics limits the use of the motor. Areas of application must therefore always provide for a base load (friction torque) as in a vacuum cleaner or in pumps. A small load change always brings about a large speed change. The speed-setting options of the series-wound machine are limited to changing the terminal voltage.

Figure 16 shows the speed/torque diagram of the series-wound machine with the terminal voltage U_{Kl} as the parameter.

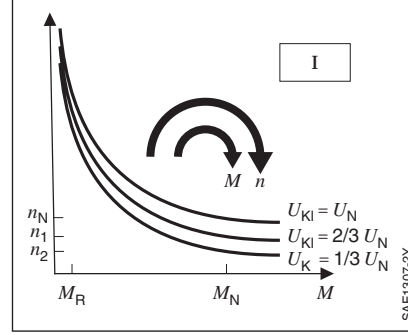
Asynchronous machine

The asynchronous machine is the main drive used in industry. In the automotive sector, for example, it is used in electrical power-assisted steering and in hybrid vehicles. The following section presents the operating concept of the asynchronous machine as an induction machine.



General setup

A distinction is made between external rotor and internal rotor machines. In the case of the external rotor machine, the rotor encloses the stator; on the internal rotor machine, the stator encloses the rotor.

The diagram of the principle (Figure 17) indicates the fundamental structure of an internal rotor asynchronous machine. The rotor consists in the simplest case of a short-circuited coil (short-circuit rotor). The stator consists of three coils with an iron core which are each assigned to a phase. The iron core consists of individual steel sheets insulated against one another to keep the eddy-current losses to a minimum. The rotating stator magnetic field induces in the short-circuited coil a current which for its part causes a magnetic field which is coupled to the rotating stator field and thus becomes effective in terms of torque.

Figure 16: Operation characteristic curves of the series-wound machine

n Motor speed, n_n Rated speed, U_{Kl} Terminal voltage, U_N Rated voltage, M_M Motor torque, M_R friction torque, M_N Rated torque.

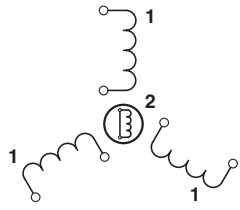
Operating characteristics

The stator winding generates a rotating field with a three-phase alternating current. There is a speed difference between the rotating-field speed and the rotor speed that enables the induction of a magnetically effective current in the rotor, which in turn contributes to the generation of torque. The physical operating concept is based on the law of magnetic induction. Figure 18 shows the rotor as a simplified conductor loop on rotating mounts. The relative movement between the rotating stator field and the rotor is described by the slip angular frequency ω_S.

The magnetic field B_R rotating with the slip angular frequency induces according to Faraday's law in the cage rotor the voltage

$$\oint E\,ds = -\int\int \frac{dB}{dt}\,dA_S. \qquad (14)$$

E denotes the electric field strength along the short-circuit rods and bridges. There follows the development of the left term
– with material ($E = J/\kappa$),
– geometric ($\int E\,ds = E \cdot 2\,(l+2r)$, and
– electrical ($J = i_{ind}/A_{nom}$) quantities



$$\oint E\,ds = \frac{2\,(l+2r)}{\kappa A_{nom}}\,i_{ind} = R_S\,i_{ind}, \qquad (15)$$

followed by the development of the right term using geometric ($A_s = 2\,l\,r$) and magnetic quantities in the frequency range

$$\int\int \frac{dB}{dt}\,dA_S = 2\,l\,r\,\hat{B}_R\,\omega_S \sin(\omega_S t) = \hat{u}_{ind}\sin(\omega_S t). \qquad (16)$$

Figure 17: Principle of a three-phase asynchronous motor

1 Fixed stator winding,
2 Rotor as rotatable short-circuited coil.
Axis of rotation perpendicular to the plane of projection.

Here, κ is the specific electric conductivity, J the current density, and R_S the conductor-loop resistance (short-circuit rods and bridges). By bringing together equations (15) and (16) and converting according to the current i_{ind} there follows

$$i_{ind} = \frac{\hat{u}_{ind}}{R_S}\sin(\omega_S t). \qquad (17)$$

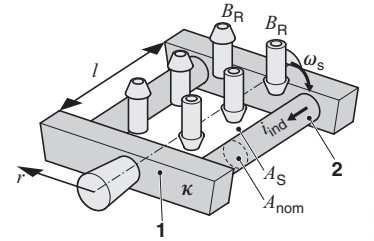
With the conductor current the tangential force F_t (Lorentz force)

$$F_t = i_{ind}\,l\,\hat{B}_R \sin(\omega_S t) \qquad (18)$$

is obtained at the conductor loop. Together with the two rotor rods the torque M follows

$$M = 2\,F_t\,r = \frac{2\,\kappa A_{nom}\,\omega_S}{l+2r}\left(l\,r\,\hat{B}_R \sin(\omega_S t)\right)^2 \qquad (19)$$

with material, geometric, and magnetic quantities. Including the trigonometric function



$$\sin^2(\omega_S t) = \frac{1}{2}\left(1 - \cos(2\,\omega_S t)\right)$$

the torque M follows again

$$M = \frac{\kappa A_{nom}\,\omega_S}{l+2r}\left(l\,r\,\hat{B}_R\right)^2 (1 - \cos(2\,\omega_S t)). \qquad (20)$$

Figure 18: Two-bar rotor as short-circuit rotor

1 Short-circuit bridge, 2 Short-circuit rod.
i_{ind} Induced current, l Short-circuit rod length,

B_R Magnetic field rotating with slip angular frequency,
A_S Cross-sectional area of conductor loop,
κ Specific electric conductivity of conductor loop,
ω_S Slip angular frequency (results from the relative movement between stator rotating field and rotor speed).

This is made up of a constant and a time-variable component of oscillating torque at twice the slip angular frequency. The amplitude of the oscillating torque corresponds to the amount of the constant component. The magnetic effect of the induced current in the conductor loop is taken into account as follows. The current causes, on account of Ampère's law, the induced magnetic field H_{ind} and the field strength the induced magnetic flux density B_{ind}:

$$H_{ind} = \frac{i_{ind} N}{l_H};\ B_{ind} = \mu H_{ind}. \quad (21)$$

Here, N is the number of conductors and l_H the field-line length. The power loss P_v obtained in the rotor is calculated at

$$P_V = R_S i_{ind}^2 = \frac{l_S}{\kappa A_{nom}} i_{ind}^2 \quad (22)$$

Figure 19 shows torque curves as a function of the slip angular frequency.

Synchronous machine

Synchronous machines are used preferably as claw pole generators. In motor operation, they are used for example in electrical power-assisted steering, to drive hybrid vehicles, and in electrically driven turbochargers.

General setup

In contrast to the asynchronous machine, in the synchronous machine the rotor rotates synchronously with the excitation field at the angular velocity $\omega_{\Phi S}$. The flux Φ_R generated by the rotor winding and the stator flux Φ_S superposition themselves in relation to the resulting flux Φ_{RS} (Figure 20):

$$\Phi_{RS} = \Phi_R + \Phi_S. \quad (23)$$

As the rotor and stator material are operated far below the magnetic saturation ($\mu_r \rightarrow \infty$), the air gap d between the rotor and stator as well as the angle α determine the magnetic circuit resistance R_m:

$$R_m = \frac{2\delta}{(\mu_0 A_R)} = \frac{2d}{(\mu_0 A_R \cos\alpha)}. \quad (24)$$

Figure 19: Torque curves of an asynchronous machine

Φ_{RS} Superpositioned flux,
$\omega_{\Phi S}$ Angular velocity of the excitation field,
I_{er} Exciting current in the rotor,
A_S Magnetically effective stator surface,
A_R Magnetically effective rotor surface,
r Radius of the rotor,
d Distance between rotor and stator,
δ Air gap length, α Deflection angle.

The factor 2 results from the fact that there are two air gaps between the rotor and stator. If the motor provides torque, the rotor rotates with the angle α from its idle position (Figure 21).

The resulting flux Φ_{RS} is calculated as:

$$\Phi_{RS} = \frac{\Theta_{er}}{R_m} + \Phi_S . \quad (25)$$

With R_m from equation (24), this results in

$$\Phi_{RS} = \frac{\Theta_{er}\mu_0 A_R \cos\alpha + 2d\Phi_S}{2d} . \quad (26)$$

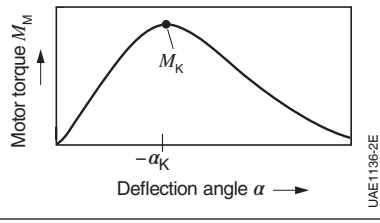
With $\Theta_{er} = NI_{er}$ the result is

$$\Phi_{RS} = \frac{NI_{er}\mu_0 A_R \cos\alpha + 2d\Phi_S}{2d} . \quad (27)$$

Θ_{er} is the magnetic rotor flooding and I_{er} is the exciting current fed to the rotor via the collector rings. The tangential force F_t affecting the torque is calculated using the Maxwell pole force formula

$$F_t = \frac{{\Phi_{RS}}^2}{\mu_0 A_R} \sin\alpha \quad (28)$$

Figure 21: Torque/load-angle characteristic curve
M_K Breakdown torque,
α_K Deflection on reaching the breakdown torque.



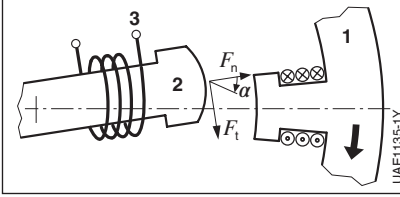


Figure 22: Forces at the rotor
1 Stator, 2 Rotor, 3 Rotor winding.
F_t Tangential force, F_n Normal force,
α Deflection angle.

[4, 5, 8]. The tangential force is used to calculate the motor torque M_M:

$$M_M = 2F_t r . \quad (29)$$

Equation (27) inserted in equation (28) and the result in equation (29) yields the following relationship:

$$M_M = \frac{r\sin\alpha}{2\mu_0 A_R d^2} \cdot [(NI_{er}\mu_0 A_R \cos\alpha)^2 + 4NI_{er}\mu_0 A_R d\Phi_S \cos\alpha + 4d^2{\Phi_S}^2] . \quad (30)$$

The first term is only dependent on the exciting current I_{er} and corresponds to the cogging torque. The second term generates the motor torque to a decisive degree. The linear dependency of the rotor flooding $\Theta = I_{er}N$ and stator flux Φ_S can be seen here. The third term also generates a torque and is only dependent on the stator flux [8]. Operation of the motor with only the third term corresponds to operation of a reluctance motor.

An increase in the outer load torque leads to an increase in the load angle α and thus to a change in motor torque M_M to be delivered (Figure 22). The maximum motor torque to be delivered is referred to as the breakdown torque M_K at the position α_K. If α_K is exceeded, the machine slips out.

Alternatively, the torque can also be calculated approximately via the Lorentz force F_L [9]. This is the force which acts on moving charges in a magnetic field and is defined as

$$\vec{F}_L = I\left(\vec{l} \times \vec{B}\right) \quad (31)$$

Here, I is the current in the conductor, l the length of the conductor, and B the flux density of the effective magnetic field. Vectorial notation and the cross product mean that conductor and magnetic field must be perpendicular to each other in order to fashion a force.

By introducing an electric loading A which fashions the currents in the individual conductors of a machine at a fictitious line current density along the periphery, the Lorentz force

$$\vec{F}_L = A\left(\vec{S} \times \vec{B}\right) \tag{32}$$

can be described with the aid of the air-gap area S between the rotor and the stator. For the effective value of the electric loading the following applies

$$A = \frac{\hat{A}}{\sqrt{2}} \tag{33}$$

with sinusoidal flux distribution. The peak value of the electric loading is expressed with the number of stator phases m, the number of turns per phase N, and the pole pitch τ_p at the middle air-gap radius r_δ as

$$\hat{A} = \frac{m\sqrt{2}NI}{p\tau_p} = \frac{m\sqrt{2}NI}{\pi r_\delta}. \tag{34}$$

With the rotor length l in the axial direction the air-gap area S is obtained

$$S = 2\pi r_\delta l. \tag{35}$$

The mean value of a pole pitch is used for the flux density B. If the flux-density distribution along the periphery has a sinusoidal characteristics with the amplitude $\hat{B}$, then its mean value is given as

$$\begin{aligned} B &= \frac{1}{\frac{\pi}{p}} \int_0^{\frac{\pi}{p}} \hat{B}\sin(p\alpha)\,d\alpha \\ &= \frac{2}{\pi}\hat{B} \\ &\approx 0.64\hat{B}\,. \end{aligned} \tag{36}$$

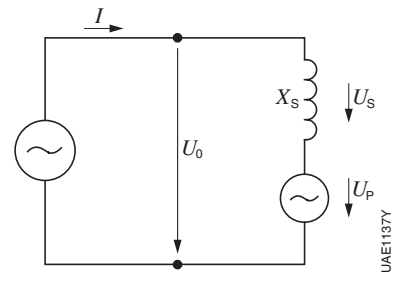
With the relationship $M = r_\delta F_L$ the torque

$$M_M = 2mNIBlr_\delta \tag{37}$$

follows for a stationary operating state.

Suppression of harmonics

A sinusoidal flux distribution along the periphery of a stator is technically not feasible, therefore harmonics occur during operation in addition to the principal wave of the magnetic field. These lead to unwanted fluctuations of torque, vibrations, and additional losses. In order to specifically suppress the influence of certain magnetic-field harmonics, the rotor or stator slots are often skewed in electric machines. The skewing is intended to ensure that the same face of north and south poles of the harmonic to be neutralized are enclosed by the turns of a coil. The magnetic fluxes of these poles thus counterbalance each other and no longer impact negatively on the machine's operating characteristics.



Another way of suppressing harmonics comes from the spatial distribution and chording of the coils. The effect of spatial distribution and chording is reflected in the winding factor. This is a measure of the coupling of windings with the respective magnetic flux-density waves.

Operating characteristics

A drawing of the synchronous machine can be made in a single-phase equivalent electric circuit diagram in that the voltage induced by the rotor in the stator (pole-wheel voltage U_P) is assumed as the voltage source and remaining reactances (inductive resistances) are summarized

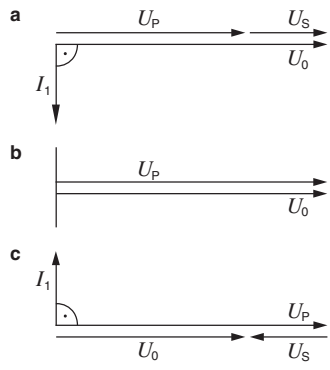
Figure 23: Single-phase equivalent circuit diagram of the synchronous machine

U_P Pole-wheel voltage,
U_S Reactance voltage,
U_0 Terminal voltage,
I Current,
X_S Synchronous reactance.

to form the synchronous reactance X_S (Figure 23). The voltage above the synchronous reactance is designated U_S and the terminal voltage U_0. The direction of the current is specified in accordance with the consumer unit counting arrow system. Whereas current flows into the consumer units during motor operation, current flows out of the generator during generator operation. Setting up the mesh equation yields the current I

$$I = \frac{U_0 - U_P}{X_S}. \tag{38}$$

The amount of the pole-wheel voltage is influenced by the exciting current. The relationships are to be derived below. The following applies:



$$U_P = -\frac{d\Phi_R}{dt}. \tag{39}$$

With the cosinoidal flux Φ_R and the relationship

$$\Phi_R = BA_S \tag{40}$$

including its temporal derivation, this leads to

Figure 24: Operating states of the synchronous machine at idle
a) Underexcitation (inductive),
b) $I = 0$ (resistive),
c) Overexcitation (capacitive).
U_P Pole-wheel voltage,
U_S Reactance voltage,
U_0 Terminal voltage, I_1 Stator current.

$$\begin{aligned} u_P &= \Phi_R \omega_{\Phi S} \sin(\omega_{\Phi S} t) \\ &= B_R A_S \omega_{\Phi S} \sin(\omega_{\Phi S} t) \\ &= \mu H_R A_S \omega_{\Phi S} \sin(\omega_{\Phi S} t). \end{aligned} \tag{41}$$

The magnetic field intensity created in the rotor is described by Ampère's law. The pole-wheel voltage

$$\begin{aligned} u_P &= \mu \frac{\Theta_R}{2\delta} A_S \omega_{\Phi S} \sin(\omega_{\Phi S} t) \\ &= I_{er} \frac{\mu N}{2\delta} A_S \omega_{\Phi S} \sin(\omega_{\Phi S} t) \\ &= \hat{u}_P \sin(\omega_{\Phi S} t) \end{aligned} \tag{42}$$

is then linear-dependent on the exciting current I_{er}. The temporally changeable pole-wheel voltage is converted into its effective value using

$$U_P = \frac{\hat{u}_P}{\sqrt{2}}. \tag{43}$$

On the basis of the mesh equation (38), three operating states of the synchronous machine can be derived depending on the pole-wheel voltage (Figure 24):
Case 1: $U_P < U_0$, underexcitation, inductive,
Case 2: $U_P = U_0$, resistive,
Case 3: $U_P > U_0$, overexcitation, capacitive.

The first case occurs as long as U_P is $< U_0$. If $I_{er} = 0$, only the self-induction voltage is effective as induced voltage. If current is applied to the rotor, the mutual induction caused by the rotor also takes effect. The first case is referred to as underexcitation. The current lags behind the voltage by 90° ($\varphi(I,U) < 0$). The synchronous machine shows inductive characteristics.

Another increase in the exciting current leads to $U_P = U_0$. This produces the second operating case (Figure 24b). The current I_1 becomes zero if no more voltage is supplied via the synchronous reactance.

Another increase in the rotor current leads with $U_P > U_0$ to the third operating case (overexcitation).

All three cases apply to motor and generator operation. For the single-phase equivalent circuit diagram, the pointers are applied to the voltages and currents. Furthermore, the load angle β that sets

in between the voltages U_0 and U_S is defined. For motor operation, the load angle β is < 0 (Figure 25a). The voltage triangle is closed by the voltage U_S.

The synchronous reactance means that the current I_1 leading by 90° in relation to the voltage U_S flows. This is broken down into its components: the active current I_W and reactive current I_B (Figure 25a).

If the pole-wheel voltage is reduced so that the pointer of the reactance voltage is vertically on the pointer of the terminal voltage U_0, the motor only consumes active current (Figure 25b).

A further reduction in the pole-wheel voltage leads to underexcitation. The current I_1 lags behind the voltage U_S by 90°, which is the equivalent of inductive characteristics of the motor (Figure 25c). If torque is applied to the motor, it switches to generator operation. Generator operation features the positive load angle β (Figure 26). The sign of the current becomes negative. Current flows out of the machine. In the case of overexcitation, the machine behaves like a capacitor. It delivers reactive power (Figure 26a).

If the pole-wheel voltage is reduced so that the pointer of the reactance voltage U_S is vertically on the pointer of the terminal voltage, the generator only delivers active current (Figure 26b).

A further reduction in the pole-wheel voltage leads to a case of underexcitation. The machine behaves inductively. It consumes reactive power (Figure 26c).

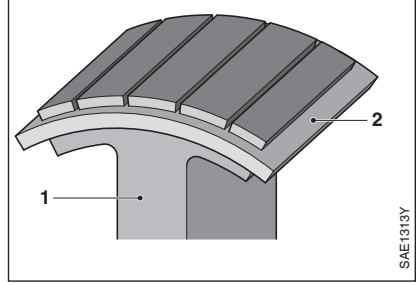
Starting synchronous motors
Synchronous motors then only generate a permanently positive torque when the rotor and rotating-field speeds match. If this is not the case, the rotor's magnet poles are alternately attracted and repelled. The rotor starts to oscillate and also heats up strongly since the current consumption is not limited by the induced pole-wheel voltage. In the worst case the insulation of the windings is destroyed by the thermal load. To stop this from happening, the machine rotor must first be accelerated to synchronous speed. Three procedures have proven successful in the past for this purpose.

Procedure 1
The rotor is accelerated with the aid of a DC motor to synchronous speed before being put into operation.

Procedure 2
In salient-pole rotors a cage winding, also called a damper winding, can be integrated in the pole shoe. A structure of this type is pictured in Figure 27. This winding delivers in asynchronous mode the necessary torque to accelerate to synchronous speed. The windings are additionally short-circuited and deliver a further small torque contribution during running-up. If the machine is already at rotational speed, no further currents are induced on account of the absence of relative speed between rotor and stator speeds.



Procedure 3
The rotating-field speed is adapted with frequency converters to the rotor speed and slowly increased up to synchronous speed.

Switched reluctance motor

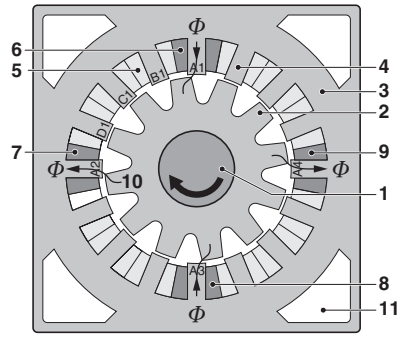
Properties of the switched reluctance motor
The "switched reluctance motor" (SRM) belongs to the class of synchronous motors. Its mode of operation is based on the effect of force on a boundary layer (reluctance force). Its design is comparable with many parallel-switched magnetic circuits which are continuously cyclically energized. Cyclic energization (switching with the necessary ECU) of stator-magnet teeth makes possible a rotary motion whereby the rotor teeth are brought into line with the stator teeth. Since rare-earth materials do not have to be used, areas of application open up in which motors with permanent-magnet material cannot be used. Areas of application at high temperatures are mentioned here by way of example.

The switched reluctance motor is suitable for variable-speed drive tasks and for positioning tasks. Thanks to its design, it can generate a holding torque over an extended period of time. It also generates high torque fluctuations.

Figure 27: Salient pole with integrated cage winding
1 Salient pole,
2 Cage winding.

Design of the switched reluctance motor

Figure 28 shows a cross-section of a four-phase ($m = 4$) switched reluctance motor. In the snapshot of Figure 28 the stator windings are energized (marked in dark gray in the figure). The current drives a magnetic flux through the four-pole arrangement of teeth A1, A2, A3, and A4. Since the rotor and stator teeth do not line up, a reluctance force is generated at the rotor-tooth surfaces whose tangential component has a torque-producing effect and can thus turn the rotor clockwise. The torque becomes zero as soon as the rotor and stator teeth line up. It is necessary to switch to further windings at the latest at the onset of this condition (see also [7], [10], [13]).



Calculating the number of stator and rotor teeth

A magnetic circuit provided with a phase winding contains a ferromagnetic flux concentrator (yoke and armature) and always an air gap for energy conversion. Two series-connected air gaps are required in the same magnetic circuit to facilitate a rotation of the armature. The magnetic flux penetrates the air gap once from the rotor to the stator and back from the stator to the rotor to complete the circuit. This is combined in a pole pair of the reluctance motor $Z_p = 1$. This also means that in this example $2Z_p$ is equal to the number of pole pairs per phase. The number of stator teeth N_S will be inferred by means of consideration whereby two rotor/stator teeth pairs in line (rotor tooth facing stator tooth) per phase form a magnetic circuit with the lowest reluctance (greatest inductance). Multiplying the number of poles per phase by the number of phases m produces the number of stator teeth $N_S = 2mZ_p$. To obtain a relative movement of the rotor in relation to the stator, it is necessary to achieve asymmetry of the numbers of teeth of stator and rotor. A practicable formulation for calculating the number of rotor teeth N_R is

$$\begin{aligned} N_R &= N_S \pm \Delta N \\ &= m \cdot 2\,Z_p \pm 1 \cdot 2Z_p \\ &= 2\,Z_p(m \pm 1)\,. \end{aligned} \tag{44}$$

The number of rotor teeth differs here precisely by an in-line tooth pair (pole pair) of a single phase (difference ΔN). Because of the magnetic flux between rotor and stator teeth, $N_R = 2Z_p(m+1)$ is preferred for an external rotor and $N_R = 2Z_p(m-1)$ is preferred for an internal rotor. For example, in Figure 28 $N_S = 2Z_p m = 2 \cdot 2 \cdot 4 = 16$ stator teeth and $N_R = 2Z_p(m-1) = 2 \cdot 2 \cdot (4-1) = 12$ rotor teeth can be seen.

Calculating the step angles

Calculation of the step angle applies to the controlled stepping motor. The difference between stator angle α_S and rotor angle α_R where

$$\alpha_S = \frac{2\pi}{N_S} = \frac{2\pi}{m \cdot 2Z_p} \text{ and}$$

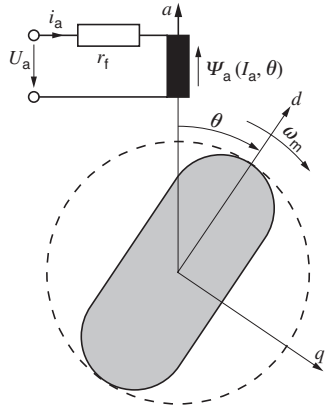
$$\alpha_R = \frac{2\pi}{N_R} = \frac{2\pi}{2Z_p(m \pm 1)} \tag{45}$$

yields the step angle θ where

$$\theta = \alpha_S - \alpha_R$$

$$= \frac{2\pi}{m \cdot 2Z_p} - \frac{2\pi}{2Z_p(m \pm 1)}$$

$$= \frac{\pm\pi}{Z_p m(m \pm 1)}$$



$$\theta = \frac{-\pi}{Z_p m(m-1)} = \frac{-\pi}{2 \cdot 4(4-1)} = -\frac{\pi}{24}. \quad (46)$$

Changing the step angle θ after the time t produces the angular velocity ω_m, from which the rotational frequency f_r is calculated. For example, for the stepping motor from Figure 28 a step angle $\theta = -\pi/24$ (see equation (46)) with a rotational frequency f_r is obtained:

$$f_r = \frac{1}{2\pi} \frac{d\theta}{dt}. \quad (47)$$

The rotor runs opposite to the phase switching direction.

Single-phase equivalent circuit diagram of the switched reluctance motor

The equivalent circuit diagram of the switched reluctance motor reduced to a phase a is depicted in Figure 29. The symbols and designations have been taken from VDI/VDE 3680 [10].

Operating characteristics of the switched reluctance motor

Voltage relationship

The operating characteristics are presented using the example of the voltage-differential and torque equation. The voltage-differential equation of the nonlinear magnetic circuit

$$u_a(t) = u_R(t) + u_L(t)$$

$$= i_a(t) r_f + \frac{d\Psi_a(I_a, \theta)}{dt} \quad (48)$$

is set up with the aid of Figure 29. By forming the total differential of $\Psi_a(I_a, \theta)$ and inserting in the voltage-differential equation it follows that

$$u_a(t) = i_a(t) r_f + \frac{\partial \Psi_a}{\partial I} \frac{di_a}{dt} + \frac{\partial \Psi_a}{\partial \theta} \frac{d\theta}{dt}. \quad (49)$$

To emphasize the angle dependence of the inductance, there follows with $\Psi_a = L_r(\theta) I_a$ the first-order non-homogeneous voltage-differential equation

$$u_a(t) = L_r(\theta) \frac{di_a}{dt} + \left(r_f + \frac{\partial L_r(\theta)}{\partial \theta} \frac{d\theta}{dt} \right) i_a. \quad (50)$$

It is clear that the induced voltage exhibits a proportionality to the rotor angular velocity. As the angular velocity increases the induced voltage rises, which has a current-lowering and thus torque-reducing effect, as is shown in the following.

Torque relationship

With the aid of the angle-dependent co-energy W_{mag}^{Co} of the linear (Figure 30a) and nonlinear magnetic circuits (Figure 30b) the mechanical energy W_{mech} follows where

$$\Delta W_{mag}^{Co} = W_{mag}^{Co}(\theta_1) - W_{mag}^{Co}(\theta_2)$$

$$= W_{mech}. \quad (51)$$

The magnetic co-energy W_{mag}^{Co} corresponds to the area (energy) below the respective characteristic.

The co-energy together with the magnetic energy always produce a rectangle or a square in the diagram. With the restriction to the linear magnetic circuit according to Figure 30a it follows that

$$\Delta W_{mag}^{Co} = \frac{1}{2} I_a^2 \left(L(\theta_1) - L(\theta_1) \right)$$

$$= W_{mech} .$$

What is clear is the quadratic current function, which decisively influences the area W_{mech}. The larger this area, the greater the rated torque m_A,

$$m_A = \frac{\partial W_{mech}}{\partial \theta},$$

which is calculated with the angle-dependent co-energy. In the angle position θ_1 the rotor and stator teeth face each other in line. In this angle position the minimum reluctance and consequently the maximum interlinked flux Ψ_{max} are obtained. The torque equals zero in this position. A torque is obtained in the angle position θ_2. The stator tooth faces the rotor grove. The reluctance value assumes a maximum, the flux Ψ a minimum.

The symbols and abbreviations used have been taken from VDI/VDE 3680 [10].

Electronic motors

In the case of electronically commutating motors (electronic motor, EC motor), the rotor excitation winding, including the electrical contacting with collector rings, is not required. Electronic motors are brushless synchronous motors where the rotors are fitted with permanent magnets. The permanent magnets can be arranged, for example, on the rotor surface or in the rotor (Figure 31). The commutation of the current takes place generally in the fixed stator winding by means of an electronic assembly (Figure 33).

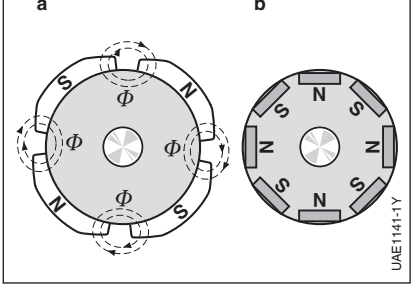

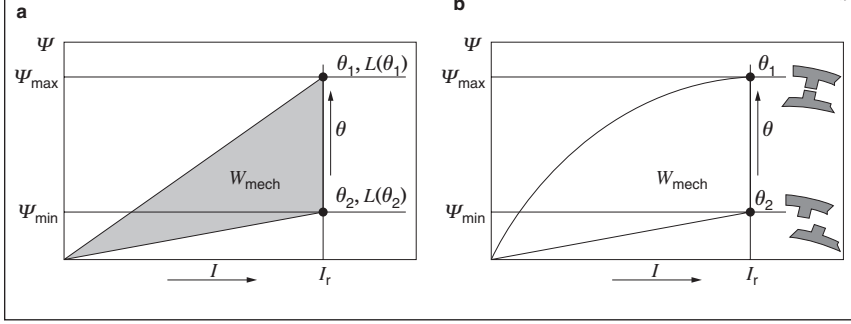

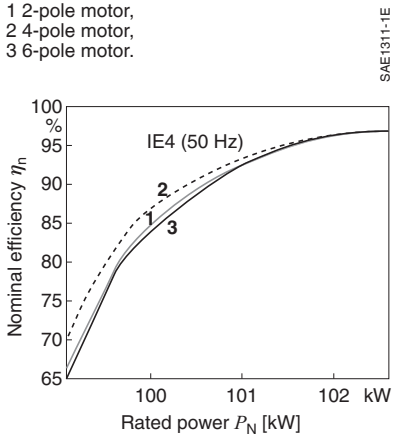

Figure 30: Torque-producing mechanical energy
a) Linear magnetic circuit,
b) Nonlinear magnetic circuit.

The rotational speed of the electronic motor is set by the frequency of the surrounding stator field. Sensors are required to pick up the rotor position. Widespread use is made of Hall sensors fitted in the working air gap to enable cyclic relaying between the winding phases with the help of activation electronics.

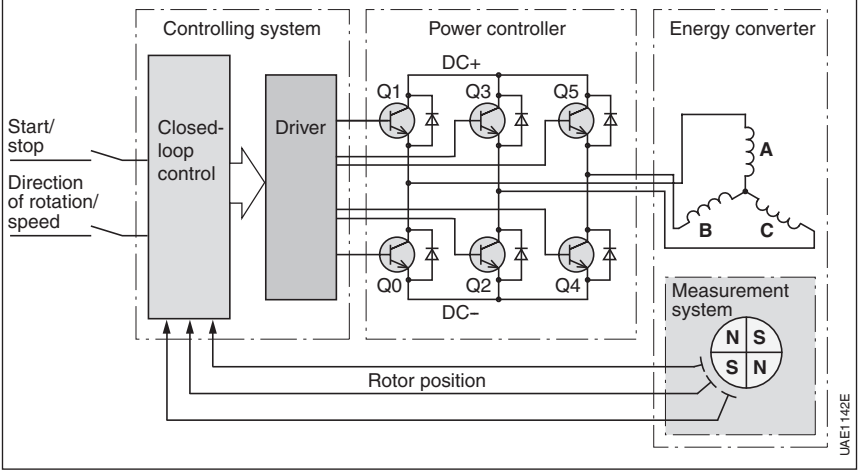
Energy-efficiency classes



The International Electrotechnical Commission (IEC) intends with the standard IEC 60034 Part 30-1 [8] to harmonize internationally efficiency classes for electric motors. The standard applies to all types of electric motors which are rated for direct start-up at the power system. The efficiency classes are named in Table 3. In Figure 32 the motor efficiencies are plotted against the rated power for 2-, 4- and 6-pole motors at 50 Hz.

The area of application of the IE4 standard is presented in a shortened version:
– Rated power P_N:
  0.12 kW through 1000 kW;
– Rated voltage U_N:
  50 V through 1 kV;
– Number of poles from 2, 4, 6 or 8.

Table 3: Efficiency classes

Abbreviation	Name
IE1	Standard-Efficiency
IE2	High-Efficiency
IE3	Premium-Efficiency
IE4	Super-Premium-Efficiency

Figure 33: Activation electronics of the electronic motor

Three-phase current system

Technically relevant is the application of the three-phase alternating current system as a three-phase current system, the major feature of which is that the total of all voltages and currents is zero at all times.

Definitions
The electric circuits are referred to as phases m. The total of the electric circuits in which voltages of the same frequency have an effect and are phase-shifted are referred to as multiphase systems. A multiphase system consists of winding phases. On a three-phase system, $n = 3$ symmetrical systems are possible (Figure 34). On all symmetrical systems – with the exception of the zero system – the total of all pointers is zero. m phases result in n different symmetrical systems depending on the phase difference α:

$$\alpha = \frac{2\pi\, n}{m} . \qquad (52)$$

The task of windings is to generate a rotating field. Asynchronous and synchronous machines have the same stator structure. In the air gap, a magnetic field with constant amplitude is to be created, rotating at constant angular velocity. For this rotating field to be generated, the temporal phase positions of the currents must match the spatial position of the corresponding strands. For a simple symmetrical system ($n = 1$) with $m = 3$, the three strands (designated with U, V and W) and therefore the windings must be evenly distributed over the circumference. Figure 35 shows the arrangement of a three-strand winding with one coil per pair of poles and strand The terminal markings of the phases comply with DIN EN 60034, Part 8 [8].

Figure 34: Symmetrical systems

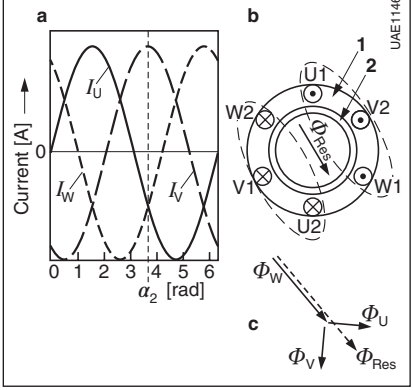
Rotating-field generation

In order to generate a rotating field in the case of a simple symmetrical system ($n = 1$) with the number of strands $m = 3$, the strands must be geometrically offset by the electrically effective angle

$$\alpha_{el} = 360° \cdot \frac{1}{3} = 120°.$$



With one coil per pair of poles and strand, the resulting magnetic field rotates counterclockwise in that the "indicator bar" shifting in Figure 36a to the right (at $\alpha = 90°$) indicates the phase current in each of the strands in Figure 36b in flux direction. The arrangement forms a pair of poles. The associated magnetic fluxes emerge vertically in relation to the winding plane of the strands (Figure 36b).

The flux Φ_{Res} (Figure 36c) resulting from the three strands as well as its direction are achieved by geometrically adding up the three individual fluxes Φ_U, Φ_V and Φ_W.

A progression of the indicator bar up to $\alpha = 180°$ leads to a current-direction reversal in strand W and therefore to a further turn to the right of the resulting field Φ_{Res} (Figure 37).

Figure 37: Generating a rotating field with one coil per strand

a) Strand currents,
b) Strand currents with $\alpha = \alpha_2$,
c) Direction of the rotating field (spatial directions).
1 Stator, 2 Rotor.
U, V, W Strands.

When two coils per strand are used, the conductor arrangement is "doubled". If the winding is to form two pairs of poles ($p = 2$), the windings have to be divided into groups (Figure 38). With this, the mechanically effective angle

$$\alpha_m = 360° \cdot \frac{1}{m\,p} = 60° \text{ sets in.}$$

Figure 38: Winding with two pairs of poles per strand

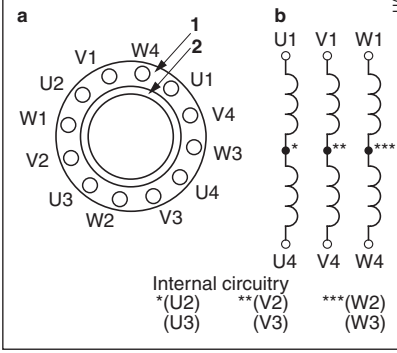

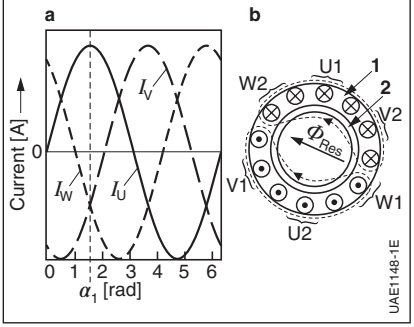

Figure 39: Rotating-field generation with two coils per strand

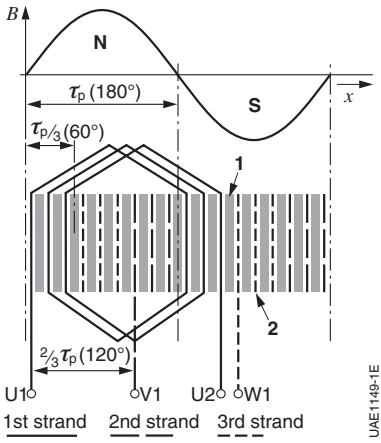
a) Strand currents with angle $\alpha = \alpha_1$,
b) Resulting magnetic field with $\alpha = \alpha_1$.
1 Stator, 2 Rotor.
U, V, W Strands.

The electrically effective angle remains unchanged. In the case of both the two-pole and four-pole arrangement, the field rotates counterclockwise (Figure 39). The rotating-field speed

$$n_d = \frac{f_n}{p}$$

can be calculated with the mains frequency f_n and the number of pole pairs p. For p = 1, the rotating-field speed is equal to the mains frequency (Table 4).

Together with the number of pole pairs, the pole pitch



$$\tau_p = \pi d_{si}/2p$$

can be calculated as a stator circumference proportion, where d_{si} is the inner diameter of the stator. It corresponds to the length of a sinusoidal half wave that corresponds to the induction distribution of the rotor field. In the case of a two-pole machine (p=1), the pole pitch is α_{el}=180° (electrical angle) at all times and matches the mechanical angle α_m. The relationship of the two angles is indicated by $\alpha_{el} = p\,\alpha_m$. So that voltages of equal size are induced in the windings, the winding phases have to be offset in relation to one another by α_{el} = 120° or $2\tau_p/3$ and the coil structure and number of turns must be the same. One third of the pole pitch is apportioned to each strand.

Chemistry

Elements

Periodic table

Structure of the periodic table

The atoms of the chemical elements are made up of positively charged protons, uncharged neutrons, and negatively charged electrons [1]. In the periodic table (Tables 1 and 2) the elements are laid out in order of increasing number of protons – i.e. increasing nuclear charge number – and in order of their atomic mass. The atomic mass is essentially determined by the total number of nuclear constituents, i.e. the sum total of protons and neutrons. The total number of protons and neutrons is also called the mass number. The number of protons corresponds to the atomic number. The neutral element atoms always have as many protons and electrons.

Groups and periods

The elements are divided in the periodic table into different groups (vertical columns) and periods (horizontal rows). The nested structure of the groups is due to the fact that the electrons always occupy the lowest energy levels. The position of these energy levels, which are also called electron orbitals and indicate the probability of electrons being present around the atomic nucleus, can be derived using quantum mechanics.

Quantum numbers

The structure of the periodic table is based on four quantum numbers (principal, secondary, magnetic, and spin quantum numbers), with which the four electron orbitals with the designations s, p, d and f can be calculated. When the electrons are arranged into these orbitals in order of increasing energy, this creates groups of elements which demonstrate a similar manner of reaction across all the periods. This manner of reaction is only minimally influenced by the electrons on the inner orbitals. The crucial factors are the energy and number of outer electrons. The outer electrons are frequently referred to as “valence electrons”.

Main groups

The elements in groups Ia, IIa and IIIa…VIIIa are called main-group elements. The main-group elements include hydrogen and the alkali metals (Ia), the alkaline-earth metals (IIa), the boron (IIIa), carbon (IVa) and nitrogen groups (Va), the chalcogens (VIa), the halogens (VIIa), and the noble gases (VIIIa). The electrons of the main-group elements of the 1st period, hydrogen and helium, are found exclusively in s-orbitals. In the case of the other main-group elements in the 2nd through 7th periods, the electrons also occupy p-orbitals starting from the main group IIIa.

Secondary groups

The elements of the secondary groups Ib, IIb and IIIb…VIIIb with electrons in d-orbitals all have a metallic character. The copper group is assigned to the secondary group Ib because its electron configuration shows similarities to the main group Ia. The elements in both groups tend to form salts from monovalent ions. The same applies to the groups IIa and IIb. Divalent metal compounds are formed in the group of alkaline-earth metals and the zinc group IIb. The designations for the secondary groups IIIb…VIIb likewise have their roots in the electron configuration and provide an indication of the maximum valence of these metal ions. The elements iron, cobalt and nickel as well as the elements underneath called higher homologs are brought together as secondary group VIIIb due to their marked chemical similarity.

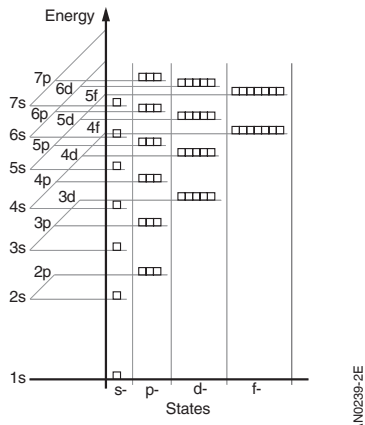
All elements are arranged sequentially according to atomic number (proton number). The horizontal rows are called periods, the vertical columns are called groups. The relative atomic masses are indicated below the element symbols.
The values given in parentheses are the mass numbers (nucleon numbers) of the stablest isotopes of radioactive elements.

Table 2: Designations of chemical elements



Element	Symbol	Atomic number
Actinium	Ac	89
Aluminum	Al	13
Americium [1]	Am	95
Antimony	Sb	51
Argon	Ar	18
Arsenic	As	33
Astatine	At	85
Barium	Ba	56

Yttrium	Y	39
Zinc	Zn	30
Zirconium	Zr	40

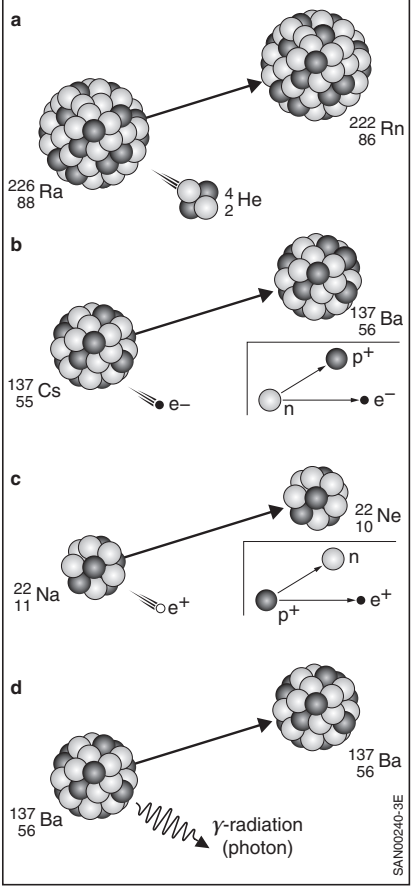
[1] Artificially produced; does not occur naturally.

Periods with f-orbitals
In the 6th and 7th periods a further series of energy levels, the f-orbitals, are available in each case after the secondary group IIIb lanthanum and actinium. These are taken up by the electrons of the elements of the lanthanides (6th period) and actinides (7th period). The lanthanides are also known by the term “rare earths”. All actinides are radioactive.

The arrangement of the elements in the periodic table according to the energy position of their electron orbitals becomes clear in the energy-level diagram (Figure 1). It can be seen that for higher orbital energies after the occupation of the s-orbital the p-, d- and f-orbitals subordinate to this principal quantum number are no longer automatically filled with electrons. For example, it is now understandable why the secondary-group elements scandium through zinc with the orbital energies 3d after the element calcium are placed into the 4th period of the periodic table. For higher nuclear charge numbers, however, the differences between the orbital energies are so small that the energy sequence of the orbitals shown in the energy-level diagram no longer applies to each individual element in the periodic table. In these cases the exact energy position is influenced by the partial, semi- or full occupation of the orbitals by electrons. This can be seen in the case of the lanthanides with the 4f-orbitals, which are only placed after the element lanthanum into the 6th period and not – as would be expected according to the energy-level diagram – already after the element barium.

Figure 1: Energy-level diagram of the electron orbitals

Isotopes
Isotopes are atoms of the same element with the same number of protons but with a different mass number, i.e. with a different number of neutrons. To give isotopes a unique designation, the mass number is given at top left next to the atom symbol and the number of protons is given at bottom left so that the number of neutrons can be calculated straight away by subtraction. Most naturally occurring elements are isotopic mixtures. Carbon, for example, is made up 98.89 % of ${}^{12}_{6}C$ and 1.11 % of ${}^{13}_{6}C$. The proportion of ${}^{14}_{6}C$ is at 10^{-10} % very low. ${}^{14}_{6}C$ in comparison with ${}^{12}_{6}C$ and ${}^{13}_{6}C$ not a stable isotope. The ratio of ${}^{14}_{6}C$ to ${}^{12}_{6}C$ is used in the radiocarbon method to determine the age of organic matter.



Nuclides
The term nuclide is broadly defined. All atoms that differ in the constitution of their nucleus are called nuclides. The number of nuclides therefore corresponds to the number atom types. The 8th Edition of the Karlsruhe Nuclide Chart in 2012 lists 3,847 experimentally verified nuclides and isomers. Isomers are nuclides which have the same mass number and thus the same number of protons and neutrons. Isomeric nuclides, however, show differences in the internal state of the atomic nuclei. Atomic nuclei can assume excited states as well as the normal state. Only around 270 nuclides are stable. The majority of nuclides are radioactive and are therefore called radionuclides.

Radioactive decay

α-decay

In the case of natural radioactivity [2] α-decay is observed when the atomic nucleus emits a double positively charged helium nucleus He^{2+} consisting of two protons and two neutrons. The mass number of the atomic nucleus is reduced by 4 and the nuclear charge number by 2. A different element is created (example, see Figure 2a).

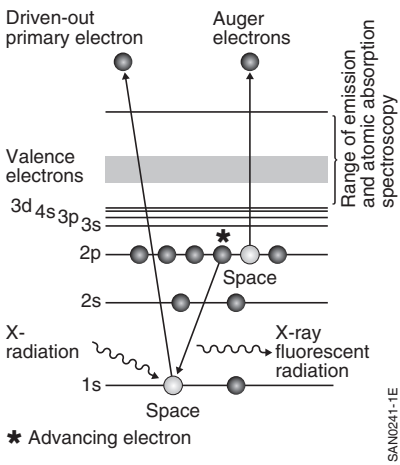
Figure 2: Types of radiation for natural radioactive decay
a) α-radiation,
b) β^--radiation,
c) β^+-radiation,
d) γ-radiation,
n Neutron,
p Proton,
e^- Electron,
e^+ Positron.

β-decay

An element transmutation also occurs in the case of radioactive β-decay. β^- decay is observed when a neutron from the atomic nucleus emits an electron (example, see Figure 2b). This increases the number of protons by 1 and the element with the next higher atomic number is created. When instead of an electron a positron, i.e. a positively charged particle, is emitted, β^+-decay takes place. A proton is transformed into a neutron in the case of β^+-decay. Where the mass number is the same, the nuclear charge number is therefore decreased by 1 such that the preceding element in the periodic table is created (example, see Figure 2c). β-decay also witnesses the release of antineutrinos (in the case of β^--delay) or neutrinos (in the case of β^+-decay), which cannot be discussed further at this stage.

γ-decay

In the case of γ-decay the atomic nucleus emits internal energy from excited nucleus states which for the most part arise during α- or β-decay. The γ-radiation emitted during γ-decay does not change the mass number; the element remains intact (example, see Figure 2d).



Artificial element transmutation

Elements can also be artificially transmuted into each other by bombardment with high-energy particles. Neutrons, singly or doubly positively charged hydrogen (H^+) and helium nuclei (He^{2+}), but also γ-radiation are suitable for this purpose. Depending on the type and acceleration of the particles, this results in the particle being absorbed in the atomic nucleus – sometimes also involving the emission of a proton or neutron – or in nuclear fission.

Half-life
Radioactive decay is a monomolecular reaction (first-order reaction) in which the decaying share per unit of time is directly proportional to the available quantity. Because the available quantity constantly diminishes due to the radioactive decay continuously taking place, the reaction rate decreases more and more. The half-life of the radionuclide is specified so that the rate of radioactive decay can be described independently of the quantity. The half-life is the period of time after which half the atomic nuclei have decayed. The shorter the half-life of the radioactive element, the higher its specific activity, i. e. the more nuclear decays occur per unit of mass.

Element spectroscopy
All chemical elements differ in their atomic structure and can therefore be identified by means of their electron spectra and quantified into mixtures [3]. To release electrons from their energy levels, it is necessary to supply energy to the order of their binding energy from an outside source.

Figure 3: Electron migrations in element spectroscopy

X-ray fluorescence analysis
The inner electrons more tightly bound by the attraction of the positive atomic nucleus can only be released with X-radiation or with electrons of sufficient energy. X-ray fluorescence analysis (XRF) is based on the fact that the spaces created on the more favorable inner energy levels are filled by higher-energy electrons. These advancing electrons release the excess energy in the form of fluorescent radiation. The energy of the fluorescent radiation corresponds exactly to the difference between the higher and the lower energy levels and is thus element-specific (Figure 3).

Auger electron spectroscopy
The energy released by advancing electrons can be output as fluorescent radiation, but can also be transmitted to other electrons. An electron can leave the atom with the transmitted energy. These electrons from the so-called Auger process likewise contain highly specific element information, since the following contributions determine the energy of the Auger electron: The orbital energy of the originally driven-out electron, the energy that is released by the advancing electron, and the energy of the electron emitted in the Auger process itself (Figure 3). The energy of the emitted electrons is analyzed in Auger electron spectroscopy.

Emission spectrometry
The less tightly bound outer valence electrons can already be thermally excited and thereby raised to higher, unoccupied energy levels. Because the energy from the flame of a gas torch is not sufficient to excite the valence electrons of all the elements, a plasma is often used for excitation. In the case of inductively coupled plasma optical emission spectrometry (ICP-OES), the light released during the fallback of the valence electrons that is in the visible and ultraviolet range is registered. As with the inner electrons, the energy difference between the outer occupied and unoccupied energy levels is also element-specific.

Atomic absorption spectroscopy
Instead of emitted radiation, light absorption can also be measured through the excitation of the valence electrons. To this end, in atomic absorption spectroscopy (AAS) the emitted radiation of the element to be analyzed is irradiated by a hollow-cathode lamp. When the element in the sample matches the element of the hollow cathode, the excitation of the electrons in the sample causes a weakening in the intensity of the excitation light. Because the verification of different elements accordingly requires an extensive range of materials for hollow-cathode lamps and can only be measured sequentially, atomic absorption spectroscopy has not established itself in multi-element analyses.

X-ray photoelectron spectroscopy
In X-ray photoelectron spectroscopy (XPS) electrons are driven out from all the energy levels in the atom by high-energy X-rays. The element-specific binding energy can be inferred from the kinetic energy of these electrons. Only the valence electrons are released by the ultraviolet light used instead of X-rays in ultraviolet photoelectron spectroscopy (UPS). The kinetic energy of valence electrons can be determined very precisely such that even conclusions can be made as to the type of chemical bonds by way of differences in the orbital energies.

X-ray diffraction
X-ray diffraction on solids is, as the name suggests, not a spectroscopic procedure. The X-radiation diffracted on the crystal lattice is registered with angular resolution, i.e. according to its diffraction angle [4]. The angle position, intensity and width of the diffraction peaks enable the lattice structure to be analyzed and thus crystals to be identified (crystal-structure analysis). Crystallite size, preferred orientations (textures) and lattice distortions can also be determined in mixtures. Internal mechanical stresses of components can likewise be determined.

Chemical bonds

The type of bond which tends to be adopted by the individual elements is determined by the number and arrangement of electrons around the atomic nucleus (electron configuration) [5]. The nature of these bonds can differ greatly. A distinction is made between ionic, covalent and metallic bonds. Single atoms without a chemical bond occur in nature in noble gases and in some elements in the vapor phase.

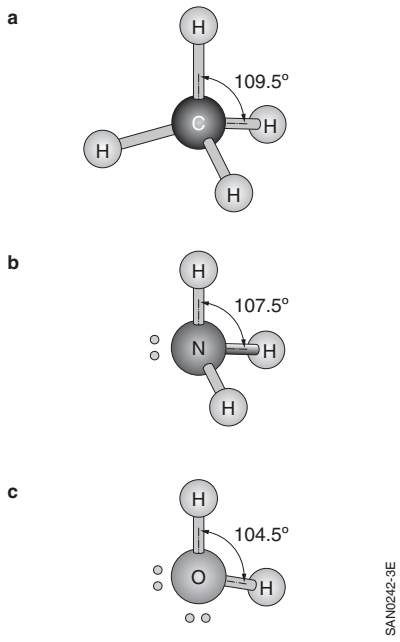
Additional, but far weaker interactions exist between molecules, i.e. particles which are composed of two or more atoms. The weak attractive forces, which have different physical causes, mean that not only ions but also molecules adopt a short-range order, which is only eliminated in the gaseous phase.

Ionic bonds
Ionic bonds tend to form in compounds between metallic and non-metallic elements. This results in the transfer of electrons. Metal atoms (electron donors) lose electrons and become positively charged cations. By gaining electrons, the non-metal atoms (electron acceptors) become negatively charged anions. The terms “cation” for a positively and “anion” for a negatively charged ion are so called because these ions move in an aqueous solution in the electric field to the oppositely charged electrodes, i.e. the cation to the negatively charged cathode and the anion to the positively charged anode.

The number of lost and gained electrons is determined by the electron configuration of the element. Ionic compounds with configurations in which the p-, d- and f-orbitals are empty, half-full and full are especially preferred.

The ionic compounds created are called salts. In a solid the cation and anion are arranged in an ionic lattice whose structure is determined by the ratio of ionic radii. When salts are melted or dissolved in water, the forces between the ions in the lattice must be overcome. Therefore heat of fusion (enthalpy of fusion) must be supplied. The energy required for dissolving (heat of solution) is determined by two opposing components. Firstly, energy to dissolve the crystal lattice must be applied (heat of dissociation); secondly, energy is released by coordination of the solvent molecules to the dissolved-out ions (heat of solvation). If the solvent is water, the heat is called heat of hydration. If the energy of dissociation is greater than the heat of solvation, the solution cools during the dissolving process. When anhydrous metal salts are dissolved in which initially water is also introduced into the ionic lattice, the heat released by hydration is often greater than the energy consumption to overcome the lattice forces, and the solution heats up.

Covalent bonds



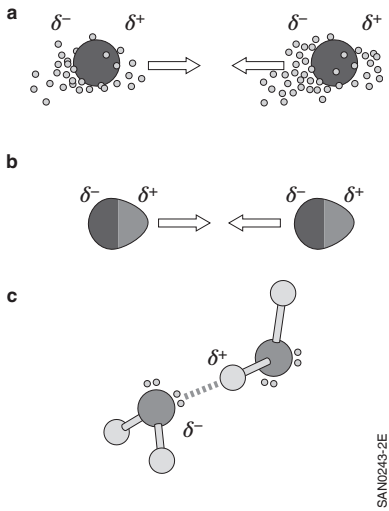
Bonds of electron pairs which are created between two neutral atoms from the unpaired electrons in the outer orbitals (valence electrons) are called atomic bonds. The term "covalent" illustrates that two identical or similar atoms can, by forming a common electron pair, achieve an energetically more favorable electron configuration without involving an electron transfer and with it a change in the valency by the formation of ions. The configuration of the noble gas from the period in which the element is found is usually adopted as an energetically more favorable state.

In a methane molecule (CH_4) all the atoms have a noble-gas configuration. Carbon has in the p-orbitals two valence electrons and four free spaces for further electrons which are made available by the four hydrogen atoms. Carbon thus achieves the noble-gas configuration of neon. Because the two atoms share the common bonding-electron pair, the hydrogen atoms, which only have in each case one valence electron in the s-orbital, also attain the noble-gas configuration of helium through the common electron pairs with the carbon. In the case of the main-group elements of the 2nd period, the filling of empty orbitals with valence electrons of other atoms until the noble-gas configuration is attained is called the octet rule, because then a total of eight electrons, two in s- and six in p-orbitals, are present.

An atom can enter into several covalent bonds with a neighboring atom, such as for example carbon double bonds in ethylene ($H_2C=CH_2$) or triple bonds in acetylene ($H-C\equiv C-H$).

In the octet rule existing free electron pairs which have not bonding function are also taken into account. The three-dimensional structure of molecules is determined by the total number of atoms, by the type and number of bonding-electron pairs, and by the available free electron pairs. For example, methane (CH_4), ammonia (NH_3) and water (H_2O) have a tetrahedral basic structure. However, only the methane molecule represents an ideal tetrahedron with a bond angle of 109.5° (Figure 4). Free electron pairs require a greater amount of space then bonding-electron pairs. The available free electron pair in ammonia reduces the bond angle to 107.5°. The water molecule has two available free electron pairs, further reducing the bond angle to 104.5°.

Figure 4: Influence of free electron pairs on the structure of molecules
a) Methane (CH_4),
b) Ammonia (NH_3),
c) Water (H_2O).



In the simplified model presented here covalent atomic bonds are put down to the formation of pairs of valence electrons from atomic orbitals. However, solely examining atomic orbitals only touches the surface of the complex conditions in a molecule. All the atomic nuclei and electrons in a molecule influence each other, and the bonding conditions are therefore better described by molecular orbitals. A quantum-mechanical examination of molecular orbitals is required to describe double and triple bonds and delocalized bonding systems in aromatic compounds; it is perfectly sufficient in this case to confine oneself to the valence electrons.

Metallic bonds
In metals the atoms are arranged in three-dimensional lattices where the valence electrons of the atoms move freely and are therefore often referred to as electron gas. Metals are good conductors of electricity and heat, which can be put down to the free valence electrons. The lattice vibrations of the atoms also control to the thermal conductivity; here the atoms vibrate freely in their positions in the metal lattice and can easily transmit heat in this way. Here too, a quantum-mechanical examination of molecular orbitals is required to better understand the greater complexities of the electric conductivity of metals. It is possible to derive from this that the electrons reside in energy bands which are formed from molecular orbitals with the smallest energy differences. Between the energy bands are zones which cannot be occupied by electrons.

Interactions between molecules
Van der Waals forces
Partial charges which are created by three-dimensional fluctuations of the positive and negative charge concentrations in the molecule induce electric dipoles (Figure 5a). Interactions that are created between the molecules polarized in this way are called van der Waals forces. The bigger the molecule, the more it can be polarized and the stronger the intermolecular forces.

Dipole-dipole interactions
In molecules which are composed of different atoms the charge concentration is continuously displaced (Figure 5b). Depending on the size and the charge of the atomic nuclei and inner electrons involved, the valence-electron pair is subjected to different degrees of attraction. The property of atoms to attract the bonding-electron pair is known as electronegativity. The more strongly attracting, more electronegative atom receives a partially negative charge. Correspondingly, the more weakly attracting atom receives a partially positive charge. The permanent dipoles brought about by a difference in the electronegativity exhibit intermolecular forces that are much stronger than van der Waals forces. These phenomena are called dipole-dipole interactions.

Figure 5: Types of interactions between molecules
a) Van der Waals forces,
b) Dipole-dipole interaction,
c) Hydrogen bond.
δ^+ Positive partial charge,
δ^- Negative partial charge.
Arrows indicate the force action.

The dipole-dipole interactions are also influenced by the three-dimensional structure of the molecule. Although there are differences in the electronegativity of carbon and oxygen, carbon dioxide (CO_2) for example is not a dipole on account of its linear structure. Water (H_2O) with the same atomic ratio 2:1, however, is a dipole, because the central oxygen atom has two free electron pairs, which result in an angled structure.

Hydrogen bonds
The angled structure of the water molecule facilitates additional dipole-dipole interactions (Figure 5c). The partially positively charged hydrogen atoms can interact with the free electron pairs of neighboring molecules. In liquid water the additional dipole-dipole interactions provide a particular short-range structure, which is responsible for water having the highest density at 4 °C. This enables fish to survive in winter because water with the highest density collects at the bottom of frozen lakes.

Molecular spectroscopy
Molecules, like atoms, can absorb energy and assume defined energy states. Valence electrons can be excited with ultraviolet or visible light (UV/VIS spectroscopy) and vibrations and rotations with infrared light (IR spectroscopy) respectively [6]. These procedures are used to explain structures because energy absorption allows conclusions to be drawn about molecular structure. In Raman spectroscopy the inelastic scattering of monochromatic light of molecules is analyzed. The frequency-shifted portions for example resulting from excitation of vibrations provide structural information.

Mass spectroscopy on the other hand is not based on the excitation of energy states. In this procedure molecules are ionized and the ions obtained are separated according to their mass-to-charge ratio and identified.

Substances

Substance term in chemistry
The chemical properties of a body are determined by its material and not by its size and shape. The material of a body is therefore also called substance. Even where the body has a very fine distribution the chemical properties remain the same. However, a large surface can increase the reactivity, as can be seen in nanoparticles.

Homogeneous and heterogeneous substances
Substances with a uniform structure are termed single-phase or homogeneous. A substance that is made up of two or more parts which cannot be mixed with each other is termed heterogeneous. An example of a homogeneous solid substance is elementary sulfur. Typical of a heterogeneous solid mixture is granite, which is made up of quartz, feldspar and mica.

Dispersion
Heterogeneous mixtures are always dispersions. Dispersions consist of at least two different substances which under the prevailing conditions do not or barely dissolve in each other and do not chemically react with each other. Depending on the phases, a distinction is made between suspensions (liquid and solid), emulsions (liquid and liquid) and aerosols (gas and solid or gas and liquid).

Suspension
If, for example, clay is added to pure water – a homogeneous liquid – this creates a heterogeneous mixture of a liquid and a solid which is termed a suspension.

Emulsion
Heterogeneous mixtures of two liquids, e.g. water and oil, are called emulsions.

Aerosol
A heterogeneous mixture of solid or liquid floating particles and a gas is called an aerosol. An example of an aerosol of gases and solids is exhaust gas with soot particles. Exhaust gas with white smoke, which is produced when water and sulfuric acid condense during the starting operation in the still cold exhaust gas, is on the other hand an aerosol of gases and liquids.

Colloid
The term colloid is used for particles or droplets ranging in size between 1 nm and 1 µm, irrespective of whether the heterogeneous mixtures are suspensions, emulsions or aerosols.

States of aggregation
The three classic states of aggregation (phases) are solid, liquid and gaseous – depending on whether the particles are in a fixed position in a solid body, can move in a liquid while maintaining a short-range order, or are far apart from each other in a gas. Plasma is a non-classic state of aggregation and consists of free electrons and ionized atoms.

The states of aggregation of substances are pressure- and temperature-dependent and are described in the state or phase diagrams. State diagrams, in which pressure is plotted against temperature, explain the conditions under which a solid is present, if necessary in different forms, the so-called modifications. Modifications refer to the phenomenon when a substance in the solid state occurs in different structural forms. Also following from the state diagrams are the ranges in which a liquid or a gaseous phase is present.

State diagram for carbon
The state diagram for carbon shows the solid modifications of graphite and diamond (Figure 6), where in ranges of these phases the other modification exists in parallel as a metastable form. Metastable means that the transformation of a modification is inhibited despite its higher energy content for small changes of state. Graphite is the stable modification at room temperature and atmospheric pressure; diamonds exist however as a metastable structure variant because the transformation into the more stable graphite form is strongly curbed by a high activation energy.

State diagram for water

The three areas in the state diagram for water show the existence ranges of ice, liquid water and vapor (Figure 7). Within these areas only the respective state of aggregation prevails. The curves between the areas describe the equilibrium between the liquid and gaseous phases (vaporization curve), the solid and liquid phases (fusion curve), and the solid and gaseous phases (sublimation curve). Each point on the curves corresponds to a state of equilibrium between the adjacent phases. At the point where the three curves intersect, the triple point TP (0.01 °C; 6.1 mbar), all three phases of water at equilibrium with one another. If the temperature or pressure is changed, only one state of aggregation still exists. If temperature and pressure are simultaneously changed in such a way that the new state corresponds to a point on one of the equilibrium curves, two phases exist next to each other.

An increase in temperature always results in a higher proportion of gaseous water, either through greater sublimation or through a higher vapor pressure. Conversely, a higher ambient pressure results in more condensation or resublimation of water vapor. The vapor-pressure curve demonstrates that the boiling point of water is dependent on external pressure. At low air pressure or in a vacuum water boils at temperatures below 100 °C.

What is conspicuous is the anomaly that can be observed at the phase transition from solid to liquid. An increase in both temperature and pressure causes ice to liquify. The transformation of ice into liquid water is furthered by pressure, because water assumes a smaller volume than ice.

A special thermodynamic state is the critical point CP (374 °C; 220.5 bar), at which the densities of the gaseous and liquid phases become indistinguishable. At the end of the vaporization curve the two states of aggregation – fluid and gaseous – pass into a new state, the supercritical phase. Water in the supercritical state is a liquid which has a lower density than liquid water below the critical point.

Figure 6: State diagram for carbon

Substance concentrations

To be able to describe the quantitative proportion of the substances involved in a chemical reaction, it is necessary to have quantitative details which refer to the number of particles involved in the conversion.

Owing to the different structure of atomic nuclei all element atoms and naturally also all the resulting molecular compounds differ in mass. It would not be very practicable to reckon with the minute masses of individual atoms or molecules directly. Because it is also helpful for chemical reactions always to consider the same number of particles, the term amount of substance was introduced with the unit "mole".

Amount of substance
An amount of substance n of 1 mole always contains the same number of particles and was therefore previously also often referred to as mole number. Irrespective of the chemical element, molecule or type of substance, 1 mole contains approximately $6 \cdot 10^{23}$ particles. This particle number can be experimentally determined and is also known as "Avogadro's number".

Molar mass
1 mole of a substance therefore always consists of around $6 \cdot 10^{23}$ particles. For element atoms the mass of these particles (molar mass M) therefore corresponds to their relative atomic mass, e.g. 1 mole of carbon has a mass of 12.011 g.

For chemical compounds the molar mass is calculated from the molar masses of the contained elements. Carbon dioxide (CO_2) has a molar mass of 44.01 g/mole (12.011 g/mole for carbon and $2 \cdot 15.9994$ g/mole for oxygen).

The molar mass of a substance – the mass of 1 mole of particles – therefore corresponds to a macroscopically manipulable amount of substance. The molar mass M is the quotient of the mass m and the amount of substance n of a substance (unit g/mol):

$$M = \frac{m}{n}.$$

In chemistry the term weight is also used instead of mass. Mass denotes the matter contained, weight the force acting as a result of the gravitational field on this matter. Since the force of gravity on Earth is approximately always the same, often no distinction is made between mass and weight. That is why the term "molar weight" is also widely used.

Molar volume
Since 1 mole of a substance always consists of the same number of particles, the volume (molar volume V_M) that these particles assume is always the same – provided the particles do not influence each other. This limiting case is only given for an ideal gas: 1 mole of an ideal gas assumes under normal pressure (p = 1013.25 mbar) at T = 273.15 K (0 °C) a volume of 22.414 l and at T = 298.15 K (25 °C) a volume of 24.789 l. With regard to the standard conditions, weight- and volume-specific concentration details about the molar volume can be approximately converted into each other for all gases.

Mole percent
Some concentration details are given in mole percent. A distinction is made here between the amount-of-substance- and volume-related definitions. The amount-of-substance-related concentration mole percent x with the unit % (n/n) is obtained by multiplying the mole fraction x_i – i.e. the amount of substance n_i of the constituent i referred to the sum of the amounts of substance of all the constituents of the substance mixture – by 100 %:

$$x = \frac{n_i}{\sum_{j=1}^{n} n_j} \cdot 100.$$

In the case of ideal gases the same particle number always assumes the same volume so that mole percent and percent by volume are identical.

Reactions of substances

Chemical thermodynamics
In chemical reactions starting substances are converted into reaction products with different properties. Chemical thermodynamics describes the substance conversion and the accompanying change in the internal energy ΔU, i.e. in the end whether and under what conditions reactions can take place [7]. The reaction path is determined by the amount of absorbed or output energy.

Heat of reaction
Most reactions are determine in open vessels, i.e. at a constant air pressure. At a constant pressure the change in the internal energy in a chemical reaction is made up of the two components heat of reaction Q_P and work W:

$$\Delta U = Q_P + W.$$

Mechanical work is done for example in an exothermic reaction in which a gas is produced which expands against atmospheric pressure or presses against a membrane or a moving punch.

Reactions can also be effected under a constant volume. Because then the energy content can only be changed by the heat of reaction Q_V and not by work W, the change in the internal energy ΔU corresponds to the heat of reaction Q_V. The following applies:

$$\Delta U = Q_V .$$

The heat of reaction heat at constant volume Q_V is therefore always greater than Q_P at constant pressure.

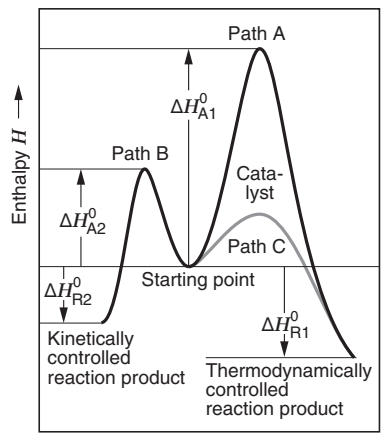
Enthalpy of reaction
The proportion of the heat of reaction Q_P or Q_V can also be described as the difference in heat contents of reaction and starting products and is called the enthalpy of reaction ΔH_R. Where heat is absorbed, the reaction is endothermic ($\Delta H_R > 0$). Chemical reactions in which heat of reaction heat is released ($\Delta H_R < 0$) are exothermic.

The relationship

$$\Delta U^0 = \Delta H_R^0 + W^0$$

is known as the first law of thermodynamics. As the change in the internal energy ΔU, the enthalpy ΔH_R and the work done W are dependent on the pressure and temperature, the standard conditions at 25 °C and 1,013 mbar are referenced and this is indicated at the symbols with a superscript zero (e.g. for ΔU^0).

Enthalpy of activation
Even exothermic reactions often have an initial energy demand despite the released enthalpy of reaction ΔH_R. This enthalpy of activation ΔH_A must be expended in order for example to break bonds and establish an activated complex of reacting agents before more energy is released by the creation of new bonds during the formation of the reaction product than was required to break the bonds in the starting products.



Thermodynamically and kinetically controlled reaction progression
The thermodynamically stable, i.e. energetically more favorable reaction product is reproduced in a reaction when the enthalpy of activation required for substance conversion is applied, e.g. through the supply of heat from the outside (Figure 8, path A). However, if the enthalpy of activation ΔH_{A1}^0 which is required to create the thermodynamically more stable product is not available, another chemical reaction may nevertheless under certain circumstances occur, namely the creation of the product kinetically controlled by the reaction rate. To create it an enthalpy of activation ΔH_{A2}^0 is likewise required (path B), but this is lower in terms of absolute amount. This product created by kinetic control of the reaction then has a higher internal energy. By choosing the reaction conditions, i.e. for example via the quantity of heat made available to the reaction, it is possible to influence whether the thermodynamically or kinetically controlled product tends to be created.

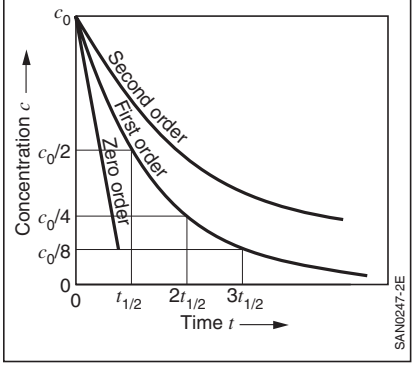
Catalyst decrease the enthalpy of activation of a reaction and thereby increase the reaction rate; but they cannot shift the thermodynamic equilibrium (path C).

Entropy

The enthalpy of reaction ΔH_R alone is not the only factor that determines the direction of a reaction. The distribution of the energy content also plays a role. The evaporation of a liquid takes place despite the required heat of evaporation $\Delta H_V > 0$ because the constraints for the individual molecules decrease as a result. The kinetic energy distributed to the individual molecules passes over from a more ordered, less probable distribution to a state of lesser order but greater probability. The change in the state of order is described by way of the characteristic entropy S [7]. Entropy increases in chemical reactions when more molecules are created than abreact, when the temperature rises, or when particles change to a less ordered state of aggregation (e.g. from solid to liquid or from liquid to gaseous). The increase in entropy ΔS is greater, the higher the heat input and the lower the temperature T at which the heat is transferred.

Figure 8: Enthalpy changes in thermodynamically and kinetically controlled reactions

Reaction kinetics



Whereas thermodynamics describes the conversion of substance and energy, reaction kinetics is concerned with the velocity or rate of reactions [7]. The reaction rate of a substances involved in the reaction is specified as a change in concentration per time interval (Figure 9). The order of a reaction is derived from the number of starting substances whose concentration changes during the reaction.

Zero-order reaction

A zero-order reaction exists for example when the decay of a gas on a platinum surface is heterogeneously catalyzed. The concentration of the gas adsorbed on the catalyst does not change during the reaction such that the reaction rate always remains the same, regardless of the reaction time.

Figure 9: Decrease in the concentration of a starting substance in reactions of different orders (assuming equal starting rates)

$t_{1/2}$ Half-life.

First-order reaction
In a first-order reaction the reaction rate depends only on the concentration of the or a starting product. Many decay processes such as radioactive decay for example follow a first-order reaction which is characterized by the fact that the time in which the concentration of the starting product decreases by half (half-life) is always the same. The half-life is therefore not dependent on the starting concentration.

Second-order reaction
A reaction between two molecules is called a second-order reaction when the reaction rate is determined by the concentration of the two starting substances. If one of the reactands is present in a very large surplus, as is the case for example in hydrolysis reactions in which water is simultaneously the solvent and the reacting agent, the reaction rate equates to that of a first-order reaction. This is called a pseudo-first-order reaction.

With equal starting concentration and starting rate a second-order reaction always runs more slowly than a first-order reaction. The rate of the two reaction types is dependent on the concentration of the starting substances. In a second-order reaction, however, it is necessary to factor in that for a substance transformation – unlike in a first-order reaction – a collision of molecules of the two reacting agents is required and also not every collision actually results in a transformation.

Third-order reaction
The probability of a trimolecular reaction, i.e. the simultaneous collision of three particles, is statistically low. For this reason, third-order reactions occur only very rarely.

Chemical equilibrium
Most chemical reactions are reversible, i.e. an equilibrium is obtained between the starting substances and the reaction products [8]. The position of equilibrium can naturally shift markedly from one side to the other and is influenced by a change in the concentration of a reacting agent, by removal of a reaction product, and by the choice of temperature.

In the reaction of two gaseous substances the conversion can be completed by increasing the pressure when the total number of molecules decreases due to the substance transformation. Low pressure would result in a worse conversion.

Similarly to pressure changes in gas reactions, changes in concentration also result in liquids. Dilution supports reactions which are accompanied by an increase in the number of particles. Catalysts on the other hand – as already described – cannot change the position of equilibrium, but can only influence the rate of its onset.

Law of mass action
Chemical equilibrium is described by the law of mass action [8]. The equilibrium constant K is obtained from the product of the concentrations c of substances C and D, which take part in the back reaction, divided by the product of the concentrations c of substances A and B, which are involved in the direct reaction. The law of mass action applies equally to dissolving processes, chemical reactions and changes of state:

$$A + B \rightleftharpoons C + D,$$

$$K = \frac{c(C) \cdot c(D)}{c(A) \cdot c(B)}.$$

When a salt is dissolved, this creates positively and negatively charged ions, i.e. cations and anions, which are in solubility equilibrium with the undissolved sediment. In a saturated solution the number of ions which dissolve equals the number of ions which precipitate again. x describes the number of cations A and y the number of anions B in the salt A_xB_y. The dissolving process sees the creation of x dissolved cations A, whose positive charge is determined by the number y of anions B. This is accompanied by the creation of y dissolved anions B with a negative charge, which is dependent on the number x of cations A.

$$A_xB_y \rightleftharpoons xA^{y+} + yB^{x-},$$

$$K = \frac{c(A^{y+})^x \cdot c(B^{x-})^y}{c(A_xB_y)}.$$

However, the law of mass action applies in this form only to the limiting case of an ideal solution without interaction between the dissolved particles. This is approximately the case with highly diluted solutions as are created when hardly soluble salts are dissolved.

Generally speaking, the law of mass action can only be applied to solutions when the concentrations c of ions are corrected by a factor f downwards. This factor, which takes into account the mutual influence of the dissolved particles, is concentration-dependent and is known as the activity coefficient f. Thus: $f \leq 1$. The activity coefficient takes into account the tendency of ions to associate in the solution due to the difference in charge. The concentration c corrected by the activity coefficient f is called the activity a. Thus:

$$a = f \cdot c,$$

$$K = \frac{a(A^{y+})^x \cdot a(B^{x-})^y}{a(A_xB_y)}.$$

No concentration can be specified for the undissolved portion. This portion is considered to be constant and set at one. In this simplified form the law of mass action is called the solubility product K_L:

$$K_L = a(A^{y+})^x \cdot a(B^{x-})^y.$$

The unit of the solubility product depends on the number of different particle types which are created during the dissolving process. The lower the solubility product, the harder the salt is to dissolve. For improved clarity, as a rule the decimal logarithm of the numerical value of K_L multiplied by –1 is specified instead of the solubility product and denoted as pK_L. The greater the pK_L value, the lesser the solubility.

The proportion of salt that dissolves decays into cations and anions. The process of splitting into separate ions of different charge is frequently called dissociation. The dissolving of salts creates many charge carriers which help to conduct electric current. In aqueous solutions chemists refer to strong electrolytes.

In daily laboratory practice calculations are made approximately with concentrations c instead of with activities a. The term "concentration" is used instead of "activity" in the following text, even if the activity is retained as the physical variable in the formulae.

Acids in water

Even acids (HA, A stands for acid) dissociate in water with the delivery of hydrogen ions H^+ to the water molecules and creation of hydroxonium ions H_3O^+ (protolysis). Here too the law of mass action can be applied [8].

$$HA + H_2O \rightleftharpoons H_3O^+ + A^-,$$

$$K = \frac{a(H_3O^+) \cdot a(A^-)}{a(HA) \cdot a(H_2O)},$$

$$K_a = K \cdot a(H_2O) = \frac{a(H_3O^+) \cdot a(A^-)}{a(HA)}.$$

The concentration of water with 55.3 mol/l remains virtually constant and is incorporated into the equilibrium constant, which is then called the acidity constant or K_a value and has the unit of a concentration in mol/l. When the K_a value is high, the equilibrium moves markedly to the right. The concentration of hydroxonium ions (H_3O^+) is high. The acid therefore has a high acidic strength.

The K_a value is as a rule converted into the pK_a value, whereby the K_a value is initially divided by the standard concentration of 1 mol/l. The decimal logarithm multiplied by –1 then produces the pK_a value. Strong acids have a low or even negative pK_a value.

Acidic strength of water
Even in chemically pure water the water molecules are present in equilibrium with hydroxonium ions (H_3O^+) and hydroxide ions (OH^-).

$$2\ H_2O \rightleftharpoons H_3O^+ + OH^-.$$

The ionic product K_w of water is always 10^{-14} mol^2/l^2. Autodissociation of water is therefore very low, in which hydroxonium ions (H_3O^+) and hydroxide ions (OH^-) are created in equally high concentration of 10^{-7} Mol/l.

Disregarding the water lost through dissociation, the acidic strength K_a of water ($a(H_2O)$ = 55.3 mol/l) is obtained at:

$$K = \frac{a(H_3O^+) \cdot a(OH^-)}{a(H_2O) \cdot a(H_2O)},$$

$$K_a = K \cdot a(H_2O) = \frac{a(H_3O^+) \cdot a(OH^-)}{a(H_2O)},$$

$$-\log K_a = -\log a(H_3O^+) - \log a(OH^-) + \log a\,(H_2O),$$

$$pK_a = 7 + 7 + \log 55.3 = 14 + 1.74 = 15.74.$$

Bases in water
Bases on the other hand, which dissolve in water, absorb hydrogen ions (H^+) [8]. When ammonia (NH_3) is dissolved in water, ammonia molecules adopt hydrogen ions (H^+) from the water molecules. Ammonium ions (NH_4^+) and hydroxide ions (OH^-) are created:

$$NH_3 + H_2O \rightleftharpoons NH_4^+ + OH^-.$$

According to the acidic constant K_a as the measure of acidic strength, it is also possible to describe the strength of bases by way of the base constant K_b. The basicity or base strength is derived from the law of mass action along similar lines to the acidic strength or more simply from the ionic product K_w of water via the relation

$$K_w = K_a \cdot K_b = 10^{-14}\ \text{mol}^2/l^2 \quad \text{or}$$

$$pK_w = pK_a + pK_b = 14.$$

Corresponding acid-base pairs
When an acid, e.g. hydrochloric acid (HCl), is dissociated, the hydrochloric acid represents the acid and the acid anion in equilibrium with the acid after hydrogen-ion delivery, in this example the chloride anion (Cl^-), the base. Together they are called a corresponding acid-base pair. Similarly, a base, e.g. ammonia (NH_3), in water, with its corresponding acid, the ammonium ion (NH_4^+), forms an acid-base pair.

The pK_a and pK_b values are experimentally determined for many acid-base pairs (Table 3). In the event of autodissociation of water, water acts as both an acid and a base. The property of water to act as both an acid and a base is known as amphoteric behavior. When water (pK_a = 15.74) is the acid, after hydrogen-ion delivery hydroxide ions (OH^-, pK_b = –1.74) are the corresponding base. When water (pK_b = 15.74) acts as a base, hydroxonium ions (H_3O^+, pK_a = –1.74) are the associated acid.

pH value
The pH value ("potentia hydrogenii") is defined as the negative decimal logarithm of the activity a^* of the hydroxonium ions (H_3O^+). To obtain a dimensionless quantity, the activity a of the H_3O^+ ions is divided before logarithmization by the standard concentration of 1 mol/l. The decimal logarithm then multiplied by –1 produces the pH value.

$$a^*(H_3O^+) = a(H_3O^+)\ [\text{mol}/l] \cdot \frac{1}{[\text{mol}/l]},$$

$$pH = -\log a^*(H_3O^+).$$

For simplification purposes the activity of the hydroxonium ions is often equated with the concentration.

The pH value is therefore a measure of the concentration of an acid; acid concentration (pH value) and acidic strength (pK_a value) do not necessary run parallel. A diluted hydrochloric-acid solution with a concentration of 10^{-4} mol/*l* can despite the high acidic strength ($pK_a = -6$) be more weakly acidic (pH = 4) than an acetic-acid solution ($pK_a = 4.75$) with a higher concentration of 10^{-1} mol/*l* (pH = 2.87) (Figure 10).

In the event of autodissociation of water, as already described above, hydroxonium ions (H_3O^+) and hydroxide ions (OH^-) in equal concentration of 10^{-7} mol/*l* are created. The pH value is therefore 7, pure water is neutral.

In the laboratory in actual fact pure water often reacts slightly acidly because CO_2 from the air dissolves with the formation of carbonic acid (H_2CO_3) in the water. Carbonic acid dissociates slightly to hydroxonium ions (H_3O^+) and hydrogencarbonate ions (HCO_3^-), pushing the pH value slightly in the acid direction.

The ratio of hydroxonium ions (H_3O^+) to hydroxide ions (OH^-) determines whether a solution is acidic, neutral or basic (Figure 10):

Acidic $a(H_3O^+) > a(OH^-)$: pH < 7.
Neutral $a(H_3O^+) = a(OH^-)$: pH = 7.
Basic $a(H_3O^+) < a(OH^-)$: pH > 7.

Figure 10: pH scale with examples of strong and weak acids and bases

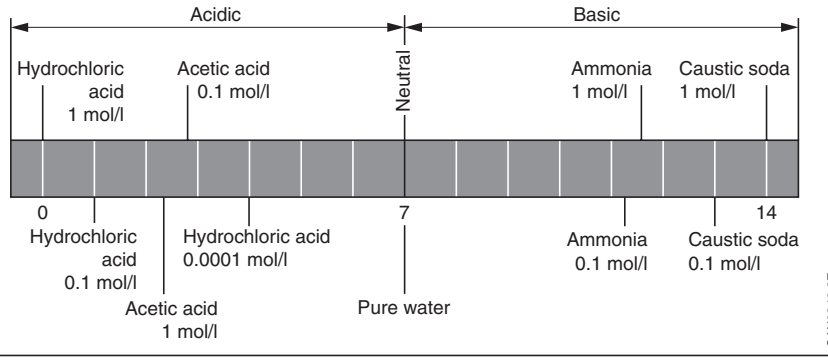


Table 3: pK_a and pK_b values of strong and weak acids

Name	Acidic strength pK_a	Corresponding acid-base pairs		Base strength pK_b
Hydrochloric acid	–6	HCl	Cl^-	20
Sulfuric acid	–3	H_2SO_4	HSO_4^-	17
Hydroxonium ion	–1.74	H_3O^+	H_2O	15.74
Nitric acid	–1.32	HNO_3	NO_3^-	15.32

Hydrogen fluoride	3.14	HF	F^-	10.68
Acetic acid	4.75	CH_3COOH	CH_3COO^-	9.25
Carbonic acid	6.52	H_2CO_3	HCO_3^-	7.48
Ammonium ion	9.25	NH_4^+	NH_3	4.75
Hydrogen-carbonate ion	10.40	HCO_3^-	CO_3^{2-}	3.60
Hydrogen-phosphate ion	12.36	HPO_4^{2-}	PO_4^{3-}	1.64
Water	15.74	H_2O	OH^-	–1.74

pH value, strong acids

Strong acids like hydrogen chloride dissociate completely in water, during which they transfer positively charged hydrogen ions (H^+) to water molecules with the formation of hydroxonium ions (H_3O^+). 0.1 mol (3.65 g) hydrochloric acid in 1 liter of water produces 0.1 mol hydroxonium ions and 0.1 mol chloride anions (Cl^-). A 10^{-1} molar hydrochloric-acid solution therefore has a pH value of 1.

pH value, weak acids

In the case of weak acids, a certain amount of the acid remains undissociated in the water. But because the pH value of weak acids is only determined by the share of dissociated acid molecules, the calculation of the pH value is more complicated. This will be explained here using an acetic-acid solution by way of example:

In solutions of acetic acid in water less than 1% of all the acetic-acid molecules dissolved in water (CH_3COOH) are actually dissociated to hydroxonium ions (H_3O^+) and acetate ions (CH_3COO^-). In an aqueous acetic-acid solution, in contrast to an aqueous table-salt or hydrochloric-acid solution, the electrolyte is weak. The dissociation equilibrium can again be described using the law of mass action:

$$CH_3COOH + H_2O \rightleftharpoons H_3O^+ + CH_3COO^-,$$

$$K_a = \frac{a(H_3O^+) \cdot a(CH_3COO^-)}{a(CH_3COOH) \cdot a(H_2O)}.$$

The concentration of water can again be set at one on account of the large surplus.

Acetic acid has an acidic strength K_a of $1.8 \cdot 10^{-5}$ mol/l or put another way a pK_a value of 4.75. During dissociation as many hydroxonium ions (H_3O^+) as acetate ions (CH_3COO^-) are created. As the dissociation is minimal, the dissociated part compared with the total concentration of acetic acid CH_3COOH can be disregarded.

With $a(H_2O) = 1$ and $a(H_3O^+) = a(CH_3COO^-)$ it follows that:

$$K_a = \frac{a(H_3O^+)^2}{a(CH_3COOH)},$$

$$a(H_3O^+)^2 = K_a \cdot a(CH_3COOH),$$

$$a(H_3O^+) = \sqrt{K_a \cdot a(CH_3COOH)},$$

$$-\log a(H_3O^+) =$$

$$-\frac{1}{2}(\log K_a + \log a(CH_3COOH)) =$$

$$\frac{1}{2}(-\log K_a - \log a(CH_3COOH)).$$

Taking into account the definitions for the pH and pK_a values, the following is obtained:

$$pH = \frac{1}{2}(pK_a - \log a(CH_3COOH)).$$

An acetic-acid solution with a concentration of 0.1 mol/l therefore has a pH value of

$$pH = \frac{1}{2}(4.75 - \log 0.1)$$

$$= \frac{1}{2}(4.75 + 1) = 2.87.$$

pH values of other weak acids and bases can be similarly calculated.

Electrochemistry

When a salt is dissolved in water, the constituents of the salt are present in the water in the form of ions. These ions are charged in such a way that they move when an electric field is applied and thereby generate an electric current. This phenomenon is known as electrolytic conduction. In comparison, the current in an electric conductor such as copper or iron is transported by electrons. In addition to aqueous solutions, molten salts but also certain solids (such as zirconium oxide in the catalytic converter of a passenger car) can function as electrolytes ([9], [10] and [11]).

Negatively charged ions move towards the anode and are therefore called anions, while positively charged ions (cations) migrate towards the cathode. A chemical reaction takes place at these electrodes whereby the ions either absorb electrons from the cathode or discharge electrons to the anode. These reactions can only occur when the cathode and anode have an electrically conductive connection with each other in order to facilitate the exchange of electrons between the two.

If a battery is used as the voltage source, i.e., discharged, the electrons flow from the anode via the external electric circuit to the cathode. Thus, for the user the anode is the negative pole and the cathode is the positive pole.

Electrochemical series of metals

The intensity with which this ion reaction takes place is expressed by the electrochemical series of metals, which is set out in Table 4. The normal potential E^0, applicable to an ion concentration of 1 mol/*l*, is specified. This "normal" concentration is indicated by the superscript index 0. The voltages specified in the table refer to the normal hydrogen electrode, to which a potential of 0 V is therefore allocated. The following therefore applies:

$$E^0(2H^+ + 2e^- \leftrightarrow H_2) = 0\ \text{V}.$$

In Table 4, a positive sign with E^0 indicates an electron absorption (reduction), and a negative sign an electron discharge (oxidation). For example, lithium by preference discharges an electron ($E^0 < 0$) and is oxidized to become the singly charged lithium ion Li^+, while fluorine absorbs electrons ($E^0 > 0$) and is thus reduced.

Oxidation: $2\ Li \rightarrow 2\ Li^+ + 2e^-$,
$E_{Li} = +3.045\ \text{V}$.

Reduction: $F_2 + 2e^- \rightarrow 2\ F^-$,
$E_F = +2.87\ \text{V}$.

Balance equation: $2\ Li + F_2 \rightarrow 2\ Li^+ + 2\ F^-$,
$E = +5.915\text{V}$.

An electrochemical reaction therefore always comprises the two partial steps of oxidation and reduction. Because the lithium discharges the electrons, the electrons appear on the right side of the reaction equation compared with the indication in the electrochemical series of metals (Table 4). The sign preceding the voltage must therefore be reversed for this oxidation equation. The total voltage E of

Table 4: Electrochemical series of metals ([11]) with the associated ion reactions (normal potentials at 25 °C)

Half reactions	E^0 [V]
$Li^+ + e^- \leftrightarrow Li$	−3.045
$Na^+ + e^- \leftrightarrow Na$	−2.714
$Mg^{2+} + 2e^- \leftrightarrow Mg$	−2.363
$Al^{3+} + 3e^- \leftrightarrow Al$	−1.662
$2H_2O + 2e^- \leftrightarrow H_2 + 2OH^-$	−0.828
$Zn^{2+} + 2e^- \leftrightarrow Zn$	−0.763
$Cr^{3+} + 3e^- \leftrightarrow Cr$	−0.744
$Fe^{2+} + 2e^- \leftrightarrow Fe$	−0.440
$PbSO_4 + 2e^- \leftrightarrow Pb + SO_4^{2-}$	−0.356
$Ni^{2+} + 2e^- \leftrightarrow Ni$	−0.250
$Pb^{2+} + 2e^- \leftrightarrow Pb$	−0.13
$Sn^{2+} + 2e^- \leftrightarrow Sn$	−0.136
$2H^+ + 2e^- \leftrightarrow H_2$	0
$Cu^{2+} + 2e^- \leftrightarrow Cu$	+0.337
$Cu^+ + e^- \leftrightarrow Cu$	+0.521
$Fe^{3+} + e^- \leftrightarrow Fe^{2+}$	+0.771
$Ag^+ + e^- \leftrightarrow Ag$	+0.799
$Pt^{2+} + 2e^- \leftrightarrow Pt$	+1.118
$4H^+ + O_2 + 4e^- \leftrightarrow 2H_2O$	+1.229
$Cl_2 + 2e^- \leftrightarrow 2Cl^-$	+1.360
$Au^{3+} + 3e^- \leftrightarrow Au$	+1.498
$PbO_2 + 4H^+ + 2e^- \leftrightarrow Pb^{2+} + 2H_2O$	+1.685
$F_2 + 2e^- \leftrightarrow 2F^-$	+2.87

the redox reaction is thus added up from the individual values. The balance equation thus does not feature any electrons, as these are only exchanged between the reacting agents.

An electrochemical reaction can thus only take place when the total voltage is positive. An acid (i.e., H^+ ions) therefore cannot dissolve copper, silver, platinum, and gold. These are referred to as noble metals. In contrast, base metals such as sodium, elemental iron, nickel and lead are attacked by acids and the metals are dissolved as ions.

To enable an electrochemical reaction to take place, at least two different reacting agents are required. The resulting electrochemical total voltage E is dependent on the concentration of ions (for applications, see Lead battery, Lithium-ion cells).

Nernst equation

The Nernst equation reads:

$$E = E^0 + \frac{RT}{nF} \ln \frac{[\mathrm{Ox}]}{[\mathrm{Red}]} = E^0 + \frac{0.0592\ \mathrm{V}}{n} \log_{10} \frac{[\mathrm{Ox}]}{[\mathrm{Red}]} \quad (\text{at } 25\ ^\circ\mathrm{C}).$$

Here, [Ox] denotes the concentration of oxidized ions, [Red] the concentration of reduced ions, n the number of electrons in the reaction equation, R the gas constant, T the absolute temperature, and F the Faraday constant.

In this way, the potential can be calculated for each chemical partial reaction of the individual ion types. The total voltage of the electrolytic reactions is obtained from the sum total of all the potentials of the partial reactions. Over and above that E is dependent on the temperature.

Application

The oxygen concentration sensor (see λ sensors) measures the residual-oxygen content of the exhaust gas in the internal-combustion engine. To this end, a zirconium-oxide ceramic (ZrO) is used as a solid electrolyte, as this conducts oxygen ions at temperatures over 300 °C. Chemically inert platinum electrodes, which are applied as a porous thick layer, are used as electrodes. The voltage generated at the electrodes U_λ can be calculated with the Nernst equation. If here [Ox] and [Red] are replaced by the oxygen partial pressures $p(O_2)$ in the reference area (ambient air) and in the exhaust-gas area, the following relationship is obtained:

$$U_\lambda = \frac{RT}{4F} \ln \frac{p_\mathrm{R}(O_2)}{p_\mathrm{A}(O_2)}.$$

Here $p_\mathrm{A}(O_2)$ denotes the oxygen partial pressure in the exhaust gas, $p_\mathrm{R}(O_2)$ the oxygen partial pressure in the reference area, R the gas constant, T the absolute temperature, and F the Faraday constant.

Mathematics

Numbers

Quantities

Numbers are divided into natural numbers $\mathbb{N}$ = {0, 1, 2, 3, etc.}, whole numbers $\mathbb{Z}$ = {…, –3, –2, –1, 0, +1, +2, +3, …}, rational numbers $\mathbb{Q}$, real numbers $\mathbb{R}$ and complex numbers $\mathbb{C}$.

In addition to all whole numbers, rational numbers also include all fractions whose numerators and denominators are whole numbers. In addition to the rational numbers, real numbers also include all (infinitely many) numbers between fractions. Two examples of real numbers are the circular constant pi (π = 3.14159…) and the Eulerian number e (e = 2.718281…). Complex numbers are an extension of real numbers. These are explained in detail below (for more information, refer to [1], [2] and [3]).

Number systems

Physical and technical quantities are described by their numerical value and their unit. Numbers are usually represented in the decimal system, i.e. using base 10. Other common number systems are the binary and the hexadecimal systems, which are based on the numbers 2 and 16, respectively. While the decimal system features the digits 0, 1, 2 and onwards through 9, only the digits 0 and 1 exist in the binary system. The hexadecimal system uses, in addition to the digits 0 through 9, the letters A through F to represent the numbers 10 through 15 (for conversion, see Tables 1 and 2).

The binary and hexadecimal systems are used primarily in the field of information technology (IT), since a computer can only process the two states “power off” (“0”) and “power on” (“1”). These two states form the basis of the binary system. When eight binary digits are combined into one byte, it is then possible to represent the numbers 0 to 255, which corresponds to the hexadecimal digits 0 – FF.

Functions

The following section describes elementary mathematics functions. Their most important properties, such as their domain and value set, their behavior for very large and very small x values, their zero points, their derivations and the fundamental arithmetic operations with them are depicted.

These functions have been selected from a very large number of functions since they can be used to illustrate many technical processes, such as the geometric correlations between a connecting rod and moving mechanical parts (see Internal-combustion engines, Crankshaft gears), vibrations and oscillations in the vehicle (see Undercarriage, Basic principles of vibration characteristics), distance measurements of the vehicle relative to other cars and people (see Driver-assistance systems, Parking systems).

Table 1: Decimal and binary system

Decimal	Hexadecimal
0, 1 – 9	0, 1 – 9
10, 11 – 15	A, B – F
16	10
17	11
30	1E
31	1F
32	20
255	FF
4096	1000
65535	FFFF

Polynomial
A polynomial of the nth degree consists of $(n+1)$ summands with real (or complex) coefficients a_0, a_1,..., a_n and the associated monomials x^i:

$$f(x)=a_0+a_1x+a_2x^2+\ldots+a_nx^n,$$

where $a_i \in \mathbb{R}$ (or $a_i \in \mathbb{C}$)
and the domain range $D_f = \mathbb{R}$ (or $D_f = \mathbb{C}$)
and the value set $W_f = \mathbb{R}$.

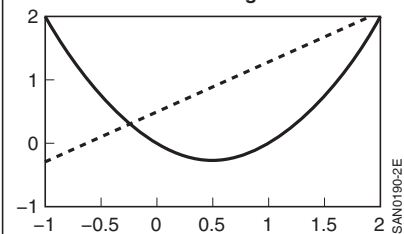
A polynomial of the nth degree may have up to n zero points and $n-1$ local extrema.

Straight line
A straight line is a polynomial of the first degree ($n=1$):

$f(x)=a_0+a_1x$ or
$y=mx+t$ (with slope m and axis intercept t).

The zero point lies at $x_0=-\frac{t}{m}$ (for $m\neq 0$).

Parabola
A parabola is a polynomial of the second degree ($n=2$, quadratic function):



$f(x)=a_0+a_1x+a_2x^2$ or
$y=ax^2+bx+c.$

Zero points: $x_{1/2}=\frac{1}{2a}\left(-b\pm\sqrt{b^2-4ac}\right)$

Table 3: Polynomial

Definition range D_f, value set W_f
$f(x)=a_0+a_1x+a_2x^2+\ldots+a_nx^n$
$D_f=\mathbb{R}$, $W_f=\mathbb{R}$ (or subset).

Figure 1: Straight line (dashed) and parabola as polynomials of the first and second degree

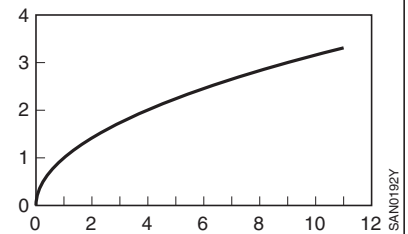
A parabola may have zero, one or two zero points.

In Table 3 and Figure 1 shows by way of example a straight line (polynomial of the first degree) and a parabola (polynomial of the second degree).

Root function
The root function $f(x)=\sqrt{x}=x^{1/2}$ (Table 4 and Figure 2) is the inverse function of the quadratic function $f(x)=x^2$. It is needed for tasks such as solving quadratic equations (e.g. searching for the zero point of a second-degree polynomial, see Polynomial).

This also results in the root term, which is used in the calculating the resonant frequency and the damping ratio of an oscillation (see Oscillations).

Similarly, for each monomial $f(x)=x^n$, $n \in \mathbb{N}$, there is a strongly monotonically growing inverse function



$$f^{-1}(x)=\sqrt[n]{x}=x^{1/n},$$

which is only defined for $x \geq 0$.

Table 4: Root function

Definition range D_f, value set W_f and behavior.	Properties.
$f(x)=\sqrt{x}=x^{1/2}$	$\sqrt{x}\cdot\sqrt{y}=\sqrt{xy}$
	$\sqrt{x^n}=(\sqrt{x})^n$, $n\in\mathbb{N}$
$D_f=\mathbb{R}_0^+$	
$W_f=\mathbb{R}_0^+$	
$x\to+\infty$: $f(x)\to+\infty$	

Figure 2: Curve of the root function

Absolute value and sign function

Each real number x can be broken down into its sign (+/–) and its absolute value $|x|$.

$x = \text{sgn}(x) \cdot |x|$.

For example, sgn(–3) = –1 and sgn(+4) = +1. The absolute value indicates the distance of the number x from a source of 0. The absolute value function (Table 5 and Figure 3) can be represented as

$$f(x) = |x| = \begin{cases} x & \text{for } x \geq 0 \\ -x & \text{for } x < 0 \end{cases}.$$

Exponential function

The exponential function is a very important function in mathematics, physics and technology, because it is the only function that is identical to its own derivative. This central property is used in solving linear differential equations such as the harmonics equation (see Oscillations).

Both the sine and cosine functions are related to the complex exponential function (see Complex numbers). This means the exponential function can be used to describe oscillations.

$f(t) = e^{-\gamma t + i\omega t} = e^{-\gamma t}$ (cos $\omega t + i$ sin ωt).

Here, the real negative exponent $-\gamma t$ represents the damping of the oscillation, while the complex exponent $i\omega t$ reflects the periodic quantity, which becomes clear from the representation of the sine and cosine functions (see Complex numbers, Linear differential equations).

Furthermore, laws of growth (e.g. interest and compound interest calculations) and laws of decay (e.g. radioactive decay) can be expressed with the exponential function. The charging and discharging processes of capacitors also follow an exponential curve (see Capacitor). The final compression pressure, final compression temperature and efficiency of a reciprocating-piston engine are exponentially related to the polytropes – more specifically, the adiabatic exponents (see Reciprocating-piston engine).

Table 6 and Figure 4 show the domain and value set, as well as the properties of the exponential function.

Table 5: Absolute value function

Definition range D_f, Value set W_f and behavior.
$f(x) = \text{sgn}(x)$ $D_f = \mathbb{R}$ $W_f = \mathbb{R}_0^+$ $x \to \pm\infty : \ f(x) \to +\infty$

Table 6: Exponential function

Definition range D_f and behavior.	Properties.
$f(x) = e^x$; $D_f = \mathbb{R}$ $x \to -\infty : f(x) \to 0$ $x \to +\infty : f(x) \to +\infty$ $f(0) = e^0 = 1$	$e^a e^b = e^{a+b}$ $(e^a)^b = e^{ab}$ $\frac{d}{dx} e^x = e^x$
Euler's number $e = 2.71828...$	

Figure 4: Curve of the exponential function

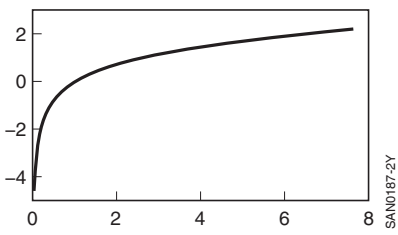
Logarithm function

The logarithm function is the inverse function of the exponential function. This is needed in order to solve equations such as the following:

$$2^x = 8 \Rightarrow x = \log_2 8 \Rightarrow x = 3.$$

Table 7 and Figure 5 show the domain and value set, as well as the properties of the logarithm function.

Application examples



The Nernst equation provides one example of application of the logarithm function. This equation calculates the voltage value from the concentration of oxygen in the surroundings and the exhaust gas, which is necessary for λ regulation (see λ sensor).

In acoustics, decibel level (dB) is defined using the logarithm of the sound pressure (see Acoustics, Decibels). Similarly, logarithms are also used to determine the sound power level and sound intensity level.

Table 7: Logarithm function

Definition range D_f and behavior.	Properties.
$f(x) = \ln x$	$\ln a + \ln b = \ln ab$
$= \log_e x\ ;\ D_f = \mathbb{R}^+$	$\ln a - \ln b = \ln \frac{a}{b}$
$x \to 0:\ f(x) \to -\infty$	$c \ln a = \ln a^c$
$x \to +\infty:\ f(x) \to \infty$	$\frac{d}{dx} \ln x = \frac{1}{x}$
$f(1) = \ln 1 = 0$	

Figure 5: Curve of the logarithm function

Converting different logarithms

The logarithm of the number z for the base a can be converted to the base b as follows (a, $b > 0$):

$$\log_a z = \frac{\log_b z}{\log_b a}$$

This results in $\lg z = \log_{10} z$ for the common (decimal) logarithm and $\mathrm{lb}\, z = \log_2 z$ for the binary logarithm:

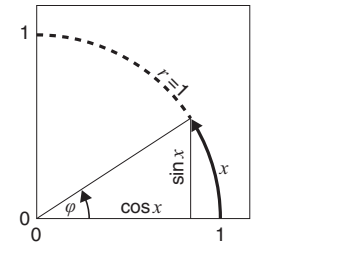
$$\log_a z = \frac{\ln z}{\ln a} = \frac{\mathrm{lb}\, z}{\mathrm{lb}\, a} = \frac{\lg z}{\lg a}.$$

Trigonometric functions

Angular measurement (radians)

In mathematics, angles are usually specified as the measure of an arc in radians and rarely in degrees. So angle $\varphi = 360°$ is equivalent to a arc of $x = 2\pi$. The circumference of a circle with a radius of 1 shares this value.

This yields the following conversions between angle φ in degrees and angle x in radians:



$$\frac{\varphi}{360°} = \frac{x}{2\pi},$$

$$\Rightarrow \varphi = \frac{180°}{\pi} x,$$

$$\Rightarrow x = \frac{\pi}{180°} \varphi.$$

The unit “rad” is often added to an arc measurement to make it clear that the information relates to an angle. Arc x of the angle φ is shown in Figure 6. Angle φ of the associated arc x is shown as a curved arrow.

Figure 6: Sine and cosine in a unit circle

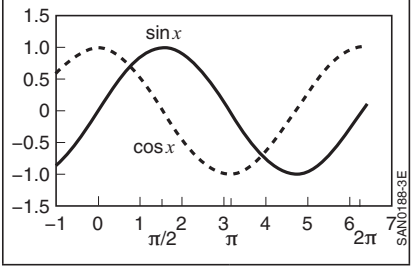
Sine and cosine functions
In a right triangle, the sine of angle φ or arc x is equal to the ratio of the opposite side to the hypotenuse. The cosine is the ratio of the adjacent side to the hypotenuse.

In a right triangle with a hypotenuse with length $r = 1$ (unit circle), the adjacent side corresponds to the cosine and the opposite side corresponds to the sine (Figure 6).

Many periodic processes such as oscillations can be expressed through the sine or cosine function (Table 8 and Figure 7). If the variable x is replaced by

$$x = \frac{2\pi}{T}\,t \text{ and } \omega = \frac{2\pi}{T}$$

where the variable t usually stands for the time, then T is the period of the oscillation. The frequency f is the reciprocal of the period:



$$f = \frac{1}{T}$$

The angular frequency ω still contains the factor 2π; thus, it specifies the angle covered (in radians) per unit of time.

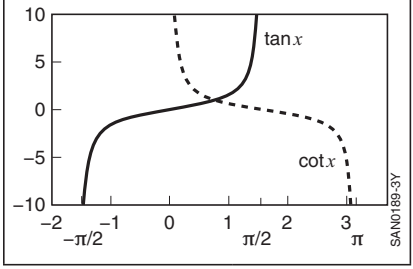
Table 8: Sine and cosine functions

Definition ranges D_f, D_g, Value sets W_f, W_g and behavior.	Properties.
$f(x) = \sin x\,;\quad D_f = \mathbb{R}$	$\sin(x + 2\pi) = \sin x$
$g(x) = \cos x\,;\, D_g = \mathbb{R}$	$\cos(x + 2\pi) = \cos x$
$W_f = W_g = [-1; +1]$	$\sin(x \pm \frac{\pi}{2}) = \pm\cos x$
Period length: 2π	$\cos(x \pm \frac{\pi}{2}) = \mp\sin x$
	$\sin^2 x + \cos^2 x = 1$

Figure 7: Curves of the sine and cosine functions

When a car drives on a street or a country road, it is constantly subjected to large and small bumps and shocks. Therefore, the undercarriage must be constructed so that it absorbs or compensates for the bumps in the road. In addition, the vibrational characteristics of the shock absorbers should be designed with precision (see Undercarriage, Basic principles of vibration characteristics).

Superpositions of oscillations are important in many applications, such as water waves, sound waves and the superposition of alternating electrical current (AC). In addition, the wave is usually formulated as a sine or cosine function



$f(t) = A\,\sin(\omega t + \varphi)$ or
$f(t) = A\,\cos(\omega t + \varphi)$

with (positive) amplitude A and phase shift φ.

Table 9: Tangent and cotangent functions

Definition ranges D_f, D_g, Value sets W_f, W_g, and behavior.	Properties.
$f(x) = \tan(x) = \frac{\sin(x)}{\cos(x)}$	$\tan(x + \pi) = \tan(x)$
$g(x) = \cot(x) = \frac{\cos(x)}{\sin(x)}$	$\cot(x + \pi) = \cot(x)$
	$\tan(x + \frac{\pi}{2}) = -\cot(x)$
	$\cot(x + \frac{\pi}{2}) = -\tan(x)$
$D_f = \mathbb{R} \setminus \{\frac{\pi}{2} + k\cdot\pi,\, k \in \mathbb{Z}\}$	$\cot(x) = \frac{1}{\tan(x)}$
$D_g = \mathbb{R} \setminus \{k\cdot\pi,\, k \in \mathbb{Z}\}$	
$W_f = W_g = \mathbb{R}$	
Period length: π	

Figure 8: Curves of tangent and cotangent functions

If oscillations with the same angular frequency are superimposed, they can be amplified (through constructive interference), weakened or even completely eliminated (through destructive interference). This depends on the phase relation and the amplitudes of the relevant oscillations.

For example, destructive interference is utilized as "anti-noise" at airports. This involves having speakers produce sounds with the same frequency as the turbine noise from airplanes. The anti-noise and noise are out of phase with one another, canceling each other out, reducing the noise for nearby residents.

Tangent and cotangent functions
In a right triangle, the tangent results from the ratio of the opposite side to the adjacent side. Therefore, the following relationship can be derived:

$$\tan x = \frac{\sin x}{\cos x}$$

The cotangent results from the ratio of the adjacent side to the opposite side. This means that

$$\cot x = \frac{\cos x}{\sin x}$$

Table 9 and Figure 8 show the properties and the curves of both of these functions. The most important properties of trigonometric functions are summarized in Table 10.

Arc functions
The arc functions are the inverse of trigonometric functions. For example, the following equation can be solved using the arcsine:

$\sin x = 0.5$ where $x \in [0; \pi/2]$

$\Rightarrow x = \arcsin(0.5) = \pi/6.$

Similarly, there are also an arccosine, arctangent and arccotangent.

In contrast to the sine, cosine, tangent and cotangent, which (with the exception of gaps) are defined for any $\mathbb{R}$, the arc functions may have a finite interval as a domain, in particular the value range of the original function. These properties and others are compiled in Table 11. The arc functions are not periodic.

Equations in the plane triangle

Figure 9 shows a triangle with any lengths of sides a, b and c and any angles α, β and γ. The relationship between these quantities is described by the following equations.

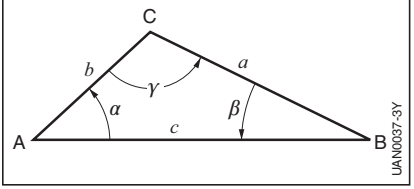
Angular sum:
$\alpha+\beta+\gamma=180°$.

Law of sines:
$a : b : c = \sin\alpha : \sin\beta : \sin\gamma$.

Law of cosines:
$c^2 = a^2 + b^2 - 2ab\cos\gamma$.

Pythagorean theorem:
$c^2 = a^2 + b^2$, where $\gamma = 90°$.

The relationships between angles in a triangle play an important role in the design of components. One example of this would be the gear design in a reciprocating piston engine, where the piston stroke and length of the connecting rod are related to one another by the angle of the crankshaft position and the leg angle of the connecting rod (see Internal-combustion engines, Gear design).



Complex numbers

In real numbers, a root can be extracted from any positive number; this is not possible with negative numbers. In order to bypass this restriction, real numbers are changed into complex numbers. Their central element is the imaginary unit i, where:

$i^2 = -1$.

A complex number z has a real component (Re) and an imaginary component (Im). The imaginary component is multiplied by the imaginary unit i. It is possible with the coordinates a and b to represent z in Cartesian form. Using a simple transformation, this can be converted into the polar coordinates r and φ (distance from the origin of the coordinates and the angle to the X-axis) (Figure 10).

Figure 9: Plane triangle
Vertices A, B and C.
Lengths of sides a, b and c;
Angles α, β and γ.

Complex number z in Cartesian form:
$z = a + ib$ where $i^2 = -1$.
$\mathrm{Re}\, z = a$, $\mathrm{Im}\, z = b$.

Complex number z in polar coordinates:
$z = re^{i\varphi}$

where $r = \sqrt{a^2 + b^2}$, $\tan\varphi = \frac{b}{a}$
$a = r\cos\varphi$, $b = r\sin\varphi$.

Complex exponential function (Euler's formula)
$e^{i\varphi} = \cos\varphi + i\sin\varphi$

Calculation rules for complex numbers
In the case of complex numbers, the same calculation rules that are used for real numbers apply, whereby addition is simpler to carry out in Cartesian notation and multiplication is simpler in polar notation.

Addition:
$z_1 + z_2 = (a_1 + a_2) + i(b_1 + b_2)$.

Multiplication:
$z_1 z_2 = (r_1 r_2)\, e^{i(\varphi_1 + \varphi_2)}$

In many cases, complex numbers aid in making complicated mathematical problems easier to solve. Frequently, only the real part or the imaginary part of the complex solution is necessary in finding the real solution.

For example, oscillation processes can be expressed using linear differential equations (see Differential equations), such as the oscillation and damping properties of shock absorbers or the current strength and voltage in an alternating-current circuit. A solution can be found quickly with the help of a complex exponential function. Finally, Euler's formula for exponential functions is used to convert a complex solution into a real solution.

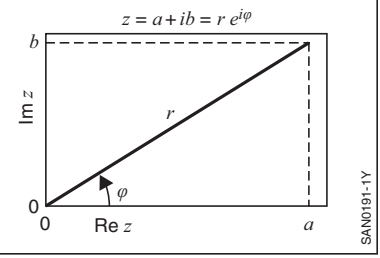
Coordinate systems

Coordinate systems on a plane
In the previous segment, a complex number z is either represented by both of its coordinates x and y or by its absolute value $r = |z|$ and the angle φ in relation to the x-axis. This number can be graphically represented as a point on a plane (Figure 10).

Similarly, all the points on a plane can be expressed by their Cartesian coordinates (x and y) or by their polar coordinates (r and φ), and converted into one another.

Conversion of Cartesian coordinates to polar coordinates:

$r = \sqrt{x^2 + y^2}$, $x, y \in \mathbb{R}$,



$\tan\varphi = \frac{y}{x}$.

Conversion of polar coordinates to Cartesian coordinates:
$x = r\cos\varphi$, $r \in \mathbb{R}_0^+$, $\varphi \in [0; 2\pi]$,
$y = r\sin\varphi$.

This conversion always yields a unique value, meaning that for each x-y pair, there is an exact r-φ pair. r is only = 0 at the coordinate origin (0, 0), but the angle φ is undefined. However, in practice this does not amount to a limitation.

Cartesian coordinates can be used for straight-line movements. Naturally, circular motion can also be represented us-

Figure 10: Complex number z
Diagram in Cartesian coordinates (a and b) and polar coordinates (r and φ).

ing Cartesian coordinates. However, the corresponding equations are significantly more complicated in comparison to a description in polar coordinates (see for example Fundamentals of vehicle engineering, Translational movement).

Coordinate systems in three dimensions

Each point in a three-dimensional space has three Cartesian coordinates (x,y,z). This representation is used frequently when the system to be described is at a right or oblique angle. However, if the problem relates to a rotationally symmetrical or a spherically symmetrical system, using cylindrical or spherical coordinates is recommended.

In Figure 11, the x, y and z coordinate axes are delineated. Here, the distance r of point P to the origin and the two angles θ and φ, which can be measured from the z or the x-axis. r, θ and φ are labeled as spherical coordinates or spatial polar coordinates.

With the exception of the origin (0, 0, 0), the coordinates for each point are clearly defined in both Cartesian and polar coordinates. Conversion between both coordinate system occurs as follows.

Conversion of Cartesian coordinates to polar coordinates:

$$r = \sqrt{x^2 + y^2 + z^2}\ ,\ x, y, z \in \mathbb{R},$$

$$\tan \varphi = \frac{y}{x},$$

$$\cos \Theta = \frac{z}{r} = \frac{z}{\sqrt{x^2+y^2+z^2}}\ .$$

Conversion of polar coordinates to Cartesian coordinates:

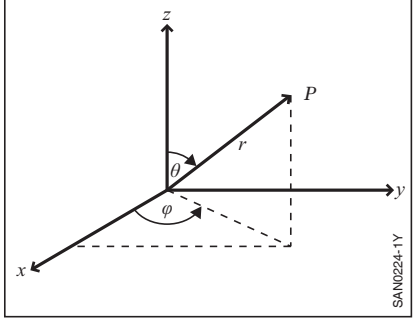
$$x = r\cos\varphi \sin\Theta,$$
$$r \in \mathbb{R}_0^+,\ \varphi \in [0; 2\pi],\ \Theta \in [0; \pi],$$
$$y = r\sin\varphi \sin\Theta,$$
$$z = r\cos\Theta\ .$$

The surface of the Earth is broken down cartographically into geographic coordinates. The geographic length is the angle φ in spherical coordinates. The geographic width is determined by an angle of −90° to +90° relative to the equator. This is equivalent to the angle θ in spherical coordinates, which is measured starting from the north pole and is between 0° and 180° (0 and π in radians).

Cylindrical coordinates

If an object or a system has rotational symmetry, cylindrical coordinates are utilized (Figure 12). The x and y coordinates, just like the polar coordinates on a plane, are converted to the radius ρ; the z component of the cylindrical coordinates

Figure 11: Spherical coordinates of a point



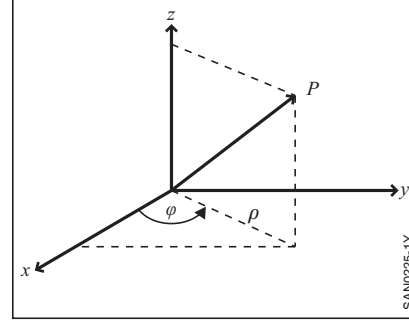


Figure 12: Cylindrical coordinates of a point

is identical to the z of the Cartesian coordinates.

Just like the spherical coordinates, any point can be clearly expressed in cylindrical coordinates, with the exception of the origin (0, 0, 0).

Conversion of Cartesian coordinates to cylindrical coordinates:

$$\rho = \sqrt{x^2 + y^2}, \quad x, y, z \in \mathbb{R},$$

$$\tan \varphi = \frac{y}{x},$$

$$z = z.$$

Conversion of cylindrical coordinates to Cartesian coordinates:

$$x = \rho \cos \varphi, \quad \rho \in \mathbb{R}_0^+, \varphi \in [0; 2\pi], z \in \mathbb{R},$$
$$y = \rho \sin \varphi,$$
$$z = z.$$

Just like the polar coordinates, cylindrical coordinates are calculated on a plane and they are expanded by the addition of the z-axis.

Cylindrical coordinates can be used in the design of rotationally symmetrical objects, such as tubes, engine cylinders, screws, nuts, and anti-friction and friction bearings.

Vectors

A distinction is made between scalar and vector variables for physical and technical concepts. Examples of scalars include mass, temperature and pressure. By comparison, vectors have a direction, such as velocity, power and electric field. Vectors, their most important arithmetic operations and calculation rules are shown below.

Representation of vectors
A vector in a three-dimensional space has the three components a_x, a_y and a_z for the x-, y and z direction. In mathematics, this is described as follows:

$$\vec{a} = \begin{pmatrix} a_x \\ a_y \\ a_z \end{pmatrix}.$$

Calculation rules
When adding and multiplying vectors with a number, the same calculation rules for adding and multiplying numbers apply.

Addition
For adding two vectors with coordinates as follows

$$\vec{a} = \begin{pmatrix} a_x \\ a_y \\ a_z \end{pmatrix} \text{ and } \vec{c} = \begin{pmatrix} c_x \\ c_y \\ c_z \end{pmatrix}$$

results in:

$$\vec{a} + \vec{c} = \begin{pmatrix} a_x + c_x \\ a_y + c_y \\ a_z + c_z \end{pmatrix}$$

The following laws apply:
– Closure property: The sum and the difference of two vectors is also a vector.
– Commutative property:
$\vec{a} + \vec{c} = \vec{c} + \vec{a}$.
– Associative property:
$\vec{a} + (\vec{c} + \vec{n}) = (\vec{a} + \vec{c}) + \vec{n}$.
– For any two vectors $\vec{a}$ and $\vec{c}$ there is always one vector $\vec{z}$ so that:
$\vec{a} + \vec{z} = \vec{c}$, in other words $\vec{z} = \vec{c} - \vec{a}$.

Multiplication of a vector with a scalar
When multiplying vector a by scalar $\lambda \in \mathbb{R}$, the following is true:

$$\lambda \vec{a} = \begin{pmatrix} \lambda a_x \\ \lambda a_y \\ \lambda a_z \end{pmatrix}$$

For vector $\vec{c}$, the following is true:

$$\vec{c} = \lambda \vec{a} \Rightarrow |\vec{c}| = |\lambda| \cdot |\vec{a}|.$$

For vectors $\vec{a}$ and $\vec{c} \in \mathbb{R}^3$ and scalars λ and $\mu \in \mathbb{R}$, the following laws apply:
– Closure property: The product of a vector and a scalar is also a vector.
– Associative property: $(\lambda \cdot \mu) \cdot \vec{a} = \lambda \cdot (\mu \cdot \vec{a})$.
– Distributive law:
$(\lambda + \mu) \cdot \vec{a} = \lambda \cdot \vec{a} + \mu \cdot \vec{a}$,
$\lambda \cdot (\vec{a} + \vec{c}) = \lambda \cdot \vec{a} + \lambda \cdot \vec{c}$.
– Multiplying by the neutral element:
$1 \cdot \vec{a} = \vec{a}$.

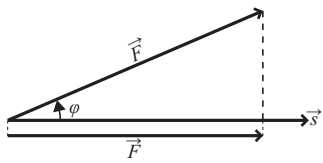
Scalar product
When multiplying two vectors with one another, two different products are defined: the scalar product and the vector product.

The result of the scalar product is a number (scalar). For example, physical work is defined as a scalar product of the force vector $\vec{F}$ and the path vector $\vec{s}$ (Figure 13). Only the components of $\vec{F}$ that point in the direction of $\vec{s}$ contribute to the work. This corresponds to the offset projection depicted in Figure 13. Thus, the following is true for the absolute value of the projection

$$|\vec{F}_s| = |\vec{F}| \cos \varphi$$

The scalar product is defined as

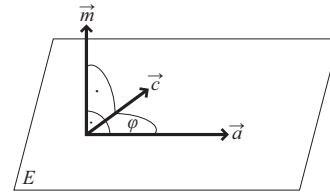
$$\vec{a} \cdot \vec{c} = |\vec{a}| \cdot |\vec{c}| \cdot \cos \varphi$$
$$= a_x c_x + a_y c_y + a_z c_z.$$



In order to clarify the product, the multiplication point "$\cdot$" is placed between both vectors.

The calculation rules for the scalar product are the same as the calculation rules for numbers.
– Commutative property:
$\vec{a} \cdot \vec{c} = \vec{c} \cdot \vec{a}$.
– Distributive law:
$\vec{a} \cdot (\vec{c} + \vec{n}) = \vec{a} \cdot \vec{c} + \vec{a} \cdot \vec{n}$.
– Multiplication with a scalar, associative property:
$\lambda (\vec{a} \cdot \vec{c}) = (\lambda \vec{a}) \cdot \vec{c} = \vec{a} \cdot (\lambda \vec{c})$.

For example, the scalar product is used to calculate the absolute value (the length) of a vector. In addition, the angles between the vectors can be determined using the same method. The scalar product in particular is used in order to find out if two vectors are perpendicular to each other. In this case, the scalar product is zero.



Cross product
A new vector results from the cross product (outer product) of two vectors; this new vector is perpendicular to both output vectors (Figure 14). Its length equals the area of a parallelogram spanning both initial vectors. The vectors $\vec{a}$, $\vec{c}$ and $\vec{m}$ form what is known as a right-handed system. According to the right-hand rule, the thumb points in the direction of $\vec{a}$, the index finger

Figure 13: Scalar product
The scalar product of both vectors $\vec{F}$ and $\vec{s}$ with the projection $\vec{F}_s$ of the vector $\vec{F}$ on $\vec{s}$. φ is the angle between both vectors $\vec{F}$ and $\vec{s}$.

SAN0226Y

Figure 14: Cross product
Both vectors $\vec{a}$ and $\vec{c}$ span the length of a plane E. The cross product (vector m) formed from $\vec{a}$ and $\vec{c}$ points perpendicular to both output vectors. φ is the angle between $\vec{a}$ and $\vec{c}$.

SAN0227Y

in the direction of $\vec{c}$ and the resulting vector $\vec{m}$ in the direction of the middle finger on the right hand.

In order to be able to distinguish the cross product from the scalar product, an "x" is placed between the vectors as a multiplication symbol.

The calculation rules for the cross product are summarized below:

$\vec{m} = \vec{a} \times \vec{c}$ where

$$|\vec{m}| = |\vec{a}| \cdot |\vec{c}| \cdot \sin\varphi = \begin{vmatrix} \vec{e}_x & \vec{e}_y & \vec{e}_z \\ a_x & a_y & a_z \\ c_x & c_y & c_z \end{vmatrix} = \begin{bmatrix} a_y c_z - a_z c_y \\ a_z c_x - a_x c_z \\ a_x c_y - a_y c_x \end{bmatrix}$$

$\vec{m} \perp \vec{a}$, $\vec{m} \perp \vec{c}$,

$\vec{a}$, $\vec{c}$, $\vec{m}$ are "right-handed"

with the unit vectors $\vec{e}_x$, $\vec{e}_y$ and $\vec{e}_z$ in x, y and z direction.

When applying the calculation rules, note that the leading sign is inverted if the order of the vectors is reversed (anticommutativity):

– Anticommutativity:
  $\vec{a} \times \vec{c} = -\vec{c} \times \vec{a}$.
– Distributive law:
  $\vec{a} \times (\vec{c} + \vec{n}) = \vec{a} \times \vec{c} + \vec{a} \times \vec{n}$.
– Multiplication with a scalar, associative property:
  $\lambda(\vec{a} \times \vec{c}) = (\lambda \vec{a}) \times \vec{c} = \vec{a} \times (\lambda \vec{c})$.

The cross product becomes zero when both vectors point in the same or opposite direction (i.e. when they are collinear). This lets you use the cross product to check if two vectors span one plane. In this case, the cross product does not equal zero.

Therefore, the cross product of a vector with itself is zero.

$\vec{a}, \vec{c} \neq \vec{0}$ where $\vec{a} \times \vec{c} = \vec{0} \Leftrightarrow \vec{a} \parallel \vec{c}$,

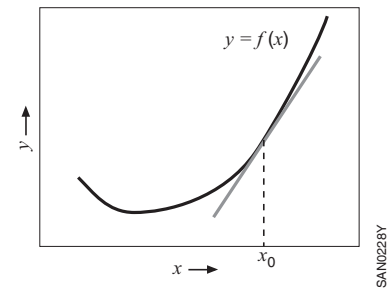
$\vec{a} \times \vec{a} = \vec{0}$.

Differential and integral calculus

Differentiation of functions

First derivative

The zero points, discontinuities and the behavior of a function can be determined at the margins of the domain using the function term $y = f(x)$. Finding out how steep a function is or where the function attains its maximum or minimum values is often of interest as well. This can be described using differentiation (the derivative) of a function.



The slope (steepness) of a function $y = f(x)$ is given via the tangent of this function (Figure 15). If a function attains a maximum or a minimum value, then the tangent is horizontal at that point. In order to calculate the slope of a function $f(x)$, it must be derived (differentiated). The following two notation systems have been established for the first derivative of a function $f(x)$ to accomplish this:

$$\frac{d}{dx} f(x) = f'(x).$$

The derivatives of elementary functions are summarized in Table 12.

The derivative of compound functions can be calculated using the following calculation rules:

Figure 15: Derivative of a function

Sum rule:

$$\frac{d}{dx}(f(x) \pm g(x)) = f'(x) \pm g'(x).$$

Multiplication with a number λ:

$$\frac{d}{dx}(\lambda f(x)) = \lambda f'(x).$$

Product rule:

$$\frac{d}{dx}(f(x) \cdot g(x)) = f'(x) \cdot g(x) + f(x) \cdot g'(x).$$

Quotient rule:

$$\frac{d}{dx}\left|\frac{f(x)}{g(x)}\right| = \frac{f'(x) \cdot g(x) - f(x) \cdot g'(x)}{[g(x)]^2}$$

Chain rule:

$$\frac{d}{dx}(F(g(x))) = F'(g(x)) \cdot g'(x).$$

Higher derivatives
If the first derivative is differentiated again, then this becomes the second derivative. Higher derivatives can be formed in a similar way.

2nd derivative:

$$\frac{d}{dx}f'(x) = f''(x) \text{ or } f''(x) = \frac{d^2}{dx^2}f(x)$$

3rd derivative:

$$\frac{d}{dx}f''(x) = f'''(x) \text{ or } f'''(x) = \frac{d^3}{dx^3}f(x).$$

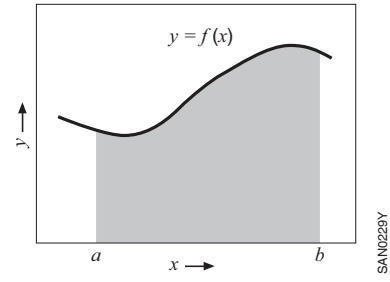
nth derivative($n > 3$):

$$\frac{d}{dx}f^{(n-1)}(x) = f^{(n)}(x) \text{ or } f^{(n)} = \frac{d^n}{dx^n}f(x).$$

Extrema of functions
If the first and the second derivative of a function $f(x)$ are on hand, then these can be used to determine the maxima and minima (extrema) of $f(x)$. Both of the following conditions apply to an extremum at x_0:

– $f'(x_0) = 0$,
– $f''(x_0) < 0$ for a maximum,
  $f''(x_0) > 0$ for a minimum.

Inflection point
The curvature properties of the function can be determined by using the second derivative. The point x_w at which a function switches from left-curved ($f''(x) > 0$, convex curvature) to right-curved ($f''(x) < 0$, concave curvature) and vice versa is of particular interest. These points are known as inflection points. The following is true here:



$$f''(x) = 0.$$

Integration of a function
A (continuous) function $f(x$ is depicted in Figure 16. Together with the X-axis in

Table 12: Elementary functions $f(x)$ and their derivatives $f'(x)$

$f(x)$	$f'(x)$
c = const	0
x^n	nx^{n-1}
$\sqrt{x} = x^{1/2}$	$\frac{1}{2}\frac{1}{\sqrt{x}} = \frac{1}{2}x^{-1/2}$
$\sin(x)$	$\cos(x)$
$\cos(x)$	$-\sin(x)$
$\tan(x)$	$\frac{1}{\cos^2(x)}$
$\cot(x)$	$-\frac{1}{\sin^2(x)}$
e^x	e^x
$a^x = e^{x \ln a}$	$(\ln a)\, a^x$
$\ln x$	$\frac{1}{x}$
$\log_a x = \frac{\ln x}{\ln a}$	$\frac{1}{\ln a}\frac{1}{x}$

Figure 16: Integral
Integration of the function $f(x)$ in the interval of a through b.

the interval [a; b], this encloses the area A marked in gray. Its dimensions can be calculated through integration.

The unknown area A is represented as an integral from a to b via the function $f(x)$ with the variable x:

$$A = \int_a^b f(x)\,dx.$$

Antiderivative

In order to find a solution to this problem, the antiderivative $F(x)$ is required for $f(x)$. Its property is expressed in the fundamental theorem of differential and integral calculus.

$$F(x) = \int_a^x f(t)\,dt$$

is an antiderivative for $f(x)$, if the following applies:

$$\frac{d}{dx}F(x) = f(x).$$

If $F(x)$ is an antiderivative for $f(x)$, then the unknown area can be calculated as

$$A = \int_a^b f(x)\,dx = F(b) - F(a).$$

Important antiderivatives are compiled in Table 13. For each function $f(x)$, there is just one antiderivative $F(x)$. This is uniquely defined with the exception of the integration constant C.

Table 13: Elementary functions and their antiderivatives (examples)

$f(x)$	$\int f(x)\,dx$
0	$c = \text{const}$
$x^n,\ c \neq -1$	$\frac{1}{n+1}x^{n+1} + C$
$\frac{1}{x}$	$\ln\lvert x\rvert + C$
$\sqrt{x} = x^{1/2}$	$\frac{2}{3}x^{3/2} + C$
$\sin x$	$-\cos x + C$
$\cos x$	$\sin x + C$
$\frac{1}{\cos^2 x}$	$\tan x + C$
$\frac{1}{\sin^2 x}$	$-\cot x + C$
e^x	$e^x + C$
$a^x = e^{x \ln a}$	$\frac{a^x}{\ln a} + C$

Calculation rules for integration

The following calculation rules apply to integration:

Sum rule:

$$\int_a^b f(x) + g(x)\,dx = \int_a^b f(x)\,dx + \int_a^b g(x)\,dx.$$

Multiplication with a number λ:

$$\int_a^b \lambda f(x)\,dx = \lambda \int_a^b f(x)\,dx.$$

Reversing the bounds of integration:

$$\int_a^b f(x)\,dx = -\int_b^a f(x)\,dx.$$

Lower parts of integration ranges in intervals ($a < c < b$):

$$\int_a^b f(x)\,dx = \int_a^c f(x)\,dx + \int_c^b f(x)\,dx.$$

Upper and lower bounds of integration are identical:

$$\int_a^a f(x)\,dx = 0.$$

Partial integration

In addition to searching for the antiderivative, there are two helpful methods for solving for integrals for partial integration and integration through substitution. Partial integration is the inverse of the product rule for the derivative.

$$\int_a^b f'(x)\cdot g(x)\,dx = f(x)\cdot g(x) - \int_a^b f(x)\cdot g'(x)\,dx.$$

The critical factor for this method is properly assigning both product terms $f'(x)$ and $g(x)$ within the integral.

Substitution

Substitution is the inverse of the chain rule. The art of substitution lies in finding the appropriate function that can be replaced (for more information, refer to [1], [2], [3]).

Linear differential equations

In many technical problems, a function is being sought that can describe the task but is not explicitly specified. Instead, information about its curvature properties (second derivative), its slope (first derivative) or a combination of the two is provided in the form of an equation.

An equation in which the function and its derivatives can be found is known as a differential equation. Equations known as common linear differential equations of the nth order with constant coefficients are covered below ([1], [2] and [3]):

$$y^{(n)}(x) + a_{n-1}y^{(n-1)}(x) + \ldots + a_0 y(x) = g(x).$$

In this equation, the nth derivative of $y(x)$ is the highest order derivative. Real numbers stand in front of individual derivatives $a_0, a_1, \ldots, a_{n-1}, a_n$, where $a_n = 1$ is selected. If the function $g(x)$ is always zero, the differential equation is homogeneous; otherwise, it is non-homogeneous. Here, x is the variable of the unknown function $y(x)$.

The differential equation above is linear, since $y(x), y'(x), \ldots y^{(n)}(x)$ are only accompanied by the coefficients and do not occur as exponents, such as $y(x)^2$, or as a nonlinear function, like $\sin(y'(x))$.

Using the formulation
$y(x) = Ae^{\lambda x}$, $A \in \mathbb{R}$, $\lambda \in \mathbb{R}$, a homogeneous differential equation is simplified to a characteristic polynomial, because the exponential term is canceled out:

$$\lambda^n + a_{n-1}\lambda^{n-1} + \ldots + a_2\lambda^2 + a_1\lambda + a_0 = 0.$$

In doing so, solving the differential equation is reduced to searching for the zero points of the characteristic polynomial. If the n zero points $\lambda_1, \lambda_2, \ldots, \lambda_n$ are determined, then the homogeneous solution $y_h(x)$ of the differential equation is yielded as

$$y_h(x) = A_1 e^{\lambda_1 x} + A_2 e^{\lambda_2 x} + \ldots + A_n e^{\lambda_n x}.$$

The numbers $A_1, A_2, \ldots A_n$ are (any) real numbers and are labeled as integration constants. If initial or ancillary conditions are given for the function, then the values $A_1, A_2, \ldots, A_n$ can be calculated from these conditions.

After finding the homogeneous solution, a special solution $y_{ih}(x)$ for the non-homogeneous differential equation needs to be found; this then provides the complete solution.

$$y(x) = y_h(x) + y_{ih}(x).$$

Linear differential equations of the second order with constant coefficients are the basis of all oscillation processes (see Vibrations and oscillations, Vibration characteristics) and also the basis for the design of safety-related sensors like acceleration and vibration sensors (see Acceleration sensors). Even regulating and control engineering technology is based on these differential equations (see Control engineering).

In addition to common linear differential equations with constant coefficients, there are also linear differential equations in which the constant coefficients are replaced by functions, such as

$$\sin(x) \cdot y'(x) + \cos(x) \cdot y(x) = 0.$$

Furthermore, the two-dimensional oscillation equation of the function $f(x,y)$ with the location coordinates x and y and time t,

$$\frac{\partial^2 f}{\partial x^2} + \frac{\partial^2 f}{\partial y^2} = \frac{1}{c^2}\frac{\partial^2 f}{\partial t^2}, \; c \in \mathbb{R},$$

is an example of a partial differential equation. It is significantly more complicated to solve both of these types of differential equations than it is to solve the linear differential equations described above. For more information and a more detailed approach to these differential equations, the extensive literature from the bibliography should be consulted, including [1], [2] and [3], or the specialized literature regarding special types of differential equations.

Laplace transform

There are many control loops in a vehicle (see Control engineering); in the engine (e.g. knock control, λ control), in the A/C unit or in the undercarriage (e.g. yaw-rate control). These control loops are often represented by linear differential equations. One way to solve this differential equation is to use the exponential approach (see Differential equations).

Alternatively, the Laplace transform can also be utilized if initial values like $y(0)$, $y'(0)$ etc. are given in addition to the differential equation ([1], [2], [3]). The advantage to this approach is that the Laplace transformation converts the differential equation into an algebraic equation. This can usually be resolved easily according to the Laplace transform function $Y(s)$. Then, the Laplace inverse transform must be carried out in order to find the unknown function $y(x)$.

The Laplace transform $\mathcal{L}\{y(x)\}$ or image function $Y(s)$ of a function $y(x)$ can be found as follows:

$$Y(s) = \mathcal{L}\{y(x)\} = \int_0^\infty e^{-sx} y(x)\,dx,\ s \in \mathbb{R}.$$

In order to solve for the integral, the absolute value of the function must be exponentially bound. s merely acts as a variable in the transformation [3].

Properties

Laplace transforms of the derivatives $y'(x)$, $y''(x)$ are very crucial when solving differential equations.

$$\mathcal{L}\{y'(x)\} = s\,Y(s) - y(0)$$

$$\mathcal{L}\{y''(x)\} = s^2\,Y(s) - s\,y(0) - y'(0)$$

$$\mathcal{L}\{c_1 y_1(x) + c_2 y_2(x)\} = c_1\,\mathcal{L}\{y_1(x)\} + c_2\,\mathcal{L}\{y_2(x)\} \qquad \text{(linearity)}$$

$$\mathcal{L}\{y(ax)\} = \frac{1}{a}\,Y\left(\frac{s}{a}\right),\quad a > 0 \qquad \text{(Similarity theorem)}$$

$$\mathcal{L}\{e^{-ax}\,y(x)\} = Y(s + a),\quad a > 0 \qquad \text{(Complex shifting theorem)}$$

As you can see, the derivatives are converted into terms with the function $Y(s)$.

A few selected examples of the Laplace transforms of functions have been compiled in Table 14.

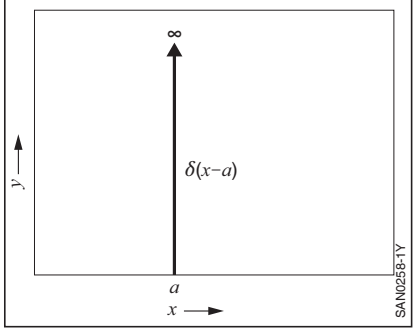
Table 14: Functions $y(x)$ and the corresponding Laplace transforms $Y(s)$

$y(x)$	$Y(s) = \mathcal{L}\{y(x)\}$
$y(x) = \begin{cases} 0 & x < 0 \\ 1 & x \geq 0 \end{cases}$	$\frac{1}{s}$
$y(x) = \begin{cases} 0 & x < 0 \\ x^{n-1} & x \geq 0 \end{cases}$	$\frac{(n-1)!}{s^n}\quad n = 1, 2, 3$
$y(x) = \begin{cases} 0 & x < 0 \\ \sin(ax) & x \geq 0 \end{cases}$	$\frac{a}{s^2 + a^2}$
$y(x) = \begin{cases} 0 & x < 0 \\ \cos(ax) & x \geq 0 \end{cases}$	$\frac{s}{s^2 + a^2}$
$y(x) = \begin{cases} 0 & x < 0 \\ e^{-ax} & x \geq 0 \end{cases}$	$\frac{1}{s + a}$

Fourier transform

During analysis, a time-dependent function is often found $f(t)$. Analysis is usually interested in the frequencies of the vibrations that underlie this function. For example, the undercarriage of a car should compensate for the bumps in the road so that the vehicle does not begin to rock back and forth. This requires a surface unevenness profile $h(x)$. If the car is driving down the road at a particular speed, it will begin to rock, which corresponds to the function $f(t)$. The characteristic frequencies must be determined from this function in order to be able to select and set the dimensions for the vehicle's shock absorbers, which will dampen the oscillations (see Undercarriage, Road excitation, Irregularity profiles).

The characteristic oscillation frequencies can be determined using the function $f(t)$, if this function $f(t)$ is subjected to a Fourier transform to form the function $F(\omega)$:



$$F(\omega) = \mathcal{F}\{f(t)\} = \int_{-\infty}^{\infty} f(t)\, e^{-i\omega t} dt,$$
where $i^2 = -1$.

This converts the time-dependent function $f(t)$ into the frequency-dependent spectral function $F(\omega)$ ([1], [2]).

This results in an inverse transformation along the lines of:

$$f(t) = \mathcal{F}^{-1}\{F(\omega)\} = \frac{1}{2\pi} \int_{-\infty}^{\infty} F(\omega) e^{i\omega t} d\omega.$$

Figure 17: Symbolic representation of a Dirac delta function

In the literature, values of 1 (like here), $1/2\pi$ or $1/\sqrt{2\pi}$ are sometimes specified as the prefactor for the Fourier transform. This also changes the factor of the inverse transform. The critical aspect here is that the product of the transform's prefactors and the inverse transform yield $1/2\pi$.

Properties

Some properties of the Fourier transform are listed below.

$$\mathcal{F}\{c_1 f_1(t) + c_2 f_2(t)\} = c_1 \mathcal{F}\{f_1(t)\} + c_2 \mathcal{F}\{f_2(t)\}$$
(Linearity)

$$\mathcal{F}\{f_1(at)\} = \frac{1}{|a|} F\left(\frac{\omega}{a}\right), \quad a \in \mathbb{R},\ a \neq 0,$$
(Similarity theorem)

$$\mathcal{F}\{f(t - t_0)\} = e^{-i\omega t_0} F(\omega), \quad t_0 \in \mathbb{R},$$
(Shift theorem in the time range)

$$\mathcal{F}\{e^{i\omega_0 t} f(t)\} = F(\omega - \omega_0), \quad \omega_0 \in \mathbb{R},$$
(Shift theorem in the frequency domain)

$$\mathcal{F}\left\{\int_{-\infty}^{\infty} f(\tau)\, g(t-\tau)\right\} d\tau = \mathcal{F}\{f(t)\}\, \mathcal{F}\{g(t)\}.$$

Using the notation

$$(f * g)(t) = \int_{-\infty}^{\infty} f(\tau)\, g(t-\tau)\, d\tau = \int_{-\infty}^{\infty} f(t-\tau)\, g(t)\, d\tau$$

the convolution theorem can be summarized as follows:

$$\mathcal{F}\{(f * g)\} = F(\omega)\, G(\omega).$$

The transform in the frequency domain can be explained by the Dirac delta function, which is defined as follows [4]:

$\delta(t) = 0$ for $t \in \mathbb{R}$, $t \neq 0$, and

$$\int_{-\infty}^{\infty} \delta(t - t_0)\, f(t)\, dt = f(t_0).$$

This can also be written as

$$\delta(t - t_0) = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{i(t-t_0)\tau}\, d\tau.$$

The Dirac delta function is always zero. However, at the point where its argument is zero, it can be said to be infinitely large. This is illustrated in Figure 17. The Fourier transform of the complex exponential function or the sine and cosine function with an angular frequency of ω_0 returns the Dirac delta function for ω_0:

$$\mathcal{F}\{e^{-i\omega_0 t}\} = 2\pi\ \delta(\omega - \omega_0)\ dx,$$

$$\mathcal{F}\{\delta(t - t_0)\} = \frac{1}{2\pi}\ e^{-i\omega t_0},$$

$$\mathcal{F}\{\sin(\omega_0 t)\} = i\pi\ [\delta(\omega + \omega_0) - \delta(\omega - \omega_0)],$$

$$\mathcal{F}\{\cos(\omega_0 t)\} = \pi\ [\delta(\omega + \omega_0) + \delta(\omega - \omega_0)].$$

For example, the Fourier transform is used to determine the frequencies of signals (e.g. the individual tones within the sound of a piano). In addition, the ratios of the corresponding amplitudes corresponding to the volume of sounds can be found. This allows sound waves to be broken down into individual sounds (frequencies) and their amplitude (volume) (see Undercarriage, Road excitation; Acoustics, Perceived sound levels).

Similarities and differenced between Laplace and Fourier transforms

The Laplace transform of a function $y(x)$

$$\mathcal{L}\{y(x)\} = \int_0^\infty e^{-sx} y(x)dx,\ s \in \mathbb{R}, \mathbb{C}$$

and the Fourier transform of $y(x)$

$$\mathcal{F}\{y(x)\} = \int_{-\infty}^{\infty} e^{-i\omega x}\ y(x)\,dx,\ \text{ where } i^2 = -1$$

are similarly defined. This means that both transforms have properties that are either similar or the same. Both transforms are linear, their similarity theorems are almost identical and the complex shifting theorem of the Laplace transform is equivalent to the shift theorem of the Fourier transform.

However, both transforms can be distinguished by their bounds of integration, because the Laplace integral begins at $x = 0$ and the Fourier integral at $-\infty$. In other words, the function $y(x)$ can be defined by for the entirety of $\mathbb{R}$ in the case of the Fourier integral, while $y(x)$ can only differ from zero for $\mathbb{R}^+$. Furthermore, the exponential function of the Laplace integral usually contains an arbitrary complex exponent $-s\,x$, while this term $-i\,\omega\,x$ is normally completely imaginary in the case of a Fourier integral.

The inverse of the Fourier transform can usually be calculated in a manner similar to that of the Fourier transform. However, calculating the inverse Laplace transform by means of complex curvilinear integrals is often difficult [1]. Tables such as Table 14 are usually helpful when solving differential equations in order to determine the original function $y(x)$ from the Laplace transform.

The direct correlation between the Laplace and the Fourier transform is depicted as follows: For the function $y(x)$, the function $g(x)$ is defined as:

$$g(x) = \begin{cases} 0 & x < 0 \\ e^{-\lambda x}\, y(x) & x \geq 0 \end{cases} \qquad \lambda \in \mathbb{C}$$

Subjecting $g(x)$ to a Fourier transform yields

$$\mathcal{F}\{g(x)\} = \int_{-\infty}^{\infty} e^{-i\omega x}\ g(x)\ dx$$
$$= \int_0^{\infty} e^{-i\omega x}\ e^{-\lambda x}\ y(x)\,dx.$$

Solving for $s = \lambda + i\omega$ then yields

$$\mathcal{F}\{g(x)\} = \int_{-\infty}^{\infty} e^{-i\omega x} g(x)dx = \int_{-\infty}^{\infty} e^{-sx} y(x)dx$$
$$= \mathcal{L}\{y(x)\}.$$

Matrix calculus

Vectors can indicate the intensity and direction of forces or of a velocity (see Vectors). In the case of a circular motion this can be easily represented using a vector, which specifies the initial direction of motion, together with a matrix, which describes the rotation.

Furthermore, matrices play the central role in solving systems of linear equations which occur in many technical questions. In order for example to calculate mechanical or thermal stresses in a component, complicated nonlinear differential equations are numerically solved. The standard method used for this purpose is the finite-element method (FEM), which ultimately (in very small time and space intervals) converts the differential equations into systems of linear equation and consequently into matrices. Reference is also made here by way of example to the use of matrices in the image processing of camera data in passenger cars (see Computer vision).

Firstly, matrices will be introduced in the following. Then arithmetical operations with matrices such as addition and multiplication will be defined. To conclude, three solution methods for systems of linear equation will be presented.

Structure of matrices
An $(m \times n)$ matrix A is made up of m rows and n columns. The component (elements, entries) a_{ik} in the ith row and kth column is a real or a complex number.

$$A = \begin{bmatrix} a_{11} & a_{12} \dots a_{1k} \dots a_{1n} \\ a_{21} & a_{22} \dots a_{2k} \dots a_{2n} \\ \vdots & \vdots \quad \vdots \quad \vdots \\ a_{i1} & a_{i2} \dots a_{ik} \dots a_{in} \\ \vdots & \vdots \quad \vdots \quad \vdots \\ a_{m1} & a_{m2} \dots a_{mk} \dots a_{mn} \end{bmatrix}$$

If the matrix has the same number of rows and columns ($m = n$), this is called a square matrix. The standouts among these are the upper and lower triangular matrices, the diagonal matrices, and the unit matrix. An upper or lower triangular matrix (A_o or A_u) has different entries on the diagonal and above or below zero; below or above the diagonals there are only zeros.

$$A_o = \begin{bmatrix} a_{11} & a_{12} \dots a_{1n} \\ 0 & a_{22} \dots a_{2n} \\ & \vdots \quad \vdots \\ 0 & 0 \dots a_{nn} \end{bmatrix}, \quad A_u = \begin{bmatrix} a_{11} & 0 \dots 0 \\ a_{21} & a_{22} \dots 0 \\ & \vdots \quad \vdots \\ a_{n1} & a_{n2} \dots a_{nn} \end{bmatrix}$$

A diagonal matrix D has different elements a_{kk} only on the diagonal. The unit matrix E is a diagonal matrix with ones as entries.

$$D = \begin{bmatrix} a_{11} & 0 \dots 0 \\ 0 & a_{22} \dots 0 \\ & \vdots \quad \vdots \\ 0 & 0 \dots a_{nn} \end{bmatrix}, \quad E = \begin{bmatrix} 1 & 0 \dots 0 \\ 0 & 1 \dots 0 \\ & \vdots \quad \vdots \\ 0 & 0 \dots 1 \end{bmatrix}$$

Arithmetical rules for matrices
Two matrices A and B are identical when they match in all components:
$A = B \Leftrightarrow a_{ik} = b_{ik}$ for all i, k.

Two matrices can only then be added or subtracted when they match both in their number of rows and their number of columns. In this case, the addition (subtraction) is performed for each component:
$C = A + B$, $c_{ik} = a_{ik} + b_{ik}$.

If a matrix is multiplied by a real or complex number λ, each individual components is multiplied by this scalar:
$B = \lambda A$, $b_{ik} = \lambda a_{ik}$.

This results in the following arithmetical rules for matrices:
$A + B = B + A$,
$A + (B + C) = (A + B) + C$,
$\lambda(\mu A) = (\lambda\mu) A$,
$(\lambda + \mu) A = \lambda A + \mu A$,
$\lambda(A + B) = \lambda A + \lambda B$.

A column vector x with n entries can be multiplied from the right by an $(m \times n)$-matrix as follows:

$$A\,x = \begin{bmatrix} a_{11} & a_{12} \ldots a_{1n} \\ a_{21} & a_{22} \ldots a_{2n} \\ & \vdots \quad \vdots \\ a_{m1} & a_{m2} \ldots a_{mn} \end{bmatrix} \cdot \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix}$$

$$= \begin{bmatrix} a_{11}x_1 + a_{12}x_2 + \ldots + a_{1n}x_n \\ a_{21}x_1 + a_{22}x_2 + \ldots + a_{2n}x_n \\ \vdots \\ a_{m1}x_1 + a_{m2}x_2 + \ldots + a_{mn}x_n \end{bmatrix}$$

If the rows of matrix A are considered as vectors, i.e. the kth row corresponds to the row vector $a_k = (a_{k1}\ a_{k2}\ a_{k3} \ldots a_{kn})$, then in this multiplication in each case the scalar product is formed from the row vector a_k and the column vector x.

Thus, for the product of an $(m \times n)$ matrix with an n-row vector, an m-row vector is produced. This multiplication is linear, i.e. for matrix A, the two vectors x, y, and the two scalars λ, μ the following applies: $A(\lambda x + \mu y) = \lambda A x + \mu A y$.

Similarly, the multiplication of a row vector can be defined from the left with a matrix; this will not be discussed here.

Two matrices can be multiplied by each other when the number of columns s of the first matrix A matches the number of rows of the second matrix B. When the columns of matrix B are interpreted as vectors, the matrix multiplication is a natural extension of the multiplication of a matrix by a vector:

$$C = AB = \begin{bmatrix} a_{11} & a_{12} \ldots a_{1s} \\ a_{21} & a_{22} \ldots a_{2s} \\ & \vdots \quad \vdots \\ a_{i1} & a_{i2} \ldots a_{is} \\ & \vdots \quad \vdots \\ a_{m1} & a_{m2} \ldots a_{ms} \end{bmatrix} \cdot \begin{bmatrix} b_{11} & b_{12} \ldots b_{1j} \ldots b_{1n} \\ b_{21} & b_{22} \ldots b_{2j} \ldots b_{2n} \\ \vdots & \vdots \quad \vdots \quad \vdots \\ b_{s1} & b_{s2} \ldots b_{sj} \ldots b_{sn} \end{bmatrix}$$

$$= \begin{bmatrix} c_{11} \ldots c_{1j} \ldots c_{1n} \\ c_{i1} \ldots c_{ij} \ldots c_{in} \\ \vdots \quad \vdots \quad \vdots \\ c_{m1} \ldots c_{mj} \ldots c_{mn} \end{bmatrix}$$

where

$c_{ij} = a_{i1}b_{1j} + a_{i2}b_{2j} \cdots a_{is}b_{sj}$.

Similarly to the above, the new element c_{ij} corresponds to the scalar product from the ith row vector $a_i = (a_{i1}\ a_{i2}\ a_{i3} \ldots a_{is})$ of matrix A with the jth column vector $b_j = (b_{1j}, b_{2j}\ b_{3j} \ldots b_{sj})$ of matrix B. Thus, for the product of an $(m \times s)$ matrix with an $(s \times n)$ matrix an $(m \times n)$ matrix is produced.

The following arithmetical rules are obtained with regard to multiplication:

$A(BC) = (AB)C$,
$A(B+C) = AB + AC$,
$(A+B)C = AC + BC$,
$AE = EA = A$,

It must be noted in this connection that when multiplying two matrices as a rule the order may not be mixed up (not commutative).

Determinants

Square matrices can be characterized by the so-called determinant. When the columns (or rows) of the determinant are interpreted as vectors, the value of the determinant indicates the volume of the parallelepiped spanned by these vectors. It is clear from this that the determinant is only then different from zero when the column or row vectors are linearly independent.

Notations for the determinants

$$\det(A) = |A| = \begin{vmatrix} a_{11} & a_{12} \ldots a_{1n} \\ a_{21} & a_{22} \ldots a_{2n} \\ \vdots & \vdots \quad \vdots \\ a_{n1} & a_{n2} \ldots a_{nn} \end{vmatrix}$$

For (2×2) and (3×3) matrices the determinant can be calculated using Sarrus' rule. Here all the elements which are on diagonals going from top left to bottom right are multiplied by each other. These diagonals are then added. The elements which are on diagonals going from top right to bottom left are also multiplied by each other and subtracted from the other values. To this end, it is appropriate particularly for (3×3) matrices to write the first two column vectors on the right next to the determinant to simplify the calculation.

$$\begin{vmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{vmatrix} = a_{11}\,a_{22} - a_{12}\,a_{21}$$

$$\begin{vmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{vmatrix} = \begin{matrix} a_{11}\,a_{22}\,a_{33} + a_{12}\,a_{23}\,a_{31} \\ + a_{13}\,a_{21}\,a_{32} - a_{13}\,a_{22}\,a_{31} \\ - a_{12}\,a_{21}\,a_{33} - a_{11}\,a_{23}\,a_{32} \end{matrix}$$

When the determinants have more than three rows (columns), the determinant can be calculated with the Laplace expansion.

For the unit matrix the following applies:
$\det(E) = 1$.

For the product of two square matrices the following applies:
$\det(A\,B) = \det(A) \cdot \det(B)$.

Inverse matrix
The square $(n \times n)$ matrix B is the inverse to the square $(n \times n)$ matrix A when the following applies:
$A\,B = B\,A = E$.

In this special case the multiplication is commutative. Then $B = A^{-1}$ is written and the preceding equation becomes
$A\,A^{-1} = A^{-1}\,A = E$.

The following is obtained for the determinant of an invertible matrix:
$\det(A) \neq 0$ and $\det(A^{-1}) = \dfrac{1}{\det(A)}$

Systems of linear equations
In the case of a system of linear equations real (or complex) numbers a_{ij} and b_j ($j = 1 \ldots m$) are given while the x_i ($i = 1 \ldots n$) are unknown and thus are to be determined.

$$\begin{aligned} a_{11}x_1 + a_{12}x_2 + \cdots + a_{1n}x_n &= b_1 \\ a_{21}x_1 + a_{22}x_2 + \cdots + a_{2n}x_n &= b_2 \\ \cdots \quad \cdots \quad \cdots \quad \cdots \\ a_{m1}x_1 + a_{m2}x_2 + \cdots + a_{mn}x_n &= b_m \end{aligned}$$

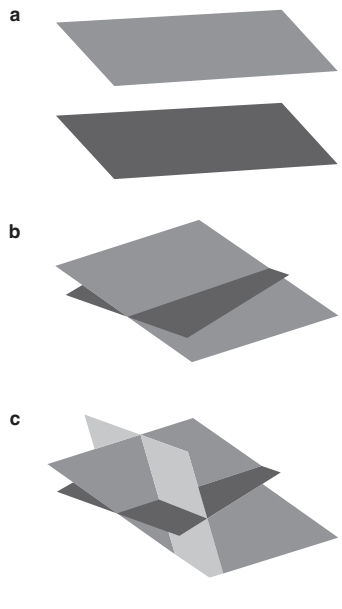
These equations can be summarized compactly with the aid of the $(m \times n)$ matrix A and the two vectors b, x

$$A = \begin{bmatrix} a_{11} & a_{12} \ldots a_{1n} \\ a_{21} & a_{22} \ldots a_{2n} \\ \vdots & \vdots \\ a_{m1} & a_{m2} \ldots a_{mn} \end{bmatrix} \quad b = \begin{bmatrix} b_1 \\ b_2 \\ \vdots \\ b_m \end{bmatrix} \quad x = \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix}$$

as a matrix-vector equation:
$A\,x = b$

Three methods which can be used to solve the system of linear equations are set out below.

1) In the case of a square and furthermore invertible matrix A the following is obtained:
$x = A^{-1}\,b$.



2) Alternatively, Cramer's rule an be used to solve a system of linear equations of a square and furthermore invertible matrix A. Here the component x_i of the solution vector x is obtained as:

$$x_i = \frac{\det(A_i)}{\det(A)}.$$

In the calculation of the auxiliary determinant A_i the $i$the column of the matrix is replaced by the vector b.

3) In the case of any $(m \times n)$ matrix the Gauss-Jordan algorithm can be used to determine the solution of the system of linear equations. Here matrix A is successively converted by row operations into an upper triangular matrix. The following are permitted as row operations:
– the multiplication of a row by a scalar (without zero), and
– the addition or subtraction of two rows.

Figure 18: Intersection of planes in space
a) Parallel planes,
b) Two planes intersect on a straight line,
c) Three planes intersect at a point.

Geometric interpretation of a system of linear equations

Each row of a system of linear equations can be interpreted geometrically as a hyperplane. Thus, the approach when solving a system of linear equations is to look for the points where these hyperplanes intersect. This is clearly shown in Figure 1 by way of example at two or three planes in $\mathbb{R}^3$: When the planes are parallel to each other, they do not intersect. Two planes intersect on a straight line. The latter corresponds exactly to a solution of the system of linear equations.

Technical statistics

Several thousand parts are required to produce an automobile. Since (random or systematic) fluctuations occur in every production process, not only the size for example of each part but also the associated tolerance is specified.

Even the measurement process is as a rule subject to random fluctuations, which are referred to as measurement uncertainty (previously the misleading term measuring error was also used). This measurement uncertainty should however be well below the tolerance limit of the part to be measured so that it can normally be disregarded.

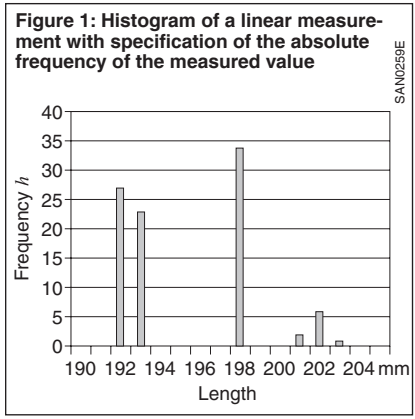
Measurements play a central role in production and hence in this connection in quality assurance. Since the required failure rate must be very low for individual parts, i.e. often in the ppm range (parts per million), it is for the most part not possible for process-technical and economic reasons to measure all the parts. Instead, samples are taken in order then to infer the quality of the components with statistical methods. These statistical methods are presented in the following.

The aim of a production process is to work accurately and precisely. Accurate means that the mean value of the target figure is close to the specified value. Precise denotes the production when the dispersion (scatter) around the mean value is low. It is possible to check using the statistical methods set out in the following whether these requirements are satisfied.

Table 1: Linear measurement and associated absolute frequency of the measured value

l [mm]	190	191	192	193	194	195
h	0	0	27	23	0	0
l [mm]	196	197	198	199	200	201
h	0	0	34	0	0	2
l [mm]	202	203	204	205	206	
h	6	1	0	0	0	

Descriptive statistics



For the purpose of obtaining an overview of extensive data material, these data are summarized and illustrated in descriptive statistics in tables and graphics. In this way, already systematic errors (or even typing errors) can often be detected and eliminated. However, it is not possible with descriptive statistics to specify error probabilities, which can only be made on the basis of statistical parameter models of inductive statistics.

Absolute frequencies of a measurement

The starting point is a data set with n values $x_1, x_2, \ldots, x_n$ (e.g., linear measurements) on n different components. These measurements are summarized according to their characteristics, where for each length l_i that occurs the associated number (absolute frequency) h_i is compiled ($i = 1, 2, \ldots, k$; $k \leq n$). This is shown by way of example for a linear measurement in Table 1 and in the associated histogram (Figure 1).

In this example the length $l = 198$ mm occurs with the most frequency. For $l = 192$ mm and $l = 193$ mm an accumulation occurs, as well as around $l = 202$ mm. Linear values $l \geq 204$ mm and $l \leq 191$ mm were not measured in this sample.

Figure 1: Histogram of a linear measurement with specification of the absolute frequency of the measured value

The sample size n corresponds to the number of measurements and results as the total of the absolute frequencies:

$$n = h_1 + h_2 + \cdots + h_k = \sum_{i=1}^{k} h_i.$$

From this is obtained the relative frequency

$$f_i = \frac{h_i}{n} \text{ where } i = 1, 2, \ldots, k.$$

When the relative frequency is added up, this produces the value 1:

$$\sum_{i=1}^{k} f_i = 1.$$

To characterize a data set and to be able to compare this with other data sets, characteristic values such as the location parameters and dispersion parameters are calculated from this.

Location parameters and location measures

The median x_{med}, also called the central value, is the value in the middle of a data series $\{x_1, x_2, \ldots, x_n\}$ when the values are sorted by size. In other words, at least half of the data is less than or equal to x_{med} and at the same time at least half of the data is greater than or equal to x_{med}. In the case of an even number of data, x_{med} is the mean value of the two data in the middle of the series.

Often also of interest is the location of the lower (or upper) portion of values. The associated threshold value $x_{p\text{Q}} \in \{x_1, x_2, \ldots, x_n\}$ is also referred to as p quantile or as percentile. Hence, therefore, at least $p \cdot 100$ % of the data is less than or equal to $x_{p\text{Q}}$. At the same time, at least $(1 - p) \cdot 100$ % of the data is greater than or equal to $x_{p\text{Q}}$. The 25% quantile is also called the first or lower quartile; the 75 % quantile the upper or third quartile.

The arithmetic mean (average value) is defined as

$$\bar{x} = \frac{1}{n}(x_1 + x_2 + \cdots + x_n) = \frac{1}{n}\sum_{i=1}^{n} x_i$$

and the geometric mean of non-negative numbers x_i as

$$\bar{x}_{\text{geo}} = \sqrt[n]{x_1 \cdot x_2 \cdot \cdots \cdot x_n}.$$

The following always applies: $\bar{x}_{\text{geo}} \le \bar{x}$.

Likewise, the arithmetic and geometric means can also be calculated via the characteristics l_i and their frequency h_i.

$$\bar{x} = \frac{1}{n}\sum_{i=1}^{k} l_i h_i,$$

$$\bar{x}_{\text{geo}} = \sqrt[n]{l_1^{h_1} l_2^{h_2} \cdots l_k^{h_k}}.$$

The symbol μ is often used as well as the symbol $\bar{x}$ for the mean value.

Dispersion parameters

In a data set it is also important to know whether the individual values are close to or far from the mean value. This is recorded by the following dispersion parameters. The variance $\text{Var}(x) = s^2$ of the data set x is calculated as

$$s^2 = \text{Var}(x) = \frac{1}{n-1}\sum_{i=1}^{n}(x_i - \bar{x})^2$$

$$= \frac{1}{n-1}\sum_{i=1}^{k} h_i (l_i - \bar{x})^2.$$

The root from this is called standard deviation s.

$$s = \sqrt{s^2} = \sqrt{\text{Var}(x)}$$

σ is often used as well as s for the standard deviation.

Example

For the above example (Figure 1 and Table 1) the mean value is obtained at $\bar{x} = 195.40$ mm. The two frequencies $h_{192\text{ mm}}$ and $h_{193\text{ mm}}$ added up produce a number 50. This is above $n/2 = 46.5$. Thus, the median follows with $x_{\text{med}} = 193$ mm. The variance has the value $s^2 = 11.48$ mm^2 and the standard deviation $s = 3.38$ mm.

Probability calculus

The quality of a production process is to be inferred from a sample (e.g., linear measurement of a certain quantity of components). This is however only possible if realistic assumptions about the distribution of this measured value are made. A number of probability distributions are presented in the following for this purpose.

The Binomial distribution, the Hypergeometric distribution and the Poisson distribution are discrete distributions. Here, a sample is taken from a quantity and then the corresponding probabilities are calculated. From a mathematical standpoint both the sample size and the size of the quantity from which the sample is taken are natural numbers.

On the other hand, the Weibull distribution and the Gaussian normal distribution apply to continuous distributions, i.e. to real variables t or x.

Discrete distributions

Binomial distribution

A sample delivers only two values (Bernoulli experiment), one value with the probability p and the second value with the probability $q = 1 - p$ (since $p + q = 1 = 100\ \%$). An example in this connection is drawing a ball from a bowl containing balls of two different colors. The ball is returned to the bowl after each draw. Hence the probability for each removal of a sample is the same.

The associated probability function $f(x)$ indicates that this event in the case of n-fold execution occurs exactly x times:

$$f(x) = \binom{n}{x} p^x q^{n-x} = \binom{n}{x} p^x (1-p)^{n-x},$$

where $x = 0, 1, 2, \ldots, n$; $\binom{n}{x} = \frac{n!}{x!\,(n-x)!}$.

The binomial distribution has the mean value $\mu = np$, the variance $\sigma^2 = npq = np(1-p)$, and the standard deviation $\sigma = \sqrt{npq} = \sqrt{np(1-p)}$.

Hypergeometric distribution

This distribution often plays a role in quality and final inspections. Similarly to the previous bowl model, there are at the start m white and $n - m$ red balls in a bowl. In contrast to the binomial distribution, this distribution corresponds to drawing a ball without putting it back, was which is customary for a sample in production. Hence, with each sample removal, the probability of drawing a white ball changes.

If now k samples are removed, this produces the probability function $f(x)$ at:

$$f(x) = \frac{\binom{m}{x}\binom{n-m}{k-x}}{\binom{n}{k}},\ x = 0, 1, 2, \ldots, k.$$

The hypergeometric distribution has the mean value

$\mu = k\frac{m}{n}$, the variance

$$\sigma^2 = \frac{km(n-m)(n-k)}{n^2(n-1)}$$

and the standard deviation

$$\sigma = \sqrt{\frac{km(n-m)(n-k)}{n^2(n-1)}}.$$

For $k < 0.05\,n$ the easier-to-calculate binomial distribution can be used as a very good approximation for the hypergeometric distribution.

Poisson distribution

If a binomial distribution exists with a very low probability of occurrence p, this can also be described by a Poisson distribution with the mean value μ and the variance $\sigma^2 = \mu$:

$$f(x, \mu) = \frac{\mu^x}{x!} e^{-\mu},\ x = 0, 1, 2, \ldots$$

The Poisson distribution has the mean value μ, the variance $\sigma^2 = \mu$, and the standard deviation $\sigma = \sqrt{\mu}$.

A binomial distribution can be well approximated by a Poisson distribution if the following two conditions are satisfied:
$np < 10$,
$n > 1500p$.

Continuous distributions
The Weibull distribution and the Gaussian normal distribution are classed as the continuous distributions. Hence they are functions of real variables x. The following functions are used to describe these: compression functions $f(x)$ and the associated distribution functions $F(x)$, which constitute their antiderivatives:

$$\frac{d}{dx}F(x) = f(x).$$

The integral over the compression function of x_1 through x_2

$$\int_{x_1}^{x_2} f(x)\,dx = F(x_2) - F(x_1)$$

specifies the probability that the random variable x is in the interval of x_1 through x_2. Accordingly, the distribution function

$$F(x_2) = \int_{-\infty}^{x_2} f(x)\,dx$$

is the probability that an event with $x \le x_2$ occurs.

Often the expectation value $E(x)$ is referred to instead of the mean value μ

$$\mu = E(x) = \int_{-\infty}^{\infty} x f(x)\,dx.$$

The variance is defined as

$$\sigma^2 = \mathrm{Var}(x) = E\left((x-\mu)^2\right) = \int_{-\infty}^{\infty} (x-\mu)^2 f(x)\,dx.$$

Weibull distribution
The fatigue of a material and the failure of a machine can often be described via a Weibull distribution over the time t (instead of the variable x) (service life T of the material or the machine, empirical or specific parameters α, β).

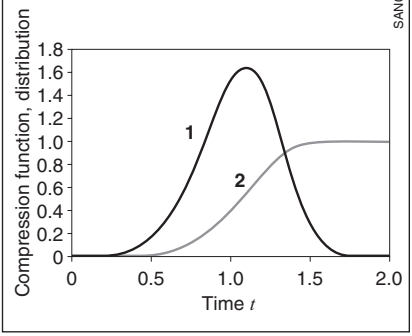
Accordingly, the probability that the service life ≤ t is at

$$F(t) = 1 - e^{-\alpha t^{\beta}}$$

and hence the survival probability (reliability)

$$R(t) = 1 - F(t) = e^{-\alpha t^{\beta}}.$$

The associated compression function $f(t)$ is the first derivation of $F(t)$:



$$f(t) = F'(t) = \alpha\,\beta\,t^{\,\beta-1}\,e^{-\alpha t^{\beta}}$$
for $t > 0$, otherwise $f(t) = 0$.

From this the failure rate is obtained at

$$\lambda = \frac{f(t)}{R(t)} = \alpha\,\beta\,t^{\,\beta-1}.$$

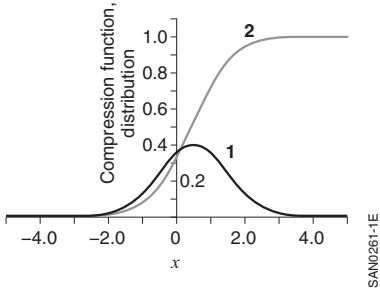
Figure 2 shows a compression function and the associated distribution for $\alpha = 0.5$ and $\beta = 5$. The greatest failure probability is at $t = 1.1$. With increasing time the failure probability does in fact decreases again, but the function $F(t)$, i.e. the total failure rate until time t, naturally approaches 1 = 100 %.

Figure 2: Weibull distribution
For $\alpha = 0.5$ and $\beta = 5.0$.
1 Compression function,
2 Distribution.

Gaussian normal distribution
Very many random processes in nature and also in technology can be described by a Gaussian normal distribution. The associated compression function contains the expectation value μ and the standard deviation σ:

$$f(x, \mu, \sigma) = \frac{1}{\sqrt{2\pi}\,\sigma} e^{-\frac{(x-\mu)^2}{2\sigma^2}}, \quad -\infty < x < \infty.$$

The associated Gaussian normal distribution function



$$F(x,\mu,\sigma) = \int_{-\infty}^{x} f(z,\mu,\sigma)dz = \frac{1}{\sqrt{2\pi}\,\sigma}\int_{-\infty}^{x} e^{-\frac{(z-\mu)^2}{2\sigma^2}}dz, \quad -\infty < x < \infty$$

is the antiderivative for $f(x,\mu,\sigma)$. As the name already suggests, this is normalized, i.e.

$$\lim_{x\to\infty} F(x,\mu,\sigma) = \frac{1}{\sqrt{2\pi}\,\sigma}\int_{-\infty}^{\infty} e^{-\frac{(z-\mu)^2}{2\sigma^2}}\,dz = 1.$$

Figure 3 shows by way of example a Gaussian compression function and the associated Gaussian normal distribution. The compression function has its maximum at the expectation value; its breadth is determined by the standard deviation. Furthermore, it is axisymmetric to $x=\mu$. This "Gaussian bell-shaped curve" drops markedly for large x values and for small x values and approaches asymptotically the x axis.

Figure 3: Gaussian normal distribution
1 Compression function with the expectation value $\mu = 0.5$ and the standard deviation $\sigma^2 = 1$,
2 Associated normal distribution for the compression function.

The Gaussian normal distribution increases from 0 (for $x \to -\infty$) to the value 1 (for $x \to \infty$). At $x=\mu$ it has the value $F(x=\mu)=0.5$.

The Gaussian normal distribution has the mean value μ, the variance σ^2, and the standard deviation σ.

With the substitution $y = \frac{x-\mu}{\sigma}$ the following standard normal distribution is obtained

$$\varphi(y) = \frac{1}{\sqrt{2\pi}} e^{-\frac{1}{2}y^2}, \quad -\infty < z < \infty$$

Accordingly, the following normal distribution is obtained from this

$$\Phi(y) = \int_{-\infty}^{y} \varphi(z)\,dz = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{y} e^{-\frac{1}{2}z^2}\,dz, \quad -\infty < y < \infty.$$

Many production processes are characterized by way of their σ level (Table 2). In the case of the 3σ level, for instance, the probability that the produced parts are defect-free is 93.3 %.

The 6σ level (Six Sigma Level) plays a central role in quality management. Departing from the above definition of the compression function, long-term mean shifts are included here. Thus, the 6σ level corresponds to 3.4 DPMO (Defects Per Million Opportunities), i.e. $3.4 \cdot 10^{-6}$ of the parts are outside the tolerance band.

For a normally distributed random variable X with the mean value μ and the standard deviation σ the following probabilities are obtained:

Table 2: σ level
The middle column specifies the probability that the values are inside the range $\mu - k\sigma < x < \mu + k\sigma$.

σ level	inside [%]	outside [%]
σ	32	68
2σ	69	31
3σ	93.3	6.7
4σ	99.38	0.62
5σ	99.977	0.023
6σ	99.99966	0.00034

$$P(X \le x) = \Phi\left(\frac{x-\mu}{\sigma}\right) = \Phi(y).$$

$$P(X > x) = 1 - P(X \le x) = 1 - \Phi(y).$$

$$P(a \le X \le b) = \Phi\left(\frac{b-\mu}{\sigma}\right) - \Phi\left(\frac{a-\mu}{\sigma}\right).$$

$$P(|X-\mu| \le k\sigma) = P(\mu - k\sigma \le X \le \mu + k\sigma) = 2\,\Phi(k) - 1.$$

Parameter estimation in the Gaussian normal distribution

Quantitative statements based on samples are to be made with the aid of statistical models (distribution models). The aim would be to determine characteristic values such as, for example, the mean value μ and the standard deviation σ. But this is not exactly possible since the sample is limited. However, it is possible to calculate from the sample estimates for the mean value and the standard deviation and for this to determine confidence intervals with which the sought-after characteristic value is in this interval with a specified probability.

To this end a random sample is taken from the sample size n, delivering the values $x_1, x_2, \ldots, x_n$. These elements are also called the realization of the sample. Calculated from these are the estimate of the mean value

$$\bar{x} = \frac{1}{n}(x_1 + x_2 + \cdots + x_n) = \frac{1}{n}\sum_{i=1}^{n} x_i$$

and the estimate of the variance

$$s^2 = \frac{1}{n-1}\sum_{i=1}^{n}(x_i - \bar{x})^2.$$

Parameter estimations are carried out in the following, where it is assumed that there is an underlying Gaussian normal distribution. This distribution underlies very many production processes. For the parameter estimations for other distributions, reference is made to the bibliography ([3], [4], [5]).

Confidence interval for unknown mean value and known variance

In the case of a specified confidence level γ (usually 95 % or 99 %) the confidence interval of the breadth Δx in which the unknown mean value μ lies with a probability of γ is to be determined, i.e.

$P(|\bar{x} - \mu| \le \Delta x) = \gamma.$

This is equivalent to the unknown mean value μ lying in the interval

$\bar{x} - \Delta x \le \mu \le \bar{x} + \Delta x$

with a probability of $\gamma \cdot 100$ %. The estimate of the mean value is calculated from the sample.

With the standardized random variable

$$z = \frac{\bar{x} - \mu}{\frac{\sigma}{\sqrt{n}}} \text{ and } \Delta z = \frac{\Delta x}{\frac{\sigma}{\sqrt{n}}}$$

the above probability can be depicted as follows:

$P(|z| \le \Delta z) = \gamma.$

From

$$P(|z| \le \Delta z) = 2\,\Phi(\Delta z) - 1 \Rightarrow \Phi(\Delta z) = 0.5\,(\gamma + 1)$$

the right side can be calculated and then Δz for example viewed in a table for the normally distributed Gaussian function, and finally from this Δx calculated.

Confidence interval for unknown mean value and unknown variance

From the sample first the estimates of the mean value $\bar{x}$ and the standard deviation s are calculated. Similarly to before, in the case of a specified confidence level γ (usually 95 % or 99 %) the confidence interval of the breadth Δx in which the unknown mean value μ lies with a probability of γ is to be determined, i.e.

$$P(|\bar{x} - \mu| \le \Delta x) = \gamma.$$

The procedure for determining Δx is performed exactly as before, where for σ now s is used here.

Sums and products of random variables

If a process is determined by a number of random variables $x_1, x_2, \ldots, x_n$, this produces for the sum total $z_S = x_1 + x_2 + \cdots + x_n$ and for the product $z_P = x_1 \cdot x_2 \cdot \cdots \cdot x_n$ the expectation values E and the variance:

$E(z_S) = E(x_1) + E(x_2) + \cdots + E(x_n)$
or $\mu_{zS} = \mu_1 + \mu_2 + \cdots + \mu_n$.

$E(z_P) = E(x_1) \cdot E(x_2) \cdot \cdots \cdot E(x_n)$
or $\mu_{zP} = \mu_1 \cdot \mu_2 \cdot \cdots \cdot \mu_n$.

$\mathrm{Var}(z_S) = \mathrm{Var}(x_1) + \mathrm{Var}(x_2) + \cdots + \mathrm{Var}(x_n)$
or $\sigma_{zS}^2 = \sigma_1^2 + \sigma_2^2 + \cdots + \sigma_n^2$.

Linear regression

In the case of a sample a linear connection between the parameter x and the measured variable y is presumed:

$$y = mx + t.$$

The sample delivers for the set parameters x_i the measured values y_i (i = 1, 2, …, n). From these values the gradient of the straight line m and the axis intercept t are to be determined so that the deviation between the straight line and the measured values (x_i, y_i) is as small as possible (minimum Gaussian deviation). These are obtained then as

$$t = \frac{\left(\sum_{i=1}^{n} x_i\right) \cdot \left(\sum_{i=1}^{n} x_i y_i\right) - \left(\sum_{i=1}^{n} x_i^2\right) \cdot \left(\sum_{i=1}^{n} y_i\right)}{\left(\sum_{i=1}^{n} x_i\right)^2 - n \sum_{i=1}^{n} x_i^2}$$

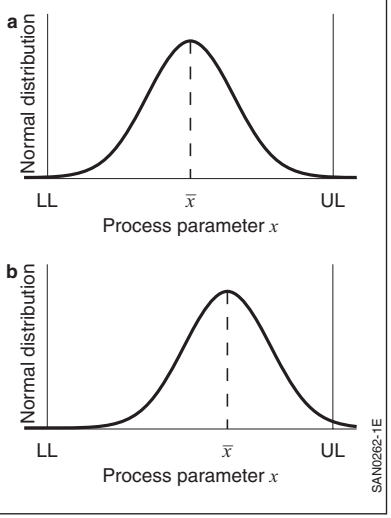
and as

$$m = \frac{\left(\sum_{i=1}^{n} x_i\right) \cdot \left(\sum_{i=1}^{n} y_i\right) - n \sum_{i=1}^{n} x_i y_i}{\left(\sum_{i=1}^{n} x_i\right)^2 - n \sum_{i=1}^{n} x_i^2}$$

In the case of a linear connection $y = mx$ without axis intercept, m is simplified at

$$m = \frac{\sum_{i=1}^{n} x_i y_i}{\sum_{i=1}^{n} x_i^2}.$$

Characteristic value in quality assurance and in quality management



Statistical Process Control (SPC) is used in production processes and in quality management to assure the quality of the manufactured goods. A Gaussian normal distribution is assumed as a rule here.

In a production process the upper and lower limits (UL and LL) are stipulated for example by customer requirements. The tolerance range T is obtained from this as

$$T = \mathrm{UL} - \mathrm{LL}.$$

The mean value $\bar{x}$ and the standard deviation s are calculated from a sample. Furthermore, the critical length Z_{crit} is determined, i.e. the amount of the difference between the mean value $\bar{x}$ and UL or between the mean value $\bar{x}$ and LL is formed, and the smaller of these is taken as Z_{crit}.

Figure 4: Gaussian distributions of two samples
a) Mean value lies exactly in the middle of the lower and upper limits,
b) Mean value is closer to the upper limit.
$\bar{x}$ Mean value,
LL Lower limit,
UL Upper limit.

$Z_{crit} = \min(|UL - \bar{x}|, |LL - \bar{x}|)$.

It can be seen in Figure 4 that the mean value is closer to the UL than to the LL. Hence here
$Z_{crit} = UL - \bar{x}$.

From this the process capability c_p is obtained as

$$c_p = \frac{T}{6s}$$

and the process capability characteristic value c_{pk} as

$$c_{pk} = \frac{Z_{crit}}{3s}.$$

In standard production $c_p \geq 1.33$ and $c_{pk} \geq 1.33$ are classed as guide values for a stable process which satisfies the quality requirements.

Finite-element method

Applications

Virtually all technical procedures can be simulated on a computer with the finite-element method FEM (the term having been introduced by Ray W. Clough at the start of the 1960s [1]). However, this involves breaking down any body (gaseous, liquid, or solid) into elements that are simple in shape (line, triangle, square, tetrahedron, pentahedron, or hexahedron), that are as small as possible, and that are permanently connected to each other at their corner points ("nodes"). Small elements are important because the behavior of elements formulated by approximation using linear equations is only applicable to infinitesimal elements. However, the computing time calls for finite elements. The approximation to reality is better the smaller the elements are.

The application of FEM in practice – also known as FEA (finite-element analysis) – began in the early 1960s in the aviation and aerospace industries and followed soon after in automobile manufacturing. Today the method is used in all fields of technology, including weather forecasting, medical science, and for many sectors of automobile manufacturing ranging from engine and chassis components through to body calculations and crash behavior.

There are two different types of application. Firstly, virtually fully automatic "Black Box" FEM contained in all CAD programs (computer-aided design) for rough calculations by the design engineer (e.g. in designing a bumper) and, secondly, the use reserved for specialists of special FEM programs (e.g. in body calculations, in axle development or in driving dynamics).

FEM program system
The software of an FEM system consists of a preprocessor, a postprocessor, and the actual FEM program. Network creation, i.e. breakdown into elements, is mainly performed in the preprocessor on the basis of a CAD geometry which is read directly or via neutral interfaces such as IGES (Initial Graphics Exchange Specification), VDA-FS (Verband der Automobilindustrie – Flächenschnittstelle) or STEP (Standard for the Exchange of Product Model Data). The FEM program calculates the computing model formulated in this way. The result found is then shown in graphic form in the postprocessor (e.g. stress distribution by means of isocolors, deformations as motion animation).

Basic knowledge for application
FEM is, like all numerical methods, an approximation process. In mechanics, the main area of application, the limitations caused by this are described in the following.

Small motions in one solution step
Bodies move on paths which are normally higher-order curves. With the basic principle of linearization of all processes, this motion is limited to a straight path which can then be described by linear equations. When transferred to the element corners (nodes), they also move on a straight line. Thus, the nodes are only able to realize very small motions correctly (node twists less than 3.5°). The actual motion along any path or nonlinear material behavior is thus solved linearly with many small steps.

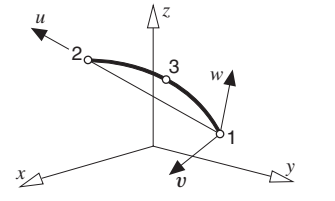
Calculation accuracy
The linear equation system is formulated and solved with the limited computing accuracy of a computer. Usually, 8 bytes (= 64 bits) are used with a computing accuracy of 13 significant digits for the number stored, i.e. only the first 13 digits of a number can be represented exactly. The further digits in this number are random numbers. As a result, this rules out the possibility of any stiffness differences of the individual components in a model. Therefore, in the deformation calculation of a body, it is necessary, as for example in the measurement of body deformation, to replace the axle springs with rigid supports.

Interpretation of results
The great danger lies in the fact that a formal computation model formulated correctly by a beginner will indeed deliver beautifully colorful images, but the results shown can center around factors far from reality.

The problems resulting from the above-mentioned limitations must therefore be identified and signaled by the computing program, so that the less experienced user is also able to obtain correct results easily.

Areas of FEM application
In technology terms, physics is generally divided into five areas – mechanics with statics and kinematics (e.g. body, axle), dynamics with acoustics (e.g. vehicle noise), thermodynamics (e.g. temperature distribution in the engine), electricity with magnetism (e.g. ignition coil, sensor technology), and optics (e.g. headlamp). When it comes to FEM, a distinction is always made between

– linear and nonlinear static and dynamic problems with the deformations as an unknown for stress calculation and dynamic analysis,
– stationary (timeless) and nonstationary (time-dependent) potential problems (e.g. temperature, sound pressure, electrical or magnetic potential) with the potentials as an unknown,
– and the linking of these different fields, e.g. to calculate a temperature field and the resulting deformations, stresses and forces in linear statics when the engine is started.



Elements of FEM
The properties of the elements define the most important performance data of an FEM program. The element quality is determined by the degree of the mathematical formulation function selected. Here, for example, a distinction is made between elements with a linear or quadratic formulation, recognizable from the midside node in the middle of the edge. The quality of a computing model is therefore dependent not just on the fineness of the used mesh, but also quite considerably on the formulation function.

A distinction is made between three different types of elements: line elements, shell elements, and volume elements.

Line elements
Line elements (Figure 1) are either straight or curved with an midside node. The cross-sections are described by specifying the numerical values for the cross-sectional area A, the reduced shear cross-sections $A_{\text{red-v-w}}$ (shear areas), the principal moments of inertia (I_v, I_w), the torsional moment of inertia (I_t) with the torsional section modulus (W_t), the sector moment of inertia for warping-force torsion, an angle α which describes the position of principal axes of inertia v and w in relation to the road plane, and the maximum four stress points (S_v, S_w) for bending-stress calculation.

Shell elements
Shell elements (Figure 2) are either triangular or quadrangular in shape – ideally an equilateral triangle or a square, usually of constant thickness. If the midside nodes are omitted, the edges are straight.

Figure 1: Line elements
With constant or linearly variable cross-section.

Volume (solid) elements
Volume elements (Figure 3) as tetrahedrons, pentahedrons and hexahedrons without midside nodes have straight edges – ideally an equilateral tetrahedron or a cube. With a sufficient number of elements in relation to the thickness (greater than or equal to three), elements with midside nodes are not necessary today. However, this does not apply to tetrahedrons, which are almost alway used in the case of a complicated geometry, such as a cylinder head for example.

Modeling and evaluation of results
The most important function in using an FEM program is the usually time-consuming task of creating the input data as a computing model with the preprocessor. The user should try to achieve this target with as few elements and nodes as possible (however, the computing model of a body today has approximately three to four million nodes). To do so, the user requires a certain level of experience, but must have an exact knowledge of the qualities of the elements used (see FEM examples). These can differ slightly in every FEM program.

The first step in modeling involves choosing the element type (line, shell or volume element) and determining the fineness of the mesh, e.g. by means of the specified middle element-edge length. The next step involves defining the properties (material data), e.g. the element thickness for unit elements, the cross-section values for line elements, and the units used (e.g. length in mm and force in N). A further step involves determining support conditions and load. The crucial factor here is considering the points where a model is fixed, and where it is loaded. In relation to loading, it is also useful to conduct a breakdown of the total load into load cases, e.g. into the mass load from gravity weight and different traffic loads.

All FEM results are available in list form or postprocessor data format, and can therefore be shown in graphic form (see FEM examples). To this end, the postprocessor offers all the conceivable forms of display.

Figure 2: Shell elements

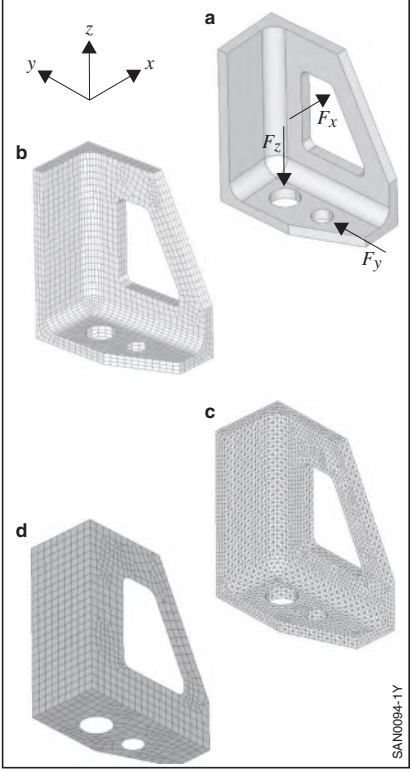
FEM examples



For the examples, modeling is performed on the basis of CAD geometry using the FEM program TP 2000. The model inputs, together with color representation of the results, can also be found on the Internet page specified in [2].

In reality, all bodies are three-dimensional. In simulation, a simplified solution is often chosen in order to save time and expense. It is much easier, for example, to realize the automatic meshing of a flat surface in shell elements than it is to realize a body in its volume elements. The frequently used tetrahedron mesh, which today every preprocessor creates for any volume geometry, does not always live up to expectations.

In automobile manufacturing, the structural components are either thick-walled and solid (e.g. engine, transmission, axles, wheels) and modeled with volume elements or they are made from thin-walled sheet metal (e.g. automobile body, truck cab) and are modeled with shell and line elements.

The first example, as a volume-element model, belongs to the first group of thick-walled, solid components. It is compared with the commonly used shell model of the second group. This also includes the line element commonly used in automobile manufacturing with the second example.

Figure 4: Cast-steel engine mount
a) CAD model with load F_x, F_y, F_z,
b) Model A1 (hexahedron),
c) Model B1 (tetrahedron),
d) Model C (shell).

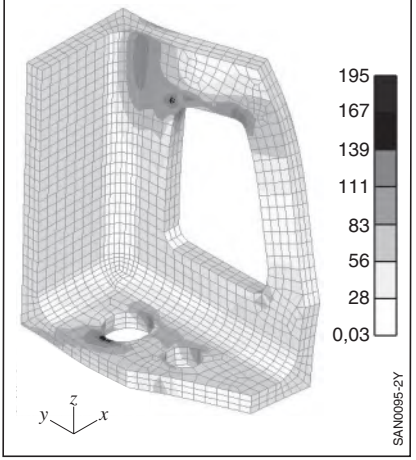
Example 1: Cast-steel engine mount as shell- and volume-element model (linear statics)

The aim is to compare shell and volume elements in linear statics on a relatively thick-walled (3.75 mm) cast-steel engine mount ($50 \times 25 \times 57$ mm^3). In the volume elements, two models A and B (each with and without midside nodes) with significantly different result qualities are compared; added to this is shell model C (Figure 4). Starting out from the CAD volume geometry, the preprocessor automatically creates volume-element networks A and B, and also shell-element model C by means of the surface model.

The material properties in the units mm, N and kg are:
Modulus of elasticity: 210,000 N/mm^2
Poisson's ratio: 0.3
Density: 0.00000785 kg/mm^3 .

In the case of models A and B, the element properties are defined with the element type "Solid" (volume) with three node degrees of freedom v_x, v_y and v_z. In the case of model C, the properties are defined with the element type "Plate" (shell) with six node degrees of freedom v_x, v_y, v_z, d_x, d_y, d_z and constant thickness d = 3.75 mm.

In model A, the meshing with volume elements (solid mesh) shows the preferred breakdown into hexahedrons (not possible fully automated for all geometries because here, for example, the geometry



first had to be broken down into basic bodies) and in model B, the automatic tetrahedron meshing. The number of elements in relation to thickness which is crucial for accuracy is specified (at least three elements here).

Support conditions
On the rectangular xz plane, $v_y = 0$ applies to all nodes. All the edge nodes on the right long leg are pinned by $v_x = 0$, and those of the lower short leg are pinned by $v_z = 0$.

Loading
$\sum F_x = 900$ N, $\sum F_y = 2006$ N, $\sum F_z = -550$ N. All the loads are defined as surface load ("on surface", for shell "on curve") at the recess at $F_x = 600$ N, at the small hole at $F_y = 2006$ N, and at the large hole at $F_z = -550$ N.

Note: "Isolated" individual loads are only permitted with line elements.

Figure 5: Deformation and stress distribution in model A2 as the correct model
$v = 0.064$ mm, $\sigma = 195$ MPa.

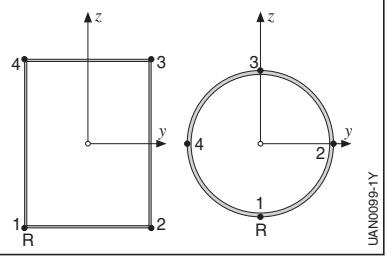
Result
The results are shown in Table 1. Figure 5 shows the result for model A with stresses as shades of gray (critical areas are shown in dark) or as isocolors in the original.

Volume elements are very sensitive to incorrectly approximated load distributions. Volume elements should therefore only ever be subjected to surface loads.

Considering Table 1 in detail: Experience shows that model A2 with midside nodes delivers the correct result ($v = 0.064$ mm, $\sigma = 195$ MPa). The deviation between averaged and maximum node stress (from all the elements at the same node) should be as small as possible (less than 15 %). This is achieved with model A1 at 11 % with three elements per thickness.

In model B1 with three tetrahedrons per thickness, the deformation is 25 % too small ($v = 0.048$ mm), and the maximum stress is also 25 %. With only two tetrahedrons in relation to the thickness, the model would even be 58 % too rigid and can barely be used with correspondingly lower stresses. However, with midside nodes (B2), it delivers virtually identical deformations and stresses to A2 with a very large number of nodes and long computing times. Caution is therefore advised with rough tetrahedron mesh without midside nodes.

Table 1: Results for engine-mount model
Values in parentheses apply to elements with midside nodes.



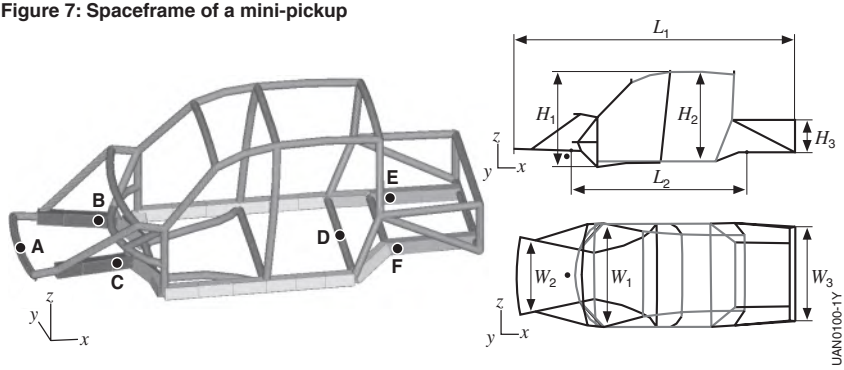
Model	Element type	No. of nodes	Weight in kg	Max. deformation in mm	Mean stress in MPa	Max. stress in MPa	Stress error max. in %	Computing time in sec
A1 (A2)	Solid hexahedron	4,000 (15,000)	0.119	0.061 (0.064)	145 (185)	164 (195)	15 (0)	10 (110)
B1 (B2)	Solid tetrahedron	10,000 (70,000)	0.119	0.048 (0.064)	115 (173)	146 (209)	30 (6)	60 (2,400)
C	Rectangular shell	766	0.114	0.081	197	223	14	2

Model C with shell elements without shear deformation (only intended for thin-walled structures) is clearly too soft (v = 0.081 mm, 21 % greater, as thick-walled with shear deformation even 30 % greater). Shell elements, whether thin- or thick-walled, deliver only partially usable deformations with relatively large thickness, particularly in the case of very compact bodies, as is the case here. However, at stresses of +14 %, it is for the most part on the safe side.

Example 2: Tubular body frame
The aim is to carry out an FEM analysis on a body in the form of a spaceframe without sheet paneling, including optimized weight and stiffness for the example of a mini-pickup (not a real vehicle). The material properties are:
Modulus of elasticity: 200,000 N/mm^2
Poisson's ratio: 0.3
Density: 0.00000785 kg/mm^3 .

For reasons of simplicity, only two shapes are used as profile sections (Figure 6). A box-type profile section (90 × 120 × 1.5 mm^3) and a tube profile section (70 x 2 mm^2), which are defined by their shape in the preprocessor in the properties directly with the element type "Bar" and its constant cross-section (different starting and end cross-sections would be "Beam"). This results in the required cross-section values as follows (in mm^2 or mm^4 and mm^3).

Figure 6: Profile sections of spaceframe
a) Box-type section, b) Tube section.



Box/tube (Figure 6)
– Cross-sectional area:
  A = 621/427.
– Reduced shear cross-sections (shear area):
  A_{redI} = 325/227,
  A_{redII} = 219/227.
– Principal moments of inertia:
  I_I = 1,348,306/247,168
  I_{II} = 869,596/247,168.
– Torsional moment of inertia:
  I_t = 1,606,083/494,261.
– Torsional section modulus:
  W_t = 7,334/2,177.
– Position of principal axes of inertia in relation to road:
  α = 0°.
– Maximum four stress points:
  S_x = –45/45/45/–45 / 0/35/0/–35,
  S_y = –60/–60/60/60 / –35/0/35/0.

The main dimensions according to the side and top views (Figure 7) are (in mm):
L_1 = 4,114 (max.)
L_2 = 2,650
W_1 = 1,517 (max.)
W_2 = 1,147 (front)
W_3 = 1,374 (rear)
H_1 = 1,402 (max.)
H_2 = 1,315
H_3 = 469 (box)

Body
The tubular consists of 18 components (Figure 8), e.g.:
2 Side pillar,
3 Pedal cross-pillar,
7 Cockpit cross-pillar,
8 Side pillar, front,
10 Auxiliary cross-pillar, front,
14 Roof frame, side,
15 Roof frame, lateral,
16 Rear subframe,
17 Side pillar, box,
19 Bumper, rear.

Support conditions
Linear statics, load case – bending (not shown):
A v_y = 0; (A – F, see Figure 7).
B, C, E, F v_z = 0; D v_x = 0, v_y = 0.

Figure 7: Spaceframe of a mini-pickup

Linear statics, load case – torsion:
A, B, C = free;
E, F $v_z = 0$;
D v_x, $v_y = 0$, $d_y = 0$, $d_z = 0$.

Free/free dynamics:
No supports, body vibrates freely in the springs.

Loading
Linear statics, load case – torsion:
Torsional moment 3,000,000 Nmm as regular unit load on
Front-axle bearings B: $F = -3593.7$ N
Front-axle bearings C: $F = 3593.7$ N

Free/free dynamics:
Only masses from gravity weight with 170 kg, no supplementary masses.

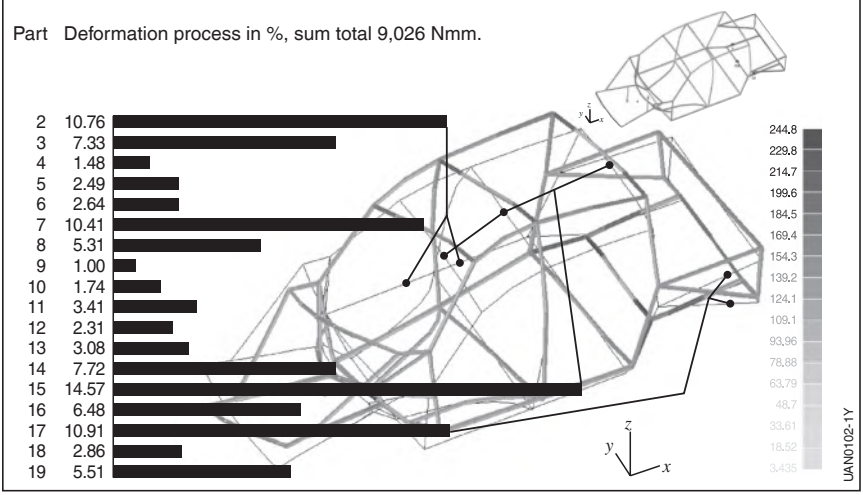
Results
Free/free dynamics:
– The body can vibrate freely in its springs, the lower eigenvalues and modes of the undamped, elastic system in ascending order; for free/free beginning with several rigid-body vibration modes (here 1 through 6) with the natural frequency 0 in each case.
– The 1st eigenvalue (38 Hz) is obtained as the 1st torsional vibration, the 3rd eigenvalue (48 Hz) as the 1st flexural vibration; with in each case the normalized deformations x, y, z at all nodes (here normalized to max. 0.1 mm), the normalized stresses in all elements, and the deformation processes important for weight optimization per element and per component 1 through 18 in % as a bar chart (as shown for linear statics in Figure 8). Absolute values are only obtained in the event of an excitation calculation.

Linear statics:
– Deformations x, y, z at all nodes,
– Reaction forces and moments at the support nodes, stresses at all elements, strain energy per element and per component in %.

Weight and stiffness optimization
The computation formula for weight and stiffness optimization has been known since the 1960s (error max. 10 % for doubled rigidity). The stiffness change of the overall structure (in %) is obtained from the stiffness change of the component multiplied by the deformation-process ratio of the component, divided by 100.

This formula is used specifically for optimization purposes in virtually all automobile-critical "Torsion" load cases with consideration of the other load cases. In this way, the structure can be reinforced using pillars that take most of the load, and reduce weight via the pillars that take less of the load.

Application of formula
1st component (see Figure 8):
Component 15 (roof frame, lateral, G =11.85 kg with 14.57 % strain energy ratio:
Produces (14.57 x 116) / 100 = 16.9 % change (i.e. reduction) of torsion between the axles when the stiffness (planar moment of inertia) of this component is increased by a factor of 2.169 (116.9 %). The weight increase here is 3.55 kg when the tube diameter is increased from 70 to 90 mm.



2nd component (see Figure 8):
Component 6 (linear reinforcement, G = 11.14 kg) with 2.64 % strain energy ratio:
Produces (2.64 x 250)/100 = 6.6 % change (i.e. only very small reduction of torsion between the axles when the stiffness (moment of inertia) of this component is reduced by a factor of 3.5 (250 %). The weight reduction is 3.34 kg when the tube diameter is reduced from 70 to 50 mm.

Result:
A minimal weight increase of 3.55 – 3.34 = 0.21 kg increases torsional stiffness by 16.9 – 6.6 = 10.3 % (checking with altered profile sections produces 9 %, this covers the low error in the computation formula).

A look at the strain energy charts of the other load cases (not pictured here) shows that this also applies to torsional vibration and is of no importance to bending. It is thus possible to significantly increase the torsional stiffness and flexural bending stiffness of this body still further and to safely reduce the total weight by reducing the cross-sections of oversized components.

Control engineering

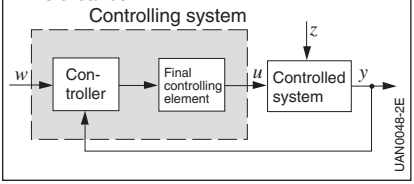
Terms and definitions

(in accordance with DIN 19226 [1])

Closed-loop control
In a technical process, the function of closed-loop control is to place and maintain a particular physical parameter (controlled variable y) at a specified value (e.g. the alternator voltage in the electrical system). Here, the controlled variable is continuously measured and compared with the specified value (the reference variable w, e.g. the setpoint input of the alternator voltage as a function of the state of charge of the battery) (Figure 1). In the event of a deviation, a suitable adjustment of the correcting variable u (e.g. influencing the excitation current in the alternator) on the process (controlled system) is carried out in such a way that the controlled variable y is again adapted to the specification. This process takes place in a closed control loop. Deviations can occur when disturbances z (e.g. the activation of a further electrical consumer) act on the controlled system and affect the controlled variable y in an undesirable way ([2], [3] and [4]).

Closed-loop control operations are performed at many points in a motor vehicle. Further examples include control of cooling-water temperature, A/C control, and many other control operations from the engine (knock control, λ control), transmission (clutch control) and chassis (yaw-rate control).

Figure 1: Basic structure of a control loop
y Controlled variable,
w Reference variable,
u Correcting variable,
z Disturbance.



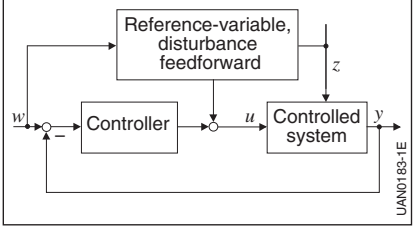


Figure 2: Control loop with open-loop-controlled functions (reference-variable and disturbance feedforward)
y Controlled variable,
w Reference variable,
u Correcting variable,
z Disturbance.

Open-loop control
Open-loop control is essentially also used instead of closed-loop control. In this case, the closed-loop controlling system is replaced by an open-loop controlling system and feedback of the controlled variable is omitted. This process is only then possible if the behavior of the controlled system is known exactly and if no (non-measurable) disturbances z are acting on the controlled system.

Open-loop control is preferred here as no stability problems can arise on account of there being no feedback. Because the previously mentioned preconditions are rarely satisfied in practice, the use of closed-loop control is for the most part unavoidable.

Combination of open- and closed-loop control
Open- and closed-loop control are, in practice, frequently combined in order to exploit the specific advantages of the two structures. Here, established interconnections between reference variable, disturbance, correcting variable and controlled variable are linked as much as possible in order to realize these as open-loop control. Deviations that still arise on account of changed parameters or non-measurable disturbances are corrected by closed-loop control (Figure 2).

Cascade control
A structure is frequently encountered in which the controlled system is separated into two or more partial systems (e.g. into the actual process and the associated actuator). On the basis of this separation, there are one or more internal controllers and one external controller, which are designed and adjusted separately. This procedure is referred to as cascade control (Figure 3).

The controller design is simplified by this separation of the control task into several manageable subtasks. There are additional advantages in the dynamic response due to the fact that disturbances which act in the internal control loop are corrected there before they affect the external control loop. This makes the entire control operation quicker. Likewise, nonlinear characteristic curves of the internal loop can be linearized.

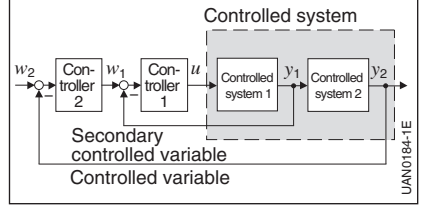
Cascade control is used in many control systems in motor vehicles, e.g. in current control for electrohydraulic actuators or in position control for electric-motor actuators.

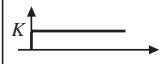
Control-engineering transfer elements

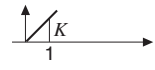
A control loop must satisfy four essential requirements in terms of performance:
– The control loop must be stable,
– The control loop must demonstrate a specific stationary accuracy,
– The response to a step change of the reference variable must be sufficiently damped,
– The control loop must be sufficiently fast.

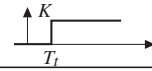
To satisfy these partly contradictory requirements, it is first necessary to describe the static and dynamic responses

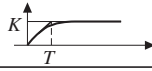
Figure 3: Cascade control loop
y_1, y_2 Controlled variables,
w_1, w_2 Reference variables,
u Correcting variable.











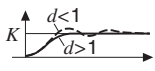


Table 1: Summary of important transfer elements

Transfer element	Differential equation (input u, output y)	Transfer function	Step response
P element	$y = Ku$	K	
I element	$y = K\int_0^t u(\tau)\,d\tau$	$\frac{K}{s}$	
D element	$y = K\dot{u}$	Ks	
Lag element	$y(t) = Ku(t-T_t)$	$Ke^{-T_t s}$	
P-T_1 element	$T\dot{y}+y = Ku$	$\frac{K}{1+Ts}$	
P-T_2 element	$T^2\ddot{y}+2dT\dot{y}+y = Ku$	$\frac{K}{1+2dTs+T^2s^2}$	

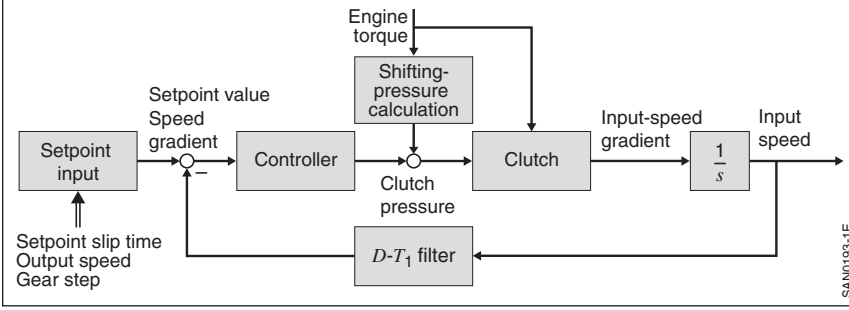
of the control-loop elements (controlled system and controller) with suitable methods in order to be able to analyze the response in the control loop and to design the controller according to the requirements. This description can be made in the time range (e.g. with differential equations) or in the frequency range (e.g. with a transfer function or a Bode diagram).

Many control-engineering transfer elements can be traced back to specific basic types or can be described by a linking of the same (Table 1).

The task of control-loop synthesis is to design, for a given controlled system, the matching controller (structure and parameters of the transfer element), which fulfills the above-mentioned requirements. There exists for this purpose a series of procedures (e.g. dynamic correction in the Bode diagram, root-locus curve procedures, pole specification, Riccati controller in the state space [4]), which are individually supplemented by specific functions or design steps.

A systematized procedure with the steps described in the following has proven to be useful in practice.

Designing a control task



Control task

Typically the control task is not specifically formulated as such, but must be elaborated as the result of requirements in the specific technical process. This involves defining the open- and closed-loop control tasks in the system in order to settle the questions as to what is to be achieved with the control function and with which variables the objective is described. Controlled demand-response shifting in an automatic transmission is mentioned as an example. With this function, the clutch pressure of the shifting clutch is to be aligned during the gear shift to the speed gradient in such a way that the slip time remains constant under all operating conditions, even with variable parameters (e.g. friction coefficient).

System and block diagrams

It is helpful with these considerations, to draw up a system diagram in which the essential interaction between electronics, mechanics, hydraulics and pneumatics and all the sensors, actuators and bus systems can be clearly seen. From this, the control-engineering block diagram must be derived, from which in turn the functional interaction of all the open- and closed-loop-controlled functions with the system to be controlled can be seen (Figure 4). The functions are described in headline form, but not yet formulated in detail.

Figure 4: Control-engineering block diagram, for example of controlled demand-response shifting in an automatic transmission

It should be possible already to obtain a fundamental system understanding of the operative connections from the system diagram and the block diagram. As long as the system (mechanics, peripherals, hardware, etc.) is still in development it should at this point still be possible to exert an influence on the structural design of the system as contemplated by an overall mechatronic approach. The filling behavior of a hydraulically actuated clutch is mentioned as an example. This should be designed in such a way that a reproducible behavior with as little dead time as possible is provided on the basis of line cross-sections, volumes and sealing behavior.

Controlled system
The controlled system is then identified. This can be done theoretically (by modeling) or practically, e.g. by measuring the step response or the frequency response. It is recommended that both methods are followed and an adjustment carried out. Identification is a very comprehensive process, depending on the task. Sometimes it is sufficient to determine only the basic type and the order of the controlled system.

Controller design
The controller is designed on the basis of the result of the identification – this is the central task of controller synthesis. It is advisable for this first to be conducted theoretically using simulations, during which the controller parameters are set at the same time. If this step is sufficiently validated, startup follows on the real controlled system on the test bench or in the vehicle. Recursion steps are usually performed once again here in order to achieve further optimizations.

Design criteria
Over and above this fundamental sequence, reference is made to the following additional criteria:

Digital (discrete-time) control
The majority of control operations in a motor vehicle are implemented on microcontrollers. In this case, it is necessary to suitably establish the sampling time, oriented towards the dynamic response of the controlled system. It is necessary to ensure here that all the function algorithms can be calculated in the time available between two samplings.

Nonlinearities
In many cases, the simple linear methods described above are not sufficient, since real controlled systems contain nonlinearities (e.g. pressure-regulator characteristics, clutch characteristics, etc.). In simple cases, where static continuous nonlinearities are involved, these can be compensated for by an additional inverse-behavior transfer element. In the case of control operations with small signal amplitudes about an operating point, the system equations can be linearized at this point, otherwise more complex procedures are called for.

Structure switchovers
Many closed-loop control operations are first initiated by open-loop-controlled signals (e.g. first fill clutch, then set shifting pressure, then start shifting control). In these cases, it is necessary when switching from the open-loop- to the closed-loop-controlled state to ensure that this takes place smoothly and that the storage devices (integrators of the I elements) are correctly initialized.

Robustness
The control is typically designed with a "nominal" controlled system. In practice, however, manufacturing tolerances dictate that controlled systems are encountered which deviate up to a defined extent from this nominal definition. Furthermore, the parameters change over the service life, e.g. due to clutch wear or depending on third variables (temperature). In none of these cases should this give rise to significant functional impairments or instability of the control loop. Different procedures from the field of "robust control" or "adaptive control" are available to master these requirements.

Adaptive controllers

Motivation
Controlled systems often do not have a constant behavior. Parameters such as time constants and gains change in many cases. Even the structure of the system can change. Adaptations match open-and closed-loop control processes to a different system behavior. Examples include:

Manufacturing tolerances
Not all the products in a batch are 100 % identical. Because an individual adjustment is complicated, the system should adapt itself automatically to different parameters (e.g. adjustment data for automatic transmissions, [5]).

Wear
Parameters change in response to wear on a reproducible (e.g. increasing clutch control travel) or random level (e.g. friction coefficient of disks). Adaptations can compensate for this different behavior (e.g. clutch-control-travel adaptation for automated clutches, [6]).

Dependence on a third variable (e.g. temperature)
The viscosity of oil is highly temperature-dependent. Because these fluctuations will also occur in the short term (e.g. repeatedly every day), they must be compensated for (e.g. interference-torque observer, lockup-clutch control, [7], [8]).

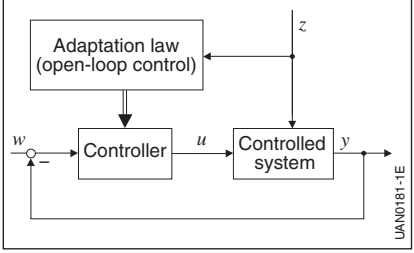
Dependence on operating point of nonlinear systems
Nonlinear systems are frequently linearized at an operating point and then controlled by a linear controller (small-signal behavior). It is possible by means of an adaptation to take into account the different behavior at the operating points (e.g. adaptation of the shifting pressure for interlaced multiple gearshifts in an automatic transmission, [9]).

The various requirements to master this problem on an open-loop control level result in the desire for adaptive systems, which are described and defined in the following.

Definition of "adaptive control"
The behavior of the control is adapted to the changing properties of the controlled system and its signals. Adaptation procedures are thus essentially divided into two steps.
– Identification: Identification of the system behavior (system parameters) from time-variable values of the system.
– Adaptation: Adaptation of the open- or closed-loop control law as a reaction to a change of the system behavior.

Open-loop-controlled adaptations
Adaptation is performed by open-loop control, a forward-pointing structure. It is assumed here that the changing properties can be recorded by means of measurable external signals z (disturbances)

Figure 5: Open-loop-control adaptive system
y Controlled variable,
w Reference variable,
u Correcting variable,
z Disturbance.



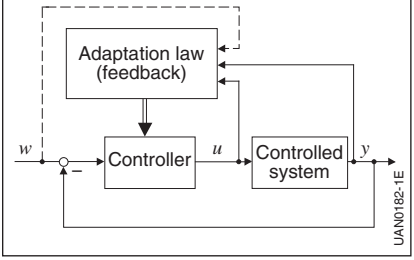


Figure 6: Adaptive system with feedback
y Controlled variable,
w Reference variable,
u Correcting variable.

and that the dependence of the control on these signals is known (Figure 5). There is no feedback on internal signals of the control loop to the setting of the controller.

Adaptation with feedback

In the case of an adaptation with feedback, the changing properties cannot be directly recorded and must be identified from measurable signals of the control loop. The identification can be a simple measurement or even a complex algorithm to estimate dynamic process models. In addition to the basic control loop, a second feedback loop is implemented by means of the adaptation law (Figure 6).

Essentially, an open-loop-controlled adaptation is initially recommended, i.e. known and metrologically recordable connections are used in open-loop-controlled form. The advantage of this forward structure can be compared with the advantages of open-loop control over closed-loop control. A feedback loop, which can possibly cause stability problems, is omitted. For the most part, open-loop-control adaptive systems are used in practical industrial applications.

Design notes

The following questions must be clarified when it comes to designing adaptive control:

– Which parameters and features must be adapted because they cannot be covered by a robust design?
– With which signals or variables can these parameters and features be determined?
– Does the system have to be specifically excited in order to determine these parameters and features, or can the adaptation take place during ongoing control operation?
– Can the adaptation be performed by open-loop control means or does feedback have to be provided for?
– How can the stability and convergence of adaptive control be tested?

A detailed treatment of the subjects areas of “Design of adaptive control operations” and “Identification of dynamic processes” can be found in [4], [10] and [11].

Artificial intelligence

Introduction to AI

The aim of "artificial intelligence" (AI) is to understand how intelligent behavior works and how it can be implemented with information-technology means on computer systems. To this end attempts are made to enable machines, robots, and software systems to process and solve abstractly described tasks and problems independently without each step being programmed by humans. Important subfields are machine learning, knowledge representation, language understanding, and logical closure [1].

AI systems [2] are expected to have a certain degree of robustness, i.e., they should be able to adapt to their environment and changing conditions and learn [3].

The term system is furthermore based on the following definition: "A system is a set of interconnected components that has an expected behavior observed at the interface with its environment" [3].

History of AI

The establishment of AI as scientific discipline in its own right can be traced back to the "Dartmouth Summer Research Project on Artificial Intelligence", which took place in 1956 at Dartmouth College in Hanover (New Hampshire) and was attended by among others John McCarthy, Marvin Minsky, Herbert Simon, Alan Newell, and Claude Shannon [4].

AI as a science is based on two fundamental assumptions:

- 1.) Intelligence is founded on the ability of physical systems to represent regularities in the behavior of external phenomena in internal models, to analyze these representations, and to use the analysis results to control system behavior.
- 2.) The actual intelligence performance is the creation and manipulation of formal systems by formal systems.

Through the symbol-processing approach cognitive performances were taken as transformations of symbol structures with symbols being directly identified with meaningful units [5]. Some progress was made with this form of highly logic-oriented AI, but primarily in areas which could be efficiently described by logical formalisms.

This approach was less successful in fields characterized by high complexity, haziness or uncertainty. Emerging disillusionment led to a marked drop in research investment in AI, the so-called "AI winter".

Advances in AI

The increasing drop-off in prices with regard to computing capacity, memory, and connection costs and the associated emergence of cloud computing provided the material basis for implementing machine learning – specifically connectionist principles in the form of artificial neural networks (ANNs) – to a greater extent. Another often used term for this class of learning method is deep learning (see Machine learning). Here "knowledge" and "meaning" are implemented not by explicit symbolic representations but in activity patterns by means of "nodes" and "connections". The process is fundamentally different from classic algorithms not based on AI. In the case of classic algorithms the programmer uses instructions to describe how a given problem is to be solved. In the case of machine learning and ANNs the developer describes not the method but instead, by means of examples, the objective of the problem. In addition, they specifies a learning algorithm which independently searches for an approach towards a solution for the problem.

The resource requirements of elaborated ANNs must not be underestimated here. Thus, in one AlphaGo training cycle (see below) 5,000 tensor processing units were used over 40 days which required 192,000 KWh, the equivalent of the annual energy requirement of 32 households in Germany.

The dominant approaches in today's AI are those based on ANNs, where even greater importance could be attached in

future to the logic-based methods in the explanation of AI algorithms.

Significant milestones
Conceptional further developments of AI consistently resulted in spectacular breakthroughs which were observed with interest by the public at large:
– In 1996 “Deep Blue” beat the reigning world champion Gary Kasparov at chess.
– In 2005 “Stanley”, a modified VW Touareg, in the “DARPA Grand Challenge” succeeded in autonomously completing a course in the Mojave Desert of 212 km in less than seven hours and winning the race. 100 teams had already failed in this task the year before.
– In 2011 “Watson”, a text-understanding and semantic-search system, beat two human opponents in the quiz show “Jeopardy”.
– In 2012 “AlexNet”, a “deep” neural network, won the “ImageNet Large Scale Visual Recognition Challenge” by a long distance with a “super human performance”.
– In 2016 “AlphaGo” defeated the champion and best player Lee Sedol at the board game Go. This achievement was all the more remarkable since Go is significantly more complex than chess and it is impossible for supercomputers to search the entire solution space exhaustively.

These successes can lead to abstracting from specific ideal competition conditions and assuming that such systems can be easily transferred to open everyday situations. In actual fact, systems that exhibit impressive superhuman abilities under ideal conditions are must less robust against disruptions or influences that can arise in everyday situations.

Significant applications
Thanks to the significant algorithmic advances artificial intelligence has today already arrived on the scene in many products in our everyday lives.

Examples
Personal assistants
A prominent example is the personal assistant, with which users can interact for the most part via speech. Users can for example have questions about the current weather or the news answered simply by their mobile end device. For this purpose various AI algorithms run in the background
– to translate the audio signals into a representation of the question that is accessible to the computer,
– to find the information in a knowledge graph,
– to generate a voice output to communicate the information to the user.

Computer vision
A second application of AI that has in the meantime become widely used is computer vision (see Computer vision). The perception of the environment by means of images is for the most part a simple tasks for humans, but was for a long time an unsolved problem for machines. Today for the most part artificial neural networks (see Artificial neural networks) are used to draw conclusions from a camera image. Essentially, this features for example in driver-assistance systems, specifically the recognition of road signs, traffic lights, the lane, pedestrians, and other general road users. AI is similarly also used for monitoring with the assistance of cameras, for example to recognize exceptional situations in advance.

Significance of AI
These problems could not be technically solved without AI algorithms. A general rule of thumb for the applications of AI is: If the problem can be easily solved by classic methods, these are to be generally preferred. AI is exciting for applications in which the path to the solution cannot be described by a few simple rules as an algorithm.

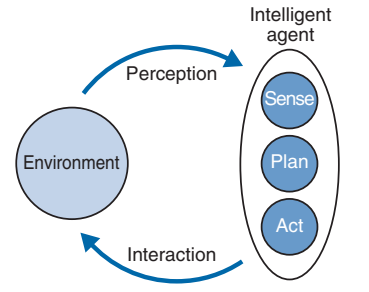
Intelligent agents
AI systems are often based on the underlying concept of an “intelligent agent” which on account of its own knowledge appears in the position to act rationally in a given context and therefore is perceived

by external human observers to be intelligent. This concept of the attribution of intelligence by an external observer on account of actions that suggest intelligent knowledge processing was formulated by A. Newell in 1980 [7].

The fundamental characteristics of the generic architecture of an intelligent agent are the "Sense Plan Act" components and the interaction with its environment (Figure 1). From the environment the agent receives via its perception information, which it processes and implements through actions, which impact on the environment. Important prerequisites for successful interactions are a sufficiently stable and reliable perception on the part of the agent and the depiction of the perceived objects in a world or domain model which facilitates planning processes and – at least for the respective part of the world – sufficient semantic understanding. Added to this is the ability to act, i.e., turn what has been learned and the object of planning into reality.

The abilities of learning, representing the content and its further processing will be addressed in the following. To conclude, aspects of the security of AI systems will be addressed.

Machine learning



Learning as prediction

Learning is a process in which expertise is generated from experience, i.e.:

"A computer program is said to learn from experience E with respect to some class of tasks T and performance measure P, if its performance at tasks T, as measured by P, improves with experience E." [8]

Here a learner should successfully generalize from individual examples, i.e., inductively infer the general from the particular. Here the learner must infer from perceptible properties of an object the affiliation with a particular class. The learning objective is achieved if the learner was able to create an applicable hypothesis or a model which facilitates the correct prediction of the affiliation with a particular class on the basis of characteristics. Learning can thus be seen as a classification problem and the classification rules are encoded in the model [9]. Formally expressed: There must be a quantity $\mathbb{X}$ of objects which are to be classified. Furthermore, a quantity $\mathbb{Y}$ of possible annotations or labels with which the affiliation of examples with a class are identified. In the simplest case with an element from {0.1}. Moreover, a finite quantity $\mathbb{M}$ of annotated training examples from $\mathbb{X} \times \mathbb{Y}$, d.h. $\mathbb{M} = ((x_1,y_1)\ldots(x_m, y_m))$. The training examples derive from a

Figure 1: Generic architecture of an artificial intelligent agent
"Sense Plan Act" components;
Sense,
Plan,
Act.

probability distribution D from $\mathbb{X}$ and the annotations of all the examples were performed by an already existing classification function $f:\mathbb{X}\rightarrow\mathbb{Y}$, i.e., $y_i=f(x_i)$.

On the basis of these training data the learner formulates a hypothesis of a suitable classification model:

$$h:\mathbb{X}\rightarrow\mathbb{Y}.$$

The success of learning, i.e., the performance measure, can be determined by way of the prediction model generated by the learner. The error L of the prediction $h:\mathbb{X}\rightarrow\mathbb{Y}$ is therefore:

$$\begin{aligned} L_{D,f}(h) &= \mathbb{P}\,|(h(x)\neq f(x))| \\ &= D(\{h(x)\neq f(x)\}) \end{aligned}$$

The error thus relates to the probability distribution and the correct annotation function.

Example

Can a Bosch hammer or a Bosch orbital sander be seen in a photo? We could solve this task for example with machine learning. The quantity $\mathbb{X}$ is in this case photos in which either a Bosch hammer or an orbital sander can be seen. The quantity $\mathbb{Y}$ of possible annotations is here "Bosch hammer" and "orbital sander". Now we have in front of us a stack of photos, each with a "Post-it" note with the text (label) "Bosch hammer" or "orbital sander", depending on the content of the photo. This is the quantity $\mathbb{S}$, the example data, which we use to learn. The already existing classification algorithm was in this case a person who has assigned the correct label (from the quantity $\mathbb{Y}$) to the photos (from the quantity $\mathbb{X}$). With the aid of these learning examples we train the algorithm to solve the problem, given a new image we see a Bosch hammer or orbital sander.

The learning success can be easily measured here: we feed the algorithm a new image x_T. We obtain a prediction $h(x_T)$ of which of the tools is involved according to the learning algorithm. We compare this prediction with the probability, $f(x_T)$. Does this match, or is the learning algorithm wrong, is therefore $h(x_T)\neq f(x_T)$? If we repeat this test very frequently (infinitely often), we can estimate the probability that the algorithm is wrong in predictions. This probability is formally described by $\mathbb{P}\,|h(x_T)\neq f(x_T)|$ and produces a measure for the learning success. If this measure is one, $h(x)$ and $f(x)$ are always different, the algorithm never makes a correct prediction. If on the other hand the probability is zero, the learning was successful and the learning algorithm always produces a correct prediction.

Learning or training in the case of machine learning incidentally almost always means the following when put simply: Using data the learning process sets its parameters in such a way that there will be a correct prediction as often as possible.

Learning strategies

Supervised learning

The learning approach outlined above in which preclassified examples are used for learning is called "supervised learning". When the correctly annotated data are available, this is a highly efficient learning process. The effort involved in providing the data, annotating, and ensuring the correct annotation is however very high.

Unsupervised learning

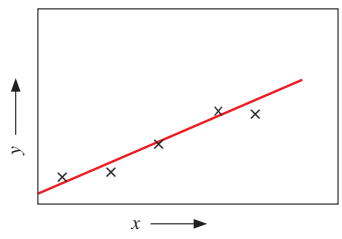
A fundamentally different learning strategy is "unsupervised learning". Here objects are with regard to their similarity categorized in a target concept and appropriate clusters are created. In each case only one example – as typical as possible – is required as well as one metric (frequently Euclidean distance) and the objects are grouped and categorized in relation to their similarity by the target object.

Reinforcement learning

A further learning strategy is "reinforcement learning", in which an algorithm as with unsupervised learning receives non-annotated training examples and is to create a model. The modeling is to be steered in the desired direction by means of positive and negative feedback. This is almost a further development of the concept of evolutionary algorithms which modify themselves and in which the selection is controlled by means of fitness functions.

Important algorithms

Linear regression



A very simple algorithm which however clearly illustrates machine learning is linear regression. Let us take for example some one-dimensional measured values, i.e., tuples at input variable x and measured value y.

In the case of linear regression we try to explain the measured values (the crosses in Figure 2) by a straight line $mx+c$. Quite specifically we must therefore define the two parameters m (straight-line gradient) and c (y axis intercept) in such a way that the distance to the measured values is minimal. We can achieve this for example with the aid of an optimization process. There are however also mathematical abbreviations so that this is not needed here and the optimal parameters can be determined directly. Optimization, i.e., adaptation of model parameters to data is called learning or training in the world of AI.

Artificial neural networks

"Artificial neural networks" (ANNs) constitute a much more complex process which is very widely used today. ANNs are based on a successful biological model – the human brain. In mathematical terms neural networks are the parallel and series connection of many simple modules.

Figure 2: Linear regression

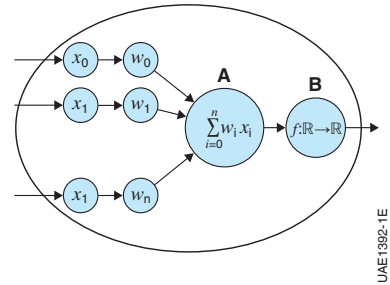
Neuron

A module (neuron, Figure 3, [10]) assumes several input values ${}_xI$, … x_n, multiplies these values by weights w_1, … w_n, and applies a more often than not simple function to the sum total of these entries:

$$\varphi:\mathbb{R}\rightarrow\mathbb{R},\ \varphi\left(\sum_{i=1}^{n} w_i x_i\right).$$

This value forms the output value of the neuron.

Structure of a neural network



Numerous, in many cases millions of such operations are now connected in series (Figure 4). The output of a number of such parallel neurons forms the input of a further layer of neurons, thereby creating connections within a network. The last layer constitutes the output of the network. The size and structure of a network are dependent on the volume of training data and the complexity of the input values. Networks with up to 100 layers and over 100 million weights are used in image processing. A network however does not get "bigger" through learning.

Learning

ANNs usually engage in supervised learning, i.e., specifically the numerous weights of the network are adjusted by optimization in such a way that the ANN supplies the correct prediction for given

Figure 3: Artificial neuron

x Input values,
w Weights.
A Sum total of input value multiplied by weight,
B Activation function (e.g., $f(x) := \max(0.x)$).

examples. In this way the learning process is ended with the learned weights stored as the learning result.

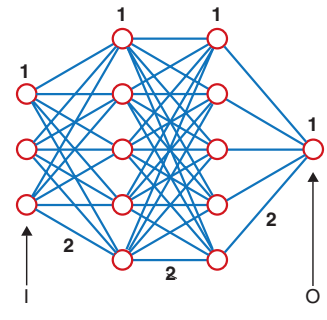
This optimization process is very computation-intensive and was only made possible by new processor technologies, such as for example current-generation graphics cards.

Applications

Specifically, ANNs are used for example to classify objects, i.e., to estimate which category is involved for a given example. The last layer supplies a value as the output, for example 0 for Bosch hammer and 1 for orbital sander. Now many examples are presented to the network and the weights are adjusted in such a way that the prediction of the learning process is always as correct as possible (see section "Learning as prediction"). The entire learning process of the ANN is also called "deep learning".

So-called generative models constitute a second application aside from the classification of objects. Instead of predicting the class Bosch hammer or orbital sander in an image, the ANN is used to generate new data. Thus, the network could generate for example a new image, which constitutes a mixture of Bosch hammer and orbital sander. However, these tasks require much more complicated processes to adjust the weights of the ANN.

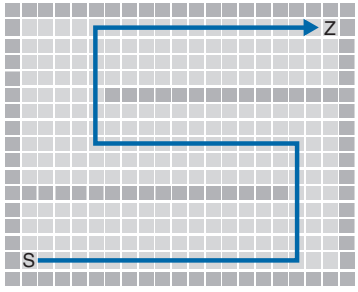
Representation of information



The representation of perceptions or experience content and subsequent further processing is one of the essential basic prerequisites for AI.

The manner of further processing is determinant for the appropriate form of representation. In those areas of AI which were greatly characterized by expert systems and the structuring of knowledge into easily communicable logical structures "knowledge representation" was practically synonymous with representation in logical formalisms together with an ontology, i.e., a systematic compilation of objects and their systematic correlation in a field of application which facilitated a semantic interpretation of the formulas.

Special neural networks, autoencoders, can be used to represent complex correlations. These are trained to learn an efficient representation for data and thus also important characteristics [11]. Significant application possibilities can be found in the compact representation of words with their context by "word embedding" in speech processing.



Generative adversarial networks (GANs) are based on a similar concept where the encoding and decoding are shared between two systems, a generator and a discriminator. The generator

Figure 4: Artificial neural network (ANN)
1 Neurons,
2 Connections.
I Input layer,
O Output layer.

has the task of creating a specific distribution of data. The discriminator attempts to distinguish these generated data from those of a "real" distribution which is present in the field of application. The aim of the generator is therefore to create such data which the discriminator evaluates as "real". GANs are used in a wide range of applications, from the creation of photo-realistic images to movement modeling in video sequences.

Figure 5: Simple example of a route-planning problem
S Start,
Z Destination.

Planning

Significance of planning

Behavior that seems rational or intelligent often requires a decision to be made or an action to be performed "now" in order to achieve an objective only very much later in the future. Many extreme challenging AI tasks have such a characteristic.

– In games like chess or Go a player must make a move in each round in order to win the game at some stage in the future. During each move they must estimate how the move will influence the game in the long term.
– Autonomous vehicles must plan on different levels. For instance, they must find a route to the destination. This is called route planning. However, the vehicles must also plan their motion, particularly the control commands such as steering angle or acceleration, in such a way that they reach their destination without collisions, even when other vehicles are moving in the same environment. This is called motion or behavior planning.

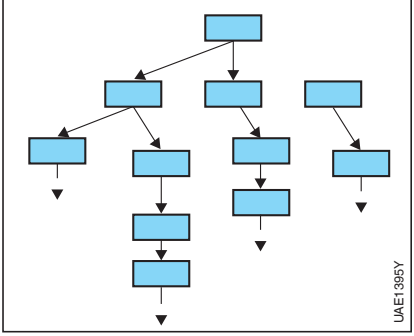
A prerequisite for planning is having an understanding of how an action will influence the future. The ability to plan also presupposes that an AI agent can answer the questions "What if …" or "What does the world look like after this action?"

More formally the agent requires a model of the environment. In a game the model is given by the game mechanism and the rules. In the navigation of an autonomous vehicle a model is obtained from the physics of the vehicle and the from the environment with all the obstacles.

Example of a planning problem

A simple and illustrative form of planning is the search for a route from a starting point to a destination (Figure 5). This planning problem can be calculated with simple graph-search methods. In this example the number of positions (also states) and possible movements are easily understandable. In real applications there can be extremely many states or action possibilities. In the game Go there are for example 10^{170} possible states on

the board. On a vehicle steering angle and acceleration can be continuously adjusted, which results in a practically infinite sphere of action. In the case of very large spheres of state and action, therefore, sampling-based methods are often used in the search in which actions are randomly selected and evaluated after a special statistical distribution.



Problem when planning
Planning is made more difficult by the fact that the future for the most part cannot be predicted accurately. In games the future always depends on the opponent's moves. Autonomous vehicles must react to other road users. Unlike the case with route planning, a clear route leading to the destination cannot therefore be found. Rather a decision must depict and react to the "anticipated" future.

Computing time and computing capacity
A huge challenge in many planning problems is the required computing time and computing capacity. In a game like chess or Go a player (also a computer) only gets a limited time to think. In the case of a vehicle safety-critical decisions must be made in real time. The huge challenge is therefore to fashion the planning efficiently. An important concept here is the "leading" of the search algorithms. In this connection a function to be easily evaluated is often use to select the actions or states considered next by the program. These rules can be for example in a search on a geographical map the Euclidean distance to the destination (this is used with the so-called A* algorithm). But this selection function can also be more complex. The celebrated AlphaGo program [12], which in 2015 defeated the world's best human Go player, uses for example a very large ANN, to direct the search. This network was trained with countless simulated games. This trick enables AlphaGo, in a new game with a new (possibly previously unseen) game situation, nevertheless to develop a plan or a strategy very quickly and to make sensible moves.

New planning
Another trick to generate rational behavior is new planning. Instead of planning a complete route to the destination every time, a shorter plan is calculated. From this plan this first action is performed and a new planning is started. This process can be extremely efficient because on the one hand the computing time can be significantly reduced and on the other hand the system can also easily react to changes in the environment thanks to the continuous new planning. However, such an approach sets new challenges with regard to the completeness and optimality of the algorithms.

Intelligence
Planning is a classic and still very important sub-area of AI. The ability of an AI agent to plan and have strategic foresight is often, when viewed from the outside, perceived to be intelligence.

Figure 6: A search tree in which the nodes represent states and the arrows possible actions

IT security of AI systems

Comparison of an AI system with a classic program

An AI system differs from a classic computer program in that in the latter there is a marked separation between the application logic encoded in algorithms and the data used. The data flow is predefined by the structure of the algorithm. In AI systems the structure of a neural network for example is encoded in a specific algorithm. However, the weights of the network and consequently also the data flow through the system are dependent on the data. There is therefore a much closer correlation between data and system behavior than in conventional systems.

If a learned model is to be permanently saved, the structure and the values of the weights must therefore be recorded.

Manipulation possibilities

The software and the executable code of an AI system are subject to the same extent to all the risks and dangers of manipulation as any other software system that is run as an application on a computer system. In the IT environment security is usually considered from the perspectives of confidentiality, integrity, and availability. With regard to AI systems and intelligent agents system integrity plays a specific role because the intended functioning of a system is referenced with this term.

Manipulation of the control flow

"Hacking" systems has this very things as its object, namely the takeover and "external control" of a system through manipulation of the control flow. Instead of processing the original program commands, a system is made to execute any other code. In other words, the original algorithm is replaced by a different one. A hacker takes advantage of weaknesses in the system design, for example missing or insufficient input validation, thereby provokes errors in the system access, and "deposits" return addresses to code fragments which they have implanted.

Data poisoning

In an AI system there are furthermore additional possible ways to influence how the system works. Because adaptive systems are not programmed in the conventional sense but instead trained, system behavior can be altered by manipulating data from which the systems learn. This is called data poisoning.

In applications in which a system learns continuously there is a high degree of vulnerability to this type of attack. A system could alter its fundamental behavior in response to new data. For this reason, in the case of safety-critical requirements the weights of a network are "frozen" to prevent this. In addition, the perception of the systems can be disrupted by "adversarial attacks". This may result in a highly automated vehicle failing to recognize a traffic scene correctly and consequently not reacting appropriately.

Protective measures

While traditional computer systems could be protected extensively against attacks on their control flow – at least theoretically – with the reality behind the given possibilities remaining, this is not the case with AI systems. Full input validation cannot be provided in open application domains. It is therefore appropriate in AI systems, aside from observing the fundamental principles of secure system development in the system architecture, to provide further functionalities that actively observe, protect and stabilize system behavior.

This involves firstly the ability of a system to detect connected sequences of actions and to assign them to typical contexts and secondly the capacity to perceive itself in the time context and to compare current behavior with earlier behavior.

Materials

Material parameters

Selecting material for a specific use is based on material parameters that describe the material properties. This process distinguishes between the physical material parameters, which result from the atomic structure, and the mechanical-technological material parameters, which are affected by manufacturing processes, for example.

Some physical material parameters are listed in tables 3 to 6 for a wide variety of materials.

Physical material parameters

Density

Density ρ is the ratio of the mass to the volume of a specific amount of substance (also see DIN 1306:1984-06 [1]). The unit of measurement is kg/m^3.

Melting temperature

The melting temperature denotes the temperature at which a material transforms from a solid to liquid state.

Boiling temperature

The boiling temperature denotes the temperature at which a material transforms from a liquid into a gas.

Heat of fusion

The specific heat of fusion of a solid (enthalpy of fusion) is the quantity of heat required to transform a material at fusion temperature from the solid to the liquid state. The unit of measurement is kJ/kg.

Heat of evaporation

The specific heat of evaporation of a liquid (enthalpy of evaporation) is the quantity of heat required to evaporate a liquid at constant boiling temperature. It is very pressure-sensitive. The unit of measurement is kJ/kg.

Thermal conductivity

Thermal conductivity is the quantity of heat that flows through a material sample with a defined surface and density due to temperature difference. In the case of liquids and gases (as opposed to solids), thermal conductivity is often highly dependent on temperature. The unit of measurement is W/(m·K).

Electric conductivity

Electric conductivity describes the physical property of a material to conduct electric current. According to the Wiedemann-Franz law, it is almost proportional to thermal conductivity. The unit of measurement is S/m (siemens per meter).

Coefficient of thermal expansion

The linear coefficient of thermal expansion α (coefficient of longitudinal expansion) indicates the relative change in length of a material during a temperature variation. For temperature change ΔT, the change in length is defined as $\Delta l = l\,\alpha\,\Delta T$. The unit of measurement is K^{-1}.

The cubic coefficient of thermal expansion (coefficient of volume expansion) is defined in a similar manner. The coefficient of volume expansion for gases is roughly 1/273 K^{-1}; For solids, it is roughly three times as large as the coefficient of linear expansion.

Heat capacity

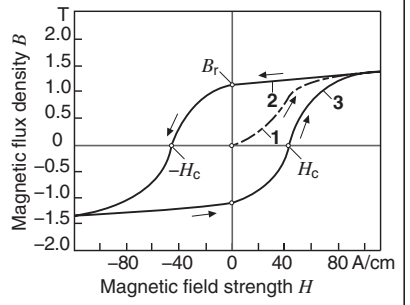
The specific heat capacity (specific heat) is the quantity of heat required to raise the temperature of a substance. It is dependent on temperature.

In the case of gases, we distinguish between specific heat capacity at constant pressure and at constant volume (symbols c_p or c_v). This difference is usually negligible in the case of solid and liquid substances. The unit of measurement is kJ/(kg · K).

Permeability
Permeability μ describes the ratio of magnetic flux density B and magnetic field strength H (see magnetic field, relative permeability):

$$B = \mu H.$$

Permeability consists of the magnetic field constant μ_0 and the material-dependent relative permeability μ_r ($\mu_0 = 4\pi \cdot 10^{-7}$ A s/V m, $\mu_r = 1$ for vacuum). Depending on the application in which the magnetic material is used, there are roughly 15 types of permeability. These are defined according to modulation range and type of loading (direct-current or alternating-current field loading). The most important parameters are listed below.



Initial permeability μ_a
The slope of the virgin curve (figure 1, also see hysteresis loop) for $H \rightarrow 0$ is designated as the initial permeability μ_a. In most cases, however, the slope for a specific field strength is specified (in mA/cm) rather than this limit value. Notation: μ_4 is the slope of the virgin curve for $H = 4$ mA/cm.

Maximum permeability μ_{max}
The maximum slope of the virgin curve is designated as the maximum permeability μ_{max}.

Recoil permeability μ_p
Recoil permeability μ_p (or μ_{rec}) is defined as the average slope of a retrograde magnetic hysteresis loop whose lowest point usually lies on the demagnetization curve:

$$\mu_p = \frac{\Delta B}{\Delta H \mu_0}.$$

Figure 1: Hysteresis loop of a magnetically hard iron grade
1 Rise path,
2, 3 Demagnetization curves.
H Magnetic field strength,
B Magnetic flux density,
B_r Remanence flux density,
H_c Coercive field strength.
The arrows indicate which magnetic flux density is set if the magnetic field strength is changed.

Temperature coefficient of magnetic polarization
The temperature coefficient of the magnetic polarization $TK(J_s)$ indicates the relative change in saturation polarization as temperature changes, it is given in percent per kelvin.

Temperature coefficient of coercive field strength
The temperature coefficient of the coercive field strength $TK(H_C)$ indicates the relative change in coercive field strength as temperature changes, it is given in percent per kelvin.

Curie point
The Curie point (Curie temperature T_C) is the temperature at which the magnetization of ferromagnetic and ferrimagnetic materials becomes zero and at which they behave like paramagnetic materials (see magnetic materials).

Mechanical-technological material parameters

Modulus of elasticity

The modulus of elasticity (E modulus) describes the linear relationship between stress and strain when deforming a solid body in the area of its elastic deformation (image 2). The unit of measurement is MPa. Examples of typical e-moduli are specified in table 1.

Table 1: Modulus of elasticity and Poisson's ratio for some materials

Material	Modulus of elasticity [MPa]	Poisson's ratio
Rubber	100	0.5
Fiber-reinforced plastic (e.g. PA66)	2,000	0.37
Aluminum	70,000	0.34
Titanium	110,000	0.28
Steel	200,000	0.3
Tungsten	400,000	0.28
Ceramics (e.g. Al_2O_3)	400,000	0.23

Poisson's ratio

The dimensionless Poisson's ratio is the proportionality factor between the longitudinal strain of a body under tension or compressive stress and the resulting transverse strain. Typical values are specified in table 1.

Yield point

The yield strength (yield point) is the amount of tensile stress starting at which a material experiences lasting plastic deformation. It is determined from the stress-strain curve (σ-ε curve) measured in the tensile test (see DIN EN ISO 6892-1:2009-12, [2]). The unit of measurement is MPa.

0.2% yield strength

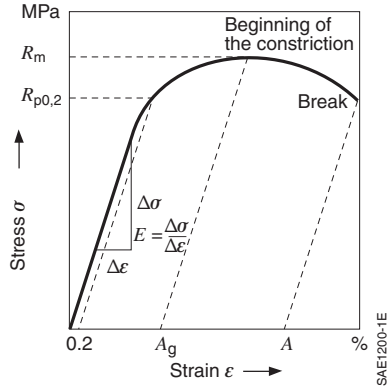
The 0.2% yield strength ($R_{p0.2}$) is the amount of tensile stress that causes a lasting (plastic) strain of 0.2% in a material. The unit of measurement is MPa.

Tensile strength

The tensile strength R_m is the stress that is calculated in the tensile test from the maximum achieved tractive force relative to the output cross-section of a standardized material sample (figure 2 and figure 3). The unit of measurement is MPa.

Figure 2: Determining the modulus of elasticity

E modulus of elasticity,
R_m tensile strength,
$R_{p0,2}$ 0.2% yield strength,
A elongation at fracture,
A_g uniform strain.



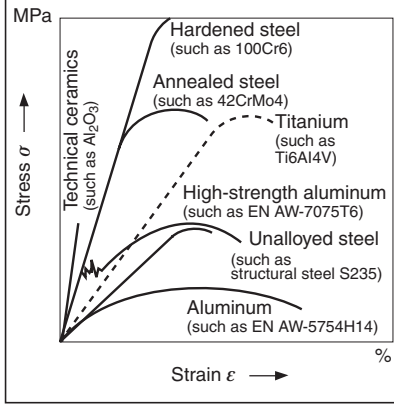


Figure 3: Stress-strain curve of some materials

Elongation at fracture
The elongation at fracture A is a dimension for the ductility (deformability) of a material. It indicates the lasting extension of a tensile specimen after the fracture relative to the initial length, specified in percent.

Fracture contraction
The fracture contraction Z, like the elongation at fracture, is a dimension for the ductility (deformability) of a material. It indicates in percent the change in cross-sectional area relative to the initial cross-section of a tensile specimen.

Uniform strain
The uniform strain A_g indicates the change in length in percent at which a tensile specimen goes through a plastic deformation without necking. For ductile materials, necking is caused on the specimen (cross-section reduction) after reaching the uniform strain (and tensile strength).

Vibration resistance
Vibration resistance is defined as the deformation and failure behavior of materials under cyclical stress. Typical vibration resistance values such as the fatigue limit have to be determined in often time-consuming Wöhler tests (fatigue tests named after August Wöhler) (image 4). These are usually carried out on electromechanical or electrohydraulic testing machines in the frequency range of 10 to 1,000 Hz.

A wide variety of test parameters influence the determined characteristic values (surface quality, test frequency, test duration, test medium, bend on tension or pressure). Here, the determined fatigue limit of a material is well below the structural strength (e.g. R_m). A simple estimate is possible using the FKM guideline (Forschungskuratorium Maschinenbau e.V., see Table 2). The tension-compression fatigue stress factor identifies the ratio of vibration resistance to tensile strength (tension-compression fatigue stress). For metals with a face-centered cubic crystal lattice, such as austenitic steel or aluminum, there is no fatigue limit since the stressability decreases when the stress duration increases.

Knowing the vibration resistance parameters is absolutely necessary for designing parts and components in mechanical engineering, since purely static stress is rare.

Fatigue strength under reversed bending stress
Fatigue strength under reversed bending stress identifies the stress in MPa that a material can withstand without breaking during cyclical bending stress (see vibration resistance).

Figure 4: Depicting the vibration resistance with the Wöhler curve with typical values for the number of stress cycles N
R_m tensile strength,
$S_{a,D}$ Fatigue limit.

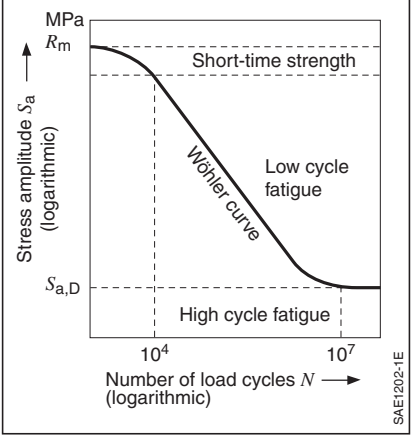

Table 2: Estimation of the vibration resistance

Material group	Tension-compression fatigue stress factor for the number of stress cycles $N = 10^6$
Aluminum, wrought and casting materials	0.30
Cast iron with flake graphite (GJL)	0.30
Cast iron with nodular graphite (GJS)	0.34
Stainless steel	0.40
Structural steel, tempering steel, etc.	0.45

Hardness
The hardness of a material identifies its resistance to the penetration of a body. Various methods for determining hardness are listed in the chapter "Heat treatment of metallic materials".

Fracture toughness
The fracture toughness is the resistance of a material to the spread of cracks. The critical stress intensity factor K_{Ic} is usually used as a characteristic of this. If K_{Ic} is known, the critical fracture load can be determined from crack length, or the critical crack length can be determined from the given external stress value.

Special characteristics for sintered material
Radial crushing strength
The radial crushing strength is a strength parameter which is specified in particular for sintered friction bearings. This is determined by buckling a hollow cylinder during the pressure test.

Porosity
The porosity is a dimensionless characteristic for sintered metals, particularly friction bearings. It describes the portion of part volume that consists of cavities and is not filled with actual material.

Compressive yield point
Comparable to the yield strength in the tensile test, the compressive yield point is added in the pressure test as a material characteristic (unit of measurement MPa). This identifies the stress starting at which an irreversible plastic deformation occurs in the material.

Special characteristics for springs
Bending stress
Bending stress occurs when stress is put on torsion springs. The maximum bending stress here should not exceed $0.7\,R_m$.

Shear stress
Shear stress occurs in the material when stress is put on pressure and tension springs. The maximum shear stress (maximum stress) should not exceed $0.5\,R_m$. Here, the shear stress is dependent on the coil diameter of the spring, spring force and wire diameter. The difference between maximum stress and minimum stress is also called stress range.

Material groups

Material requirements

Technically and economically beneficial material use requires the knowledge of the application and the stress occurring in operation to derive the material requirements. The goal is to implement the desired function in the part or component and guarantee it throughout the planned period of use. The crucial loads here are usually of mechanical nature (strength, modulus of elasticity, see Table 1), but are often supplemented by corrosion, wear or temperature loads. Furthermore, specific physical properties (e.g. magnetism, conductivity) or a combination of those mentioned can be critical for material use.

Classification of materials

Various options exist for classifying the materials now used in technical applications. One example is subdividing into the four material groups:

– Metallic materials: smelted metals, sintered metals.
– Non-metallic inorganic materials: ceramics, glass.
– Non-metallic organic materials: natural substances, plastics.
– Composite materials.

Table 1: E-modulus of some materials (example)

Material group	Material type (selection)	Abbreviation Example	E-modulus [GPa]
Cast iron and malleable cast iron	Cast iron with lamellar graphite	EN-GJL-200	80 to 140
	Cast iron with spheroid graphite	EN-GJS-400	160 to 180
	White malleable cast iron	EN-GJMW-450	175 to 195
	Black malleable cast iron	EN-GJMB-450	175 to 195
Cast steel	Cast steel for general use	GE300	≈210
Steel	Unalloyed steels	C60	≈210
	Low-alloy steels	42CrMoS4	≈210
	Austenitic steels	X5CrNi18-10	≥190
	High-alloy tool steels	HS 6-5-4	≤230
Wrought copper alloys	High-conductivity copper	Cu-ETP	110 to 130
	Brass	CuZn30	115
	Nickel silver	CuNi18Zn20	135
	Tin bronze	CuSn6	100 to 120
Casting copper alloys	Tin cast bronze	CuSn10-C	100
	Red brass	CuSn7Zn4Pb7-C	100
Aluminum alloys	Wrought aluminum alloy	EN AW-AlSi1MgMn	65 to 75
	Casting aluminum alloy	EN AC-AlSi12Cu1	65 to 80
Magnesium alloys	Wrought magnesium alloy	MgAl6Zn	40 to 45
	Cast magnesium alloy	EN-MCMgAl9Zn1	40 to 45
Titanium alloys	Wrought titanium alloy	TiAl6V4	110
Tin alloys	Cast tin alloys for composite slide bearings	SnSb12Cu6Pb	30
Zinc alloys	Die-cast zinc alloy	GD-ZnAl4Cu1	70

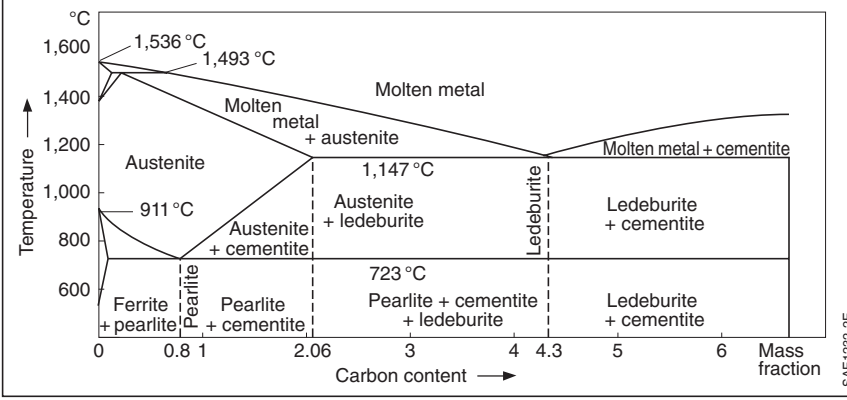
Metallic materials

The metals generally have a crystalline structure. Their atoms are arranged in a regular crystal lattice. The valence electrons of the atoms are not bound to a specific atom, but are able to move freely within the metal lattice – a metallic bond is present. This special metal-lattice structure explains the characteristic properties of metals: the ductility and resulting high level of formability, the high electric conductivity, the high level of thermal conductivity, the low light transmission and the great optical reflective ability (metallic gloss).

The metallic materials used most often in technical applications include ferrous material. Iron base alloys are primarily used for this. An alloy is defined as a metallic material that consists of at least two chemical elements.

The ferrous materials are divided into groups for steels and cast iron materials. The main difference between the two groups is carbon content. The carbon content of steel is generally less than 2 % and over 2 % for cast iron (for details, see EN metallurgy standards).

Steels



Structural compositions of steels

The majority of steels primarily consists of iron and other property-determining alloying elements such as chrome, nickel, vanadium, molybdenum and titanium. The most important alloying element is carbon, which is diffused in the iron lattice and present as iron carbide (Fe_3C), also called cementite. Various phases are present in the steel with their characteristic properties depending on the carbon content, the alloying elements and heat treatment (e.g. hardening, quenching and drawing). They can be found in the iron/carbon diagram (Figure 1). The most important phases are described below.

Ferrite

The ferritic structure exhibits a body-centered cubic atomic arrangement. It is soft, easily formable and ferromagnetic (e.g. S235). In unalloyed steels, ferrite is only present at very low carbon contents (< 0.02 %) as an individual phase (also called α phase).

Figure 1: Iron/carbon diagram

Pearlite
Pearlite has a lamellar iron-carbon structure, consisting of alternating associated areas of iron carbide (Fe_3C) and ferrite. This phase is present in steels with a carbon content higher than 0.02 %. As carbon content increase, the pearlite content present increases along with the ferrite until the structure consists entirely of pearlite at a carbon content of 0.8 % (e.g. C80). The pearlitic structure exhibits high strength.

Increasing the carbon content further results in the increased formation of iron carbide, which tends to separate out at the grain boundaries.

Austenite
If a steel is heated (between approximately 750 °C and 1,150 °C depending on the carbon content), the body-centered cubic iron lattice (α phase) transforms into a face-centered cubic iron lattice (γ phase). This austenitic structure can diffuse 100 times as much carbon as the ferritic structure. Ferrite and pearlite then form from the structure during the long cooling periods. In simple iron-carbon alloys, this lattice structure only exists at these high temperatures. Adding alloying elements such as nickel or cobalt allows the austenitic structure to be preserved stably even at room temperature. These types of austenitic alloys are very tough, easily formable, and resistant to heat and corrosion (e.g. X5CrNi1810).

Martensite
When cooling a steel very quickly from the austenite area during heat treatment (e.g. by quenching in water or oil), the carbon diffused in the lattice does not have enough time to transform into ferrite and pearlite. The austenitic structure abruptly deforms into a distorted lattice structure called martensite. The martensitic structure is very hard and brittle (e.g. 100Cr6).

Steel types
Along with many different organization and designation options, steels are often named based on their typical application, use or machining technique. Table 2 and Table 3 give an overview of properties and typical applications.

Structural steel
This is a simple steel that can usually be welded or machined easily. It is used in large quantities in general mechanical engineering and civil engineering and is reasonably priced (e.g. S235JR).

Free-cutting steel
This steel typically features high sulfur content, which causes short chips to form when machining (turning, milling). These chips can be extracted in the machinery without complications. These types of steels are usually used for volume components with low to medium-strength stresses (e.g. 11SMn30).

Tool steel
This is the umbrella term for a type of steel used for tools and molds. Depending on the application, it can feature high tensile strength, thermal stability, viscosity or corrosion resistance. This steel type can be classified as a cold-work steel (up to approx. 200 °C) or hot-work steel (up to approx. 400 °C), depending on the operating temperature. High-speed steels with high thermal stability (greater than 400 °C) and resistance to wear are also used (e.g. 90MnCrV8, X40CrMoV5-1, HS 6-5-2), particularly for machining tools such as drills and milling cutters.

Tempering steel
This type of steel is particularly well-suited for quench and draw heat treatment (hardening and draw tempering). This steel is often used for dynamically stressed shafts due to the high tensile strength and outstanding viscosity(e.g. 42CrMo4).

Table 2: Properties and typical applications for steels

Material group	Example materials	Surface hardness	Core hardness	Properties	Typical applications
Case-hardening steel (case-hardened and tempered)	C15	700 to 850 HV	200 to 450 HV	High resistance to wear	Moderately stressed gear wheels, joints
	16MnCr5	700 to 850 HV	300 to 450 HV	High resistance to wear	Piston pins, gear wheels
	18CrNiMo7-6	700 to 850 HV	400 to 550 HV	High resistance to wear, weldable	Gear wheels, drive parts
Nitriding steel (quenched, tempered and nitrided)	31CrMoV9	700 to 850 HV	250 to 400 HV	High resistance to wear	Highly-stressed piston pins, spindles
Ball and roller bearing steel (hardened and tempered)	100Cr6	60 to 64 HRC		High resistance to wear, high hardness and strength	Ball bearings, rolling elements, needle bearings
Cold-work steel (unalloyed, hardened and tempered)	C80	60 to 64 HRC		Surface hardened, tough core	Blades, chisels, striking tools
Cold-work steel (alloyed, hardened and tempered)	90MnCrV8	60 to 64 HRC		High dimensional stability, great edge retention and toughness.	Reamers, woodworking tools, thread cutters
	X210Cr12	60 to 64 HRC		Highly wear-resistant, great dimensional stability, high hardening properties	Cutting and punching tools, broaching tools, flange rollers, cold extrusion tools
Hot-work steel (hardened and tempered)	X40CrMoV5-1	43 to 45 HRC		High resistance to heat-related wear, great toughness and thermal conductivity	Forging dies, die-casting tools, extrusion dies
High-speed steel (hardened and tempered)	HS 6-5-2	61 to 65 HRC		High strength, great toughness, high hardness	Drills, countersinking tools
Stainless martensitic steel (hardened and tempered)	X20Cr13	≈40 HRC		Usable up to 550 °C, ferromagnetic, high resistance to wear	Pump parts, piston rods, nozzle needles, ship propellers
	X90CrMoV18	≥57 HRC		Good chemical resistance, resistance to wear and polishing properties	Cutting tools, ball bearings

Table 3: Properties and typical applications for steels

Material group	Example materials	Tensile strength [MPa]	Yield point [MPa]	Elongation at fracture A5 [%]	Fatigue strength under reversed bending stress [MPa]	Properties	Typical application examples
Hot-galvanized strip/ sheet	DX53D	≤ 380	≤ 260	≥ 30 (A80)	≥ 190	Good deep-drawing capability, hot-galvanized, higher strength	Automotive sheet metal parts e.g. engine hood, side panel
Structural steel	S235 JR	340 to 510	≥ 225	≥ 26	≥ 170	Good weldability, no preceding or retroactive heat handling	General construction parts, profiles
Free-cutting steel	11SMn30	380 to 570	–	–	≥ 190	High sulfur content for short chips, not suitable for welding	Moderately stressed volume components from the automotive industry such as shafts
	35S20	520 to 680	–	–	≥ 260	High sulfur content for short chips, not suitable for welding	Volume parts such as moderately stressed screws
Tempering steel	C45	700 to 850	≥ 490	≥ 14	≥ 280	Tough, heat treatable, moderate to high strength	Axles, bolts, screws
	42CrMo4	1,100 to 1,300	≥ 900	≥ 10	≥ 440		Crankshafts, axle shafts
	30CrNiMo8	1,250 to 1,450	≥ 1,050	≥ 9	≥ 500		Drive parts
Stainless ferritic steel (annealed)	X6Cr17	450 to 600	≥ 270	≥ 20	≥ 200	Good corrosion resistance, deep-draw capability, polishing properties, magnetic	Household devices, medical technology, sanitary
Stainless austenitic steel (solution annealed)	X5CrNi18 -10	500 to 700	≥ 190	≥ 45	–	Most frequently used corrosion resistant steel, good weldability, good deep-draw and polishing capability, non-magnetic	Chemical apparatus engineering, architecture, household objects
Cold strip (unalloyed)	DC05LC	270 to 330	≤ 180	≥ 40 (A80)	≥ 130	Good deep-draw properties	Automotive sheet metal parts e.g. engine hood, side panel

Table 4: Properties and typical applications for spring steel

Material	Diameter and thickness [mm]	Modulus of elasticity E [MPa]	Shear modulus G [MPa]	Minimum tensile strength [MPa]	Fracture contraction Z [%]	Permissible bending stress [MPa]	Permissible stress range for $N \geq 10^7$ [MPa]	Permissible maximum stress [MPa]	Properties and applications
Spring steel wire D, (patented and drawn cold-hammered)	1	206,000	81,500	2,230	40	1,590	380	1,115	Tension, compression, torsion springs, high static and low dynamic stress capacity
	3			1,840	40	1,280	360	920	
	10			1,350	30	930	320	675	
Stainless spring steel wire	1	185,000	73,500	2,000	40	1,400	–	1,000	Stainless springs
	3			1,600	40	1,130	–	800	
Heat-treated, alloyed valve-spring steel wire VD SiCr	1	200,000	79,000	2,060	50	–	430	1,030	High-strength spring material, high toughness e.g. passenger car valve springs
	3			1,920	50	–	430	960	
Spring steel strip Ck85	≤ 2.5	206,000	–	1,470	–	1,270	640	–	Highly stressed leaf springs
Stainless spring steel strip	≤ 1	185,000	–	1,370	–	1,230	590	–	Stainless leaf springs

Case-hardening steel
These steels feature a low carbon content (e.g. C15), which is usually increased up to 0.8 % by inserting the steel components into a carbonaceous furnace atmosphere (approx. 900 °C) in the edge region. The subsequent quenching causes martensite to form in the edge region and, in conjunction, high surface hardening at a simultaneously viscous core (ferritic, pearlitic). Applications include gear wheels and piston pins. Unlike nitriding, case hardening causes greater delays due to the martensitic hardening.

Nitriding steel
This steel forms a very hard and wear-resistant surface layer (approx. 10 µm) due to its chemical composition in combination with a corresponding heat treatment (nitriding at approx. 450 to 600 °C). Here, the viscous material core remains preserved, which makes this material particularly well-suited for gear wheels. There is less component deformation due to the lower temperature in comparison to case hardening (e.g. 31CrMoV9).

Spring steel
These are steels that have a particularly fine structure with high yield strength due to alloying silicon. They are especially well-suited for manufacturing springs in engine production (e.g. valve springs). Table 4 gives an overview of various spring steels.

Cast iron materials
Cast iron is defined as an iron-based alloy with a carbon content greater than approximately 2 %. The cast iron designation derives from these alloys' particularly high level of castability. One reason for this is the significantly lower melting temperature in comparison to steel (approximately 1,150 °C compared to approximately 1,500 °C).

Table 5 gives an overview of typical properties and applications for some materials.

Table 5: Properties and typical applications for cast irons

Material group	Example materials	Tensile strength [MPa]	Yield point [MPa]	Elongation at fracture A5 [%]	Fatigue strength under reversed bending stress [MPa]	Properties	Typical application examples
Cast iron with lamellar graphite (gray cast iron)	EN-GJL-200	≥ 200	–	–	90	Good castability, high vibration damping and heat capacity	Pump housing, cylinder head, machine bed, brake disc
Cast iron with spheroid graphite	EN-GJS-400-15	≥ 400	≥ 250	≥ 15	200	Higher strength and ductility than GJL	Crankshaft, crank-case, hubs
White malleable cast iron	EN-GJMW-400-5	≥ 400	≥ 220	≥ 5 (A3)	–	Good weldability, thin wall thicknesses, castable	Fittings
Black malleable cast iron	EN-GJMB-350-10	≥ 350	≥ 200	≥ 10 (A3)	–	Better machinability and hardening capability, can be manufactured with thick walls as white malleable cast iron	Fittings

Types of cast iron
The slow cooling during casting results in carbon mostly being present as graphite, typically in a ferritic-pearlitic matrix.

Gray cast iron
Depending on the formation of the graphite in layers or spheroids, the cast iron is referred to as either gray cast iron with lamellar graphite (GJL) or gray cast iron with spheroid graphite (GJS). The spheroid formation of the graphite is controlled in this process by treating the molten metal accordingly, such as with calcium. GJS features higher strength and better formability than GJL. Gray cast iron with vermicular graphite represents the middle ground between these two alloy types, both in terms of both graphite formation as well as properties.

Malleable cast iron
Along with these three types, the structure can also be affected by heat treatment (malleablizing) after casting. For malleable cast iron, the casted component made of white cast iron is subjected to an annealing process, where the iron carbide present in the matrix is converted into temper carbon. This increases the viscosity of the material. Based on the appearance of the fracture surface, these are referred to as white (annealed in an oxidizing, decarburizing atmosphere) and black malleable cast irons (annealed in a neutral atmosphere).

Cast steel
Cast steel is used for particularly highly stressed, weldable castings. In comparison to simple cast iron with lamellar graphite, castability is significantly worse while casting temperature and shrinkage are considerably higher.

Nonferrous metals
Along with the steels, some nonferrous metals (NF metals) have important technically relevant properties, such as those required in various applications. Special emphasis should be placed on copper alloys (heavy metal, density greater than 5 g/cm^3), which are used in many applications due to their high electric conductivity, and easily machinable, lightweight and nonmagnetic aluminum materials (light alloy, density less than 5 g/cm^3).

Classification of NF metals
NF metals (nonferrous metals and alloys with an iron percentage of less than 50 %) can generally be classified into wrought and cast alloys. Here, NF wrought alloys exhibit a very well malleable, ductile structure and can be brought to the desired shape by deep-drawing, bending, flanging, extruding or using similar deformation processes. Due to low ductility, shaping is limited to casting for NF casting alloys.

The properties of NF metals are frequently adapted to material requirements by adding alloying elements. Tables 6 through 9 give an overview of typical properties and applications of some materials.

Aluminum alloys
In aluminum alloys, adding alloying elements primarily aims to improve mechanical properties. For example, adding zinc or copper makes heat treatment possible, which results in high strength.

Copper alloys
Alloying zinc to copper forms brass (e.g. CuZn30), which leads to a higher strength compared to pure copper. Copper alloys with other alloying elements other than zinc are called bronzes. The most common bronzes are tin bronzes (e.g. CuSn6) with high strength and low ductility. Copper-nickel alloys (nickel-silver) are frequently used for plug contacts.

Table 6: Properties and typical applications for wrought copper alloys

Material group	Typical materials	Tensile strength [MPa]	Yield strength [MPa]	Fatigue strength under reversed bending stress (reference values) [MPa]	Properties	Application examples
High-conductivity copper	Cu-OF R220	220 to 260	≤140	70	High electric conductivity, solderable, weldable, deformable	Electronics, electrical engineering
Brass	CuZn30 R350	350 to 430	>170	110	Good strength properties, excellent cold-workability, can be soldered and brazed very well	Deep-drawn parts, fastening elements, screws, zippers
Nickel silver	CuNi18Zn20 R500	500 to 590	>410	–	Cold-workable, non-tarnishing, good spring properties	Relay springs, plugs
Tin bronze	CuSn6 R470	>470	≈ 350	190	Good cold-workability, good strength properties, good hardening properties, good wear and corrosion resistance, solderable	Springs, metal hoses, general machine and apparatus engineering

Table 7: Properties and typical applications for NF wrought alloys

Material group	Typical materials	Tensile strength [MPa]	Yield strength [MPa]	Fatigue strength under reversed bending stress (reference values) [MPa]	Properties	Application examples
Pure aluminum	EN AW-Al99,5 O	65	20	40	High conductivity, ductile, food-grade	Apparatus and tank engineering, deep-drawn parts
Self-hardening aluminum alloy	EN AW-AlMg2Mn0,8 H111	190	80	90	Seawater resistant, easily weldable	Automotive and ship engineering
Heat-treatable aluminum alloy	EN AW-AlSi1MgMn T6	310	260	90	Artificially aged, good combination of strength, corrosion resistance	Most frequently used heat-treatable aluminum alloy, profiles, vehicle frames, automobile transverse links
Heat-resistant aluminum alloy	EN AW-AlCu4MgSi (A) T4	390	245	120	Very good machinability, high temperature stability, good thermal stability	Components in hydraulic systems, aviation industry
High-strength aluminum alloy	EN AW-AlZn5,5MgCu T6	540	485	140	Good machinability, extremely high strength	Aviation industry, mechanical engineering
Universal aluminum casting alloy	EN AC-AlSi7Mg0,3 T6	290	210	80	Universal casting alloy, good mechanical properties, good corrosion resistance, very good weldability and machinability	Fittings, motor production, architecture
Eutectic casting alloy	EN AC-AlSi12Cu1 (Fe) DF	240	140	70	Excellent mold filling capability and casting characteristics, good chemical resistance	Thin-walled castings, fittings
Universal aluminum die-cast alloy	EN AC-AlSi9Cu3 (Fe) DF	240	140	70	Good processibility, low cost	Intake manifolds, transmission housings

Table 8: Properties and typical applications for NF casting alloys

Material group	Typical materials	Tensile strength [MPa]	Yield strength [MPa]	Fatigue strength under reversed bending stress (reference values) [MPa]	Properties	Application examples
High-strength casting alloy	EN AC-AlCu4Ti K T6	330	220	90	High strength and toughness	Transmission housings
Magnesium die-cast alloy	EN-MCMgAl9Zn1	200	140	50	Very light, low corrosion and thermal resistance, chips are combustible	Covers, housing, mobile telephone parts
Titanium forge alloy	TiAl6V4	890	820	–	High strength and corrosion resistance	Implants, aviation industry

Other NF metals
Along with aluminum and copper, the NF metals described below are of particular technical relevance.

Magnesium
At a density of approximately 1.75 g/cm^3, magnesium is significantly lighter than aluminum. The low melting temperature makes it particularly well-suited for castings. Typical applications in automotive engineering include car wheel rims, housing units and profiles.

Titanium
Hard-to-machine titanium alloys feature great corrosion resistance and a high level of thermal stability. Due to the favorable ratio of density and strength, these alloys lend themselves well to the aviation industry (e.g. air compressor turbine blades). Another application area is medical technology (implants, e.g. hip prosthetics) due to biocompatibility.

Sintered metals
Metal powder sintering
Sintered metals are generally manufactured using near-net-shape pressing of metal powders. This allows complicated shapes to be made from sintered metals at low costs, ready-to-install immediately or only requiring little finishing. After near-net-shape pressing the metal powder, a permanent connection between the grains is established by a running diffusion process at temperatures between 60 and 80 % of the melting temperature.

Metal injection molding
During MIM (metal injection molding), a process variant of sintering, a component is formed by injection molding metal powder and plastic compounds. After removing lubricants and binders with chemicals or heat, the molded articles retain their characteristic properties just like during metal powder sintering.

In addition to its chemical composition, the degree of porosity determines the properties and application of sintered metals to a large extent (see Table 10 and Table 11).

Table 9: Other alloys and cast copper alloys

Material group	Typical materials	Tensile strength [MPa]	Yield strength [MPa]	Fatigue strength under reversed bending stress (reference values) [MPa]	Properties	Application examples
Tin alloy	SnSb12Cu6Pb	–	60	28	Low hardness, good corrosion resistance	Sliding bearings
Die-cast zinc	ZP0410	330	250	80	Excellent casting characteristics, dimensional stability, surface quality	Thin-walled, low-stressed castings
Heat-conductor alloy	NiCr8020	650	–	–	High electrical resistance, high temperature stability	Heating filament
Resistance alloy	CuNi44	420	–	–	Low temperature coefficient, high oxidation stability	Resistors, potentiometer, heating filament
Cast tin bronze	CuSn10-C-GS	250	160	90	Good corrosion, resistance to wear	Fittings, pump housings
Red brass	CuSn7Zn4Pb7-C-GZ	260	150	80	Seawater resistant, good machinability, limp-home characteristics	Friction bearings, bushings

EN metallurgy standards

Standardization of steels
(In accordance with DIN EN 10020, [1])
Steel is defined as an iron alloy, usually with a carbon content of ≤ 2%. Ferrous materials with a higher carbon content are usually classified as cast iron. Steels are classified in three classes, "unalloyed steels", "stainless steels" and "other alloyed steels".

Unalloyed steels
Unalloyed steels that do not reach the defined minimum alloying element content are then divided into unalloyed high-grade steels and unalloyed stainless steels. For unalloyed high-grade steels, defined requirements apply, such as those regarding toughness and malleability.

Unalloyed stainless steels feature a higher degree of purity and, therefore, improved properties such as high yield strength, hardenability, good toughness and weldability. They are usually intended for quenching and drawing or for surface hardening.

Stainless steels
Stainless steels feature a chrome content of at least 10.5 percent by mass and a carbon content of less than 1.2 percent by mass. They are subdivided further by nickel content (more or less than 2.5 percent by mass) and by the main properties, including corrosion resistance, heat resistance and temperature stability.

Other alloyed steels
These include steels with requirements in regards to aspects such as toughness, particle size or malleability. They are usually not intended for quenching and drawing or surface hardening. A distinction is made between alloyed high-grade steels and alloyed stainless steels.

Designation system for steels with material abbreviations
(In accordance with DIN EN 10027-1, [2])
The material abbreviations for steels are divided into two groups.
– Group 1: Material abbreviations that feature information on use and mechanical and physical properties.
– Group 2: Material abbreviations that contain information on chemical composition.

Abbreviated names of Group 1
These material abbreviations include notes on use and mechanical or physical properties. The prefix G indicates that it involves a cast steel material:

S, GS	For general steel construction,
P, GP	For pressure-vessel construction,
L	For pipeline construction,
E	Engineering steels,
B	Concrete reinforcing steels,
Y	Prestressing steels,
R	Rail steels,
H	Flat products made of higher-strength steels for cold forming,
D	Flat products for cold forming,
T	Packaging steel sheet and strip,
M	Electrical steel sheet and strip.

Examples:
S235JR

S	Generally for steel construction,
235	Yield strength in MPa,
JR	Notch impact work 27 J at 20 °C.

HC240LA

H	High-strength steel,
C	Cold-rolling,
240	Minimum yield strength in MPa,
LA	Low-alloyed.

Abbreviated names of Group 2
These material abbreviations contain references to the chemical composition. The prefix G indicates that this is a cast steel material:

C, GC	Unalloyed steels (Mn < 1%),
G	Unalloyed steels (Mn low-alloyed steels),
X, GX	High-alloyed steels,
PM	Powder metallurgy,
HS	High-speed steel.

Examples:
C85S

C	Unalloyed steel (< 1% Mn),
85	0.01 times the C content, i.e. 0.85 % C,
S	For springs.

42CrMo4

42	Low-alloyed steel (Mn ≥ 1%) 0.01 times the C content, i.e. 0.42 % C,
Cr	4 times the Cr content in percent, i.e. 1% Cr,
Mo	Non-specific percentage of alloyed constituents, Mo (< 1%).

X5CrNi18-10

X	High-alloyed steel,
5	0.05 % carbon,
18	18 % Cr,
10	10 % Ni.

HS 7-4-2-5

HS	High-speed steel Percentage of alloyed constituents in whole percentages in the order of tungsten – molybdenum – vanadium – cobalt:
7	7 % tungsten,
4	4 % molybdenum,
2	2 % vanadium,
5	5 % cobalt.

In addition, special requirements can be defined, such as for the type of coating or notes on the treatment condition. Example information could read as follows:

+H	With hardenability,
+CU	With copper coating,
+Z	Hot-dip galvanized,
+ZE	Electrolytically galvanized,
+C	Work-hardened,
+M	Thermomechanically shaped,
+Q	Quenched,
+U	Untreated.

Designation system for steels based on the numbering system
(In accordance with DIN EN 10027-2, [3])
In addition to their material abbreviation, all steels are defined by a material number in accordance with the following structure:
Major group + steel group + counter.

Material major group number:

0	Pig iron, ferro-alloys,
1	Steel,
2	Nonferrous heavy metals,
3	Light metals,
4 to 8	Non-metallic materials,
9	Unassigned for internal use.

Steel group number (selection):

00	Unalloyed ordinary low-carbon steels,
01 to 07	Unalloyed high-grade steels,
10 to 18	Unalloyed stainless steels,
40 to 49	Chemically stable alloying steels,
20 to 29	Alloying tool steels.

Example:
1.4301
(material abbreviation: X5CrNi18-10)

1	Steel,
43	Stainless steel, with more than 2.5 % Ni, without any Mo, Nb or Ti,
01	Count number.

Standardization of cast-iron materials
The structure and form of the carbon (carbide or graphite) and the graphite structure are important to the properties. In standardization, a distinction is made between the following four groups of cast iron:
– Lamellar graphite cast iron (DIN EN 1561, [4]),
– Malleable cast iron (DIN EN 1562, [5]),
– Spheroidal graphite cast iron (DIN EN 1563, [6]),
– Ausferritic spheroidal graphite cast iron (DIN EN 1564, [7]).

There are two systems for designating types of cast iron: In accordance with material numbers or abbreviations.

Designation system for cast iron with abbreviations
(In accordance with DIN EN 1560, [8])
The designation is alphanumeric and consists of up to six individual positions. The first position is EN (European standard). This is followed by G (cast) and J (iron). The character for denoting the graphite structure is in the third position:

L	Lamellar,
S	Spheroidal,
M	Temper carbon,
V	Vermicular,
N	Graphite-free, ledeburitic cast chilled iron,
Y	Special structure.

Notes on the microstructure and macrostructure can be placed at position 4 if necessary, such as (as an excerpt):

A	Austenite,
F	Ferrite,
Q	Quenched.

The fifth position contains information on tensile strength, impact energy with test temperature or for hardness. Alternatively, the fifth position can specify the chemical composition.

Finally, the sixth position contains additional requirements such as:

D	As-cast casting,
H	Heat-treated casting.

Examples:
EN-GJL-150

EN	European standard,
GJ	Cast iron,
L	Lamellar graphite,
150	Tensile strength in MPa.

EN-GJV-HV400

EN	European standard,
GJ	Cast iron,
V	Vermicular graphite,
HV400	Vickers hardness.

EN-GJS-SiMo30-8

EN	European standard,
GJ	Cast iron,
S	Spheroidal graphite,
Si	Silicon content 3 %,
Mo	Molybdenum content 0.8 %.

Designation system for cast iron with material numbers
(In accordance with DIN EN 1560, [8])
The designation consists of a total of six positions. The first and second positions contain "5." followed by information on the graphite structure at the third position:

1	Lamellar,
2	Vermicular,
3	Spheroidal,
4	Temper carbon.

The fourth position describes the matrix structure (selection):

1	Ferrite,
3	Pearlite,
5	Austenite.

The fourth position is followed by a double-digit count number (00-99) that identifies the individual material.

Nonferrous-metal alloys
As for ferrous materials, the EN standard also features two options for describing and identifying each nonferrous metals (NF) material and its alloys: The first designation system uses chemical symbols (abbreviations) and the second uses a numerical designation system.

Unlike steels, NF metals are each identified with their own numerical designation system. Thus, the different properties and requirements of, for example, aluminum, copper or zinc alloys are better taken into account.

Designation system for NF metals with abbreviation
The EN standard denotes nonferrous metals (NF metals) according to the following basic system:

Example:
EN AW–Al Si1MgMn T6

EN	European standard,

Code letter for metal:

A	Aluminum,
C	Copper,
M	Magnesium.

Code letter for processing:
W Wrought (wrought alloy),
C Casting (casting alloy).

Designation system with chemical symbols, e.g. AlSi1MgMn in this case:

Material condition, here, e.g.: T6.

The system lists the alloy metals in order of base metal with falling percentages.

Special numerical designation system for aluminum (Al) and aluminum alloys
For wrought Al products (Al and wrought Al alloys in accordance with DIN EN 573-1, [9]), the alloy is determined by four digits (Example 1); for Al casting alloys (in accordance with DIN EN 1706, [10]), by five digits (Example 2).

Example 1:
EN AW–6082 T6
EN European standard,
AW Wrought aluminum alloy,
6 Indicator 6 for alloy group (Al-Mg-Si alloys),
0 Original alloy (1, 2 for modifications),
82 Designation for the alloy with about 1% Si, 0.7% Mn and 0.9% Mg,
T6 Material condition T6 (solution-annealed and artificially aged).

Example 2:
EN AC -45200
EN European standard,
AC Casting aluminum alloy,
45 AlSi5Cu alloy group,
200 Number for individual alloy (here AlSi5Cu3Mn).

Code numbers for the alloy groups:
1 Pure aluminum,
2 With copper,
3 With manganese,
4 With silicon,
5 With magnesium,
6 With magnesium-silicon,
7 With zinc,
8 Other.

Material conditions (selection):
O Soft-annealed,
H Work-hardened,
H14 Work-hardened, 1/2 hard (for sheet metal),
T6 Solution-annealed and artificially aged.

Magnetic materials

Materials which have ferromagnetic or ferrimagnetic properties are called magnetic materials and belong to one of two groups: metals (metals produced through melting or sintering) or nonmetallic inorganic materials. Composite materials such as soft magnetic composite materials and plastic-bonded permanent magnets are also playing an increasingly important role. They are characterized by their ability to exhibit a permanent external field or by their good magnetic flux conductivity (soft magnets).

In addition to ferromagnets and ferrimagnets, diamagnetic, paramagnetic, and antiferromagnetic materials also exist. They differ from each other in terms of their permeability μ, or the temperature dependence of their susceptibility κ. This variable gives the ratio of the magnetization of a substance to the magnetic field strength or excitation.

$$\mu_r = 1 + \kappa .$$

Classification

Ferromagnets and ferrimagnets

Both substances exhibit spontaneous magnetization which disappears at the Curie point (Curie temperature T_c). At temperatures above the Curie temperature, they behave like paramagnets. For susceptibility κ at $T > T_C$, the Curie-Weiss law applies as follows:

$$\kappa = \frac{C}{T - T_C},$$

where
C Curie constant,
T Temperature in K.

The saturation induction of ferromagnets is higher than for ferrimagnets because all magnetic moments are aligned in parallel. In the case of ferrimagnets, on the other hand, the magnetic moments of the two sublattices are aligned antiparallel to one another. Nevertheless, these materials are magnetic because the magnetic moments of the two sublattices have different magnitudes.

Diamagnets

For diamagnets, susceptibility κ_{Dia} is independent of the temperature.

Paramagnets

For paramagnets, susceptibility κ_{Para} drops as temperature increases. In this case, the Curie law states:

$$\kappa_{Para} = \frac{C}{T} .$$

Antiferromagnets

As in the case of ferrimagnets, adjacent magnetic moments are aligned antiparallel with respect to one another. As they are of equal magnitude, the effective magnetization of the material is zero.

At temperatures above the Néel point (Néel temperature T_N), antiferromagnets behave like paramagnets. At $T > T_N$, the susceptibility is:

$$\kappa = \frac{C}{T + \Theta},$$

where
Θ Asymptotic Curie temperature.

Examples of antiferromagnets: MnO, MnS, $FeCl_2$, FeO, NiO, Cr, V_2O_3, V_2O_4.

Soft magnetic materials

The figures specified in Table 1 are from the applicable DIN standards (soft-magnetic metallic materials, DIN IEC 60404-8-6, [1]). Many material qualities defined in this standard relate to the materials in DIN 17405 (DC relays, [2]) and DIN-IEC 60740-2 (transformers and reactors, [3]).

Designation (composition)

"Code letter" "Number 1" "Number 2" – "Number 3".

The code letter specifies the alloy class: "A" pure iron, "C" silicon-iron (SiFe), "E" nickel-iron (NiFe), "F" cobalt-iron (CoFe).

Number 1 indicates the concentration of the main alloy element.

Number 2 defines the different curves: 1 indicates a round hysteresis loop, 2 indicates a rectangular hysteresis loop.

Table 1: Soft-magnetic metallic materials

Magnet type	Alloying constituents by mass	Static magnetic properties											AC test data, 50 Hz [1]		
		Coercive field strength $H_{c(max)}$ in A/m Thickness in mm		Minimum magnetic polarization in tesla (T) at field strength H in A/m									Measuring point $\hat{H}$ in A/m	Minimum amplitude permeability μ_r Sheet thickness in mm

F31	23 to 27 Co	300									1.85	2.00			

[1] Data applies to laminated rings.

The significance of Number 3 following the hyphen varies according to the individual alloy. It indicates the minimum initial permeability μ_a/1,000 in nickel alloys; with other alloys, it designates the maximum coercive field strength in A/m. The properties of these materials are strongly geometry-dependent and highly application-specific. The material data quoted in extracts from the standard can therefore provide only a very general overview of the properties of these materials.

Electrical steel sheet and electrical steel strip

Applications and properties

Packages used for transformers or as stator or rotor packages for electric motors are composed of electrical steel strips, typically by packaging individual sheet metal plates. Electrical steel strips are often provided as long strips (wide strips or split strips) in a wound shape (called coils), but they are also available as panels (electrical steel sheet).

Electrical steel strips typically consist of iron-silicon alloys ([4] and [5]); other materials such as aluminum and manganese may function as alloy constituents in small quantities. Densities between 7.65 and 7.85 g/cm³ result depending on the composition. They are characterized by low remagnetization loss, high polarization and high permeability compared to other soft magnetic ferrous materials. The static coercive field strength H_c is typically 100 to 300 A/m for A and K types (see Designations), the maximum permeability μ_{max} is at about 5,000. For S and P types, the values are in the order of magnitude of 1 A/m for H_c and about 30,000 for μ_{max}.

Grain oriented electrical steel strip

Both grain oriented and non-oriented electrical steel strips exist. Grain oriented electrical steel strips feature a crystal structure (cubic structure), meaning the grains are oriented in a preferred direction by rolling and annealing steps during manufacturing. This gives the strip material a preferred magnetic direction in the strip direction. The magnetic properties depend on the direction (anisotropic magnetic properties). Grain oriented electrical steel strip is primarily used in components where exceptionally good magnetic flux in a specific direction comes into play (e.g. transformers, choke coils and converters).

Non-oriented electrical steel strip

In non-oriented electrical steel strip, however, there is not a structure. In other words, the crystallographic orientation of the grains is almost randomly arranged. The magnetic properties do not depend on the direction (isotropic magnetic properties). For this reason, non-oriented electrical steel strip is used in components where magnetic flux is not limited to a preferred direction (e.g. electric motors and alternators) [6].

Non-oriented electrical steel strips are usually delivered in a finally annealed (fully-finished) state. In other words, final annealing for optimizing the magnetic properties takes place at the manufacturer of the electrical steel strips. For electrical steel strips that are not finally annealed (semi-finished), final annealing still has to be carried out. This is typically done to the finished laminated core.

Coating

Electrical isolation of the individual layers suppresses eddy currents for alternating-field magnetization, reducing remagnetization losses.

Identifications

The designations for electrical steel sheets and electrical steel strips (ESS) is defined in DIN EN 10027-1 [7]:

Code letter 1 Number 1 – Number 2 Code letter 2 (see below for an example).

The first code letter is “M” for all varieties. Number 1 is one hundredfold the maximum magnetic reversal loss at 50 Hz and 1.5 T (types A and K) or 1.7 T (types S and P)in W/kg. Number 2 is one hundredfold the product’s nominal depth in mm.

Table 2: Properties of electrical steel strips and electrical sheet steel

Sheet grade		Nominal thickness	Maximum remagnetization loss in W/kg at 50 Hz and activation of			Minimum magnetic polarization in tesla (T) in an AC field at field strength H in A/m			Applications
Abbreviated name	Material number	mm	1.0 T	1.5 T	1.7 T	2,500	5,000	10,000	
M270-35A	1.0801	0.35	1.10	2.7	–	1.49	1.60	1.70	
M330-35A	1.0804	0.35	1.30	3.3	–	1.49	1.60	1.70	
M330-50A	1.0809	0.50	1.35	3.3	–	1.49	1.60	1.70	
M530-50A	1.0813	0.50	2.30	5.3	–	1.56	1.65	1.75	
M800-50A	1.0816	0.50	3.60	8.0	–	1.60	1.70	1.78	Electric motors
M400–65A	1.0821	0.65	1.70	4.0	–	1.52	1.62	1.72	
M1000–65A	1.0829	0.65	4.40	10.0	–	1.61	1.71	1.80	
M800–100A	1.0895	1.00	3.60	8.0	–	1.56	1.66	1.75	
M1300–100A	1.0897	1.00	5.80	13.0	–	1.60	1.70	1.78	
M340-50K	1.0841	0.50	1.42	3.4	–	1.54	1.62	1.72	
M560-50K	1.0844	0.50	2.42	5.6	–	1.58	1.66	1.76	
M660-50K	1.0361	0.50	2.80	6.6	–	1.62	1.70	1.79	Low-power motors for industrial and household appliances (e.g. washing machine motors, microwave transformers, refrigerator compressors)
M1050-50K	1.0363	0.50	4.30	10.5	–	1.57	1.65	1.77	
M390-65K	1.0846	0.65	1.62	3.9	–	1.54	1.62	1.72	
M630-65K	1.0849	0.65	2.72	6.3	–	1.58	1.66	1.76	
M800-65K	1.0364	0.65	3.30	8.0	–	1.62	1.70	1.79	
M1200-65K	1.0366	0.65	5.00	12.0	–	1.57	1.65	1.77	
						At field strength H = 800 A/m			
M140-30S	1.0862	0.30	–	0.92	1.40	1.78			Converters, transformers, choke coils
M150-30S	1.0861	0.30	–	0.97	1.50	1.75			
M111-30P	1.0881	0.30	–	–	1.11	1.88			

Code letter 2 provides type data:
- "A" cold rolled non-oriented electrical steel sheet and strip delivered in the fully processed state (DIN EN 10106, [8]).
- "S" conventional grain-oriented electrical steel sheet or "P" grain-oriented electrical steel strip with high permeability, both types are delivered in a fully processed state (DIN EN 10107, [9]).
- "K" cold rolled electrical non-alloy and alloy steel sheet and strip delivered in the semi-processed state (DIN EN 10341, [10]).

Example: An electrical steel strip designated M330-35A is a non-oriented electrical steel strip in a finally annealed state, exhibits a remagnetization loss of 3.3 W/kg at 50 Hz and 1.5 T and has a thickness of 0.35 mm.

Materials for transformers and reactors (DIN IEC 740-2)
These materials comprise the alloy classes C21, C22, E11, E31 and E41 from the standard for soft-magnetic materials (DIN IEC 60404-8-6). The standard essentially contains the minimum values for core-sheet permeability for specified core-sheet sections (YEI, YED, YEE, YEL, YUI, and YM).

Materials for direct-current relays (DIN 17405)
Designation comprises a letter and number combination:
a) Code letter "R" (relay material).
b) Code letters for identifying alloying constituents:
Fe = unalloyed, Si = silicon steels,
Ni = nickel steels or alloys.
c) Code number for maximum coercive field strength.
d) Code letter for the stipulated delivery state: "U" = untreated, "GB" = malleable pre-annealed, "GT" = pre-annealed for deep-drawing, "GF" = final-annealed.

DIN IEC 60404-8-10 essentially contains the limit deviations for magnetic relay materials based on iron and steel. The designation code defined in this standard is as follows (example: M 80 TH):
– Code letter "M".
– Permitted maximum value for coercive field strength in A/m.
– Code letter for material composition: "F" = pure iron, "T" = steel alloy, "U" = unalloyed steel.
– Code letter for delivery state: "H" = hot-rolled, "C" = cold-rolled or cold-drawn.

Sintered metals for soft magnetic components (DIN IEC 60404-8-9)
Designation comprises a letter and number combination:
– Code letter "S" for sintered materials.
– Hyphen followed by the identifying alloy elements, i.e. Fe plus P, Si, Ni, or Co if necessary.
– The maximum permitted coercive field strength in A/m follows the second hyphen.

Soft magnetic ferrite cores (previously DIN 41280, [11])
Soft-magnetic ferrites are formed parts made of a sintered material with the general formula $MO{\cdot}Fe_2O_3$, where M is one or more of the bivalent metals Cd, Co, Ca, Mg, Mn, Ni, Zn.

Designation comprises a letter and number combination:
The various types of soft-magnetic ferrites are classified in groups according to nominal initial permeability and are designated by capital letters. Additional numbers may be used to further subdivide them into subgroups; these numbers have no bearing on material quality.

The coercive field strength H_c of soft ferrites is usually in the range of 4 to 500 A/m. Based on a field strength of 3,000 A/m, induction B is in the range of 350 to 470 mT.

Powder composite materials
Powder composite materials are not yet standardized, but are becoming increasingly more important. They consist of ferromagnetic metal powder (iron or an alloy) and an organic or inorganic grain-boundary phase as a "binder". They are manufactured in much the same way as sintered metals. The individual manufacturing stages are:
– Mixing the starting materials (metal powder and binder).
– Shaping by injection-molding, extruding or pressing.
– Heat treatment below the sinter temperature (< 600 °C).

Depending on the shaping process, binder type and the amount of binder used, it is possible to optimize the material to achieve high saturation polarization, higher permeability or high resistivity.

They are used primarily in fields in which all the above-mentioned characteristics are important, and where no excessively high demands are placed on mechanical strength and machinability. These fields currently consist of quick-acting actuators for diesel-injection engineering and high-speed small electric motors for motor vehicles.

Materials for power applications								
W 1	1,000 to 3,000	–	–	45	1,200	>180	–	
W 2	1,000 to 3,000	–	–	25	1,500	>180	–	

[1] Nominal values. [2] tan δ/μ_i denotes the frequency-dependent material losses at a low flux density ($B < 0.1$ mT).
[3] Losses at high flux density. Measured preferably at: $f = 25$ kHz, $B = 200$ mT, $\Theta = 100$ °C.
[4] Permeability when subjected to a strong sinusoidal magnetic field. Measured at: $f \leq 25$ kHz, $B = 320$ mT, $\Theta = 100$ °C.
[5] Curie temperature Θ_c in this table is the temperature at which initial permeability μ_i drops below 10% of its value at 25 °C.
[6] Standard values.

Permanent-magnet materials
(DIN 17410, replaced by DIN IEC 60404-8-1)
If chemical symbols are used in the abbreviated names of the materials, they refer to the primary alloying constituents of the materials. The numbers in the material abbreviation before the slash denote the $(BH)_{max}$ value in kJ/m^3 and those after the slash denote one tenth of the H_cJ value in kA/m (rounded values). Permanent magnets with binders are indicated by a final p.

Designation by material abbreviation or code number
Structure of code numbers
(DIN IEC 60404-8-1:2005-8):
Code letter (group)
+ 1st digit (material type),
+ 2nd digit of 0 (isotropic) or 1 (anisotropic),
+ 3rd digit (various quality levels).

R – Hard magnetic alloys,
such as R1: Aluminum-nickel-cobalt-iron-titanium alloys (AlNiCo).

S – Hard magnetic ceramic materials,
such as S1: Hard magnetic ferrite.

U – Combined hard magnetic materials,
such as
– U1: Combined aluminum-nickel-cobalt-iron-titanium magnets (AlNiCo).
– U2: Combined rare earth-cobalt magnets (RECo).
– U3: Combined neodymium-iron-boron magnets.
– U4: Combined hard ferrites.

Comparison of permanent and soft magnets
Figure 1 shows the magnetic characteristic value ranges of some crystalline materials in widespread use. The values of soft magnetic materials are compared to the values of hard magnets (permanent magnets).

Nonmetallic inorganic materials

These materials are characterized by ionic bonds (e.g. ceramic materials), mixed (heteropolar/homopolar) bonds (e.g. glass), or homopolar bonds (e.g. carbon). These kinds of bonds, in turn, are responsible for several characteristic properties: generally poor thermal conductivity and poor electric conductivity (the latter increases with temperature), poor luminous reflectance, brittleness, and thus almost complete unsuitability for cold forming.

Ceramics
Ceramics are at least 30 % crystalline in nature; most ceramics also contain amorphous components and pores. Their manufacture is similar to that of sintered metals, however nonmetallic powders or powder mixtures are used; sintering at temperatures generally higher than 1,000 °C gives ceramics their characteristic properties. Ceramic structural parts are sometimes also shaped at high temperatures or even by a melting process, with subsequent crystallization.

Table 1 gives an overview of ceramic materials and their properties.

Glass
Glass is viewed as under-cooled, frozen liquid. Its atoms are only in a short-range order. It is regarded as amorphous. Molten glass turns to solid glass at transformation temperature T_g (T_g is derived from the former designation glass formation temperature). The transformation temperature is dependent on a variety of parameters and therefore not clearly determined (better: transformation range).

Composite materials

Composite materials consist of at least two physically or chemically different components. These components must be tightly bonded together at a specific boundary layer. Under these conditions, it is possible to bond many materials together. The resulting composite material exhibits properties that neither of the original materials has. A distinction is made between the following:
– Particle composite materials: e.g. powder-filled resins, hard metals, plastic-bonded magnets, cermets.
– Laminated composite materials: Such as thermostatic bimetals, sandwich panels.
– Fiber composite materials: Such as glass fiber or carbon fiber-reinforced plastics.

Plastics

Plastics are still a relatively "young" material group, the importance of which has continuously grown since the middle of the twentieth century. Products made of plastics play a large role in the various areas of our society today. Thus plastics are used as material in areas such as supply, medical and electrical technology, for packaging, household appliances and consumer goods.

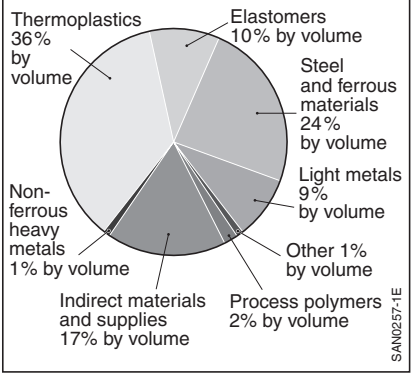
Specifically in the automotive industry, plastics have been able to gain increased use more than any other material group (Figure 1). The automotive industry is often the driver behind technological innovations for plastic.

However, the "saturation limit" for using plastics is far from having been reached. We continue to find applications in which conventional materials such as metal are being replaced by plastics.

The increasing use of plastics is mostly due to their less expensive processing options compared to other materials and to the beneficial properties of this "made-to-measure material group". In addition, new material and process developments are opening new markets and simultaneously offering enormous potential for new, innovative products made of plastic. A strong increase in the plastic content is forecast particularly due to increasing electromobilization. The greatest driver is the savings in weight compared to metallic materials.

Plastics is the general umbrella term for polymer materials. A significant characteristic is their macromolecular structure.

Figure 1: Average percentage of individual material groups in a mid-class car [1]



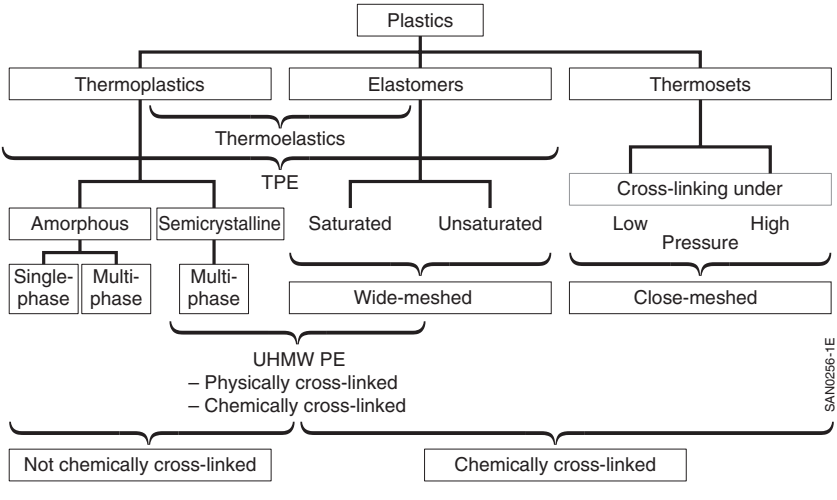


Figure 2: Classification of plastics based on [2]

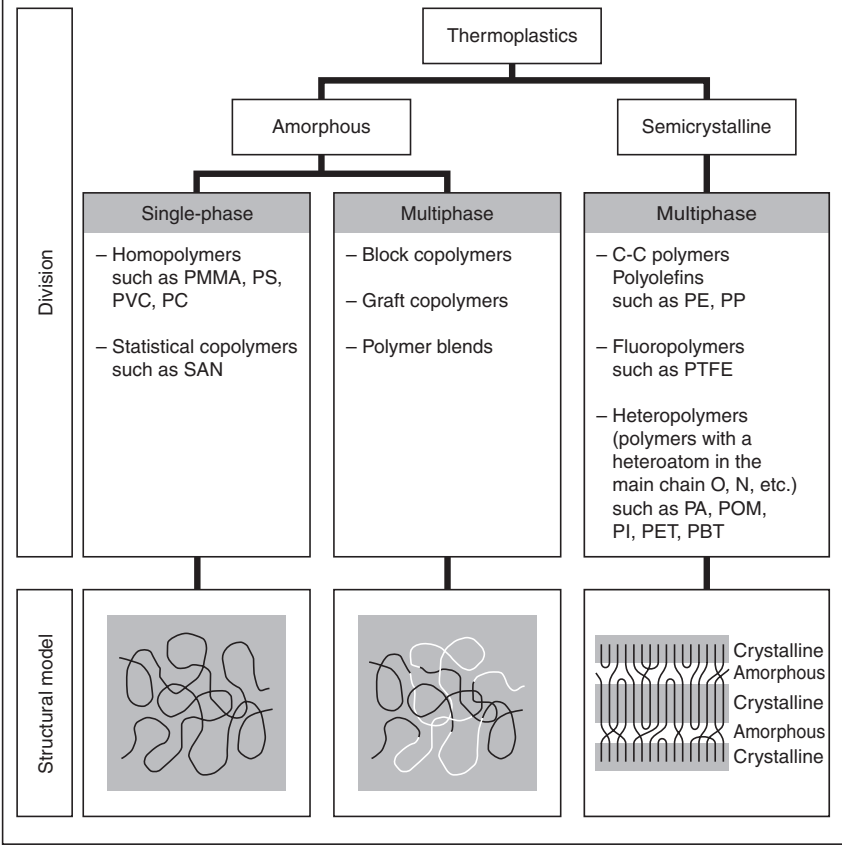
Plastics are classified into thermoplastics, thermosets, elastomers and thermoplastic elastomers (Figure 2), which are discussed in more detail in the following.



Thermoplastics

An outstanding characteristic of thermoplastics is the non-cross-linked structure between the macromolecules. This enables repeated plasticity or processability above their service temperature in the melting range. Only thermoplastics can be welded.

The material class of the thermoplastics can be further classified into amorphous thermoplastics and semicrystalline thermoplastics [3]. Semicrystalline thermoplastics are composed of amorphous and semicrystalline macromolecular structures. Unlike amorphous thermoplastics, therefore, they exist in multiple phases. Even amorphous thermoplastics can exist in multiple phases if they are modified during their synthesis into the form of a copolymer. The correlations are described in Figure 3 (based on [2]). The block copolymers existing in multiple phases form the link to the material class of thermoplastic elastomers.

The number of manufacturers and commercial types in the area of thermoplastics is very large. Most polymers come with or without different kinds and percentages of fillers and reinforcing materials. Therefore

Figure 3: Classification of thermoplastics based on [2]

the range of properties of thermoplastics available on the market is very large. Table 1 provides an overview of names, codes and example applications of widespread thermoplastics.

Mechanical properties of thermoplastics
Compared to other construction materials, thermoplastics have exceptional viscoelastic and viscoplastic deformation behavior. Consequently, the mechanical behavior is strongly influenced by temperature, load exposure period and loading rate (Figure 4). Amorphous thermoplas-

Table 1: Chemical name and properties of thermoplastics

Code	Chemical name	Description of properties; application examples
ABS	Acrylnitrile-butadien-styrene	High gloss, some transparent types; impact-resistant housing parts
PA 11, 12	Polyamide 11, 12	Tough, hard, and resistant to abrasion, low coefficient of friction, good sound absorption, approx. 1 to 3% water absorption required for good toughness; PA 11, 12 have much lower water absorption
PA6	Polyamide 6	
PA66	Polyamide 66	
PA6-GF	Polyamide 6 + GF	Impact-resistant machine housings
PA66-GF	Polyamide 66 + GF	
PA6T/6I/66-GF	Polyamide 6T/6I/66 +GF	Rigid machine housings and components even at high temperatures, low water absorption as standard PA
PA6/6T-GF	Polyamide 6/6T + GF	
PAI	Polyamid-imide	Components that are subjected to mechanical or electrical stress, favorable wear characteristics
PBT	Polybutylene terephthalate	Wear-resistant, chemically resistant, hydrolysis in water over 70 °C, very good electrical properties
PBT-GF	Polybutene terephthalate + GF	
PC	Polycarbonate	Tough and rigid over a broad temperature range, components have high rigidity
PC-GF	Polycarbonate + GF	
PE	Polyethylene	Acid-resistant containers and pipes, films
PET	Polyethylene terephthalate	Wear-resistant, chemically resistant, hydrolysis in water over 70 °C
PET-GF	Polyethylene terephthalate + GF	
LCP-GF	Liquid crystal polymers + GF	High dimensional stability under heat, low weld line strength, extremely thin-walled components, very anisotropic
PESU-GF	Polysulfone + GF	High continuous service temperature, low dependency of properties on temperature, not resistant to fuel and alcohol at higher temperatures, dimensionally stable components

Table 1 (continued): Chemical name and properties of thermoplastic plastics

Code	Chemical name	Description of properties; application examples
PEEK-GF	Polyetheretherketone + GF	High-strength components for high temperatures, good antifriction properties, and low wear; very expensive
PMMA	Polymethylmethacrylate	Transparent and in many colors, weatherproof
POM	Polyoxymethylene	Sensitive to acid-induced stress cracking; precision moldings
POM-GF	Polyoxymethylene + GF	
PPE+SB	Polyphenylene ether + SB	Resistant to hot water, flame retardant
PPS-GF	Polyphenylene sulfide + GF	High resistance to heat and media, inherently flame-retarding; underhood components
PP	Polypropylene	Household goods, battery cases, cover hoods, fan impellers (reinforced types)
PP-GF	Polypropylene + GF	
PS	Polystyrene	Transparent and in many colors
PSU-GF	Polysulfone + GF	Low dependence of properties on temperature, not resistant to fuel and alcohol
PVC-P	Polyvinyl chloride (plasticized)	Artificial leather, flexible caps, cable insulation, tubes/hoses, seals
PVC-U	Polyvinyl chloride (unplasticized)	Weatherproof exterior parts, pipes
SAN	Styrene-acrylonitrile	Molded parts with good chemical resistance, also transparent
SB	Styrene-butadiene	Impact-resistant housing parts for many applications
SPS-GF	Syndiotactic polystyrene	Low-warpage, brittle, high mold temperatures required for processing
PI	Polyimide	High resistance to heat and radiation, can be processed only by compacting and sintering
PTFE	Polytetrafluorethylene	Strong dependence of rigidity on temperature, high resistance to heat, aging and chemicals, can be processed only by compacting and sintering

tics and semicrystalline thermoplastics behave differently. This is due to the different path of the shear modulus curve and the different transition areas associated with this. They are called glass transition temperature T_g and melting range (Figure 5, based on [2] and [3]). With thermoplastics, the combination of load and higher temperature leads to creep or relaxation due to the viscoelastic and viscoplastic material behavior. In Figure 6, the creep and relaxation behavior of thermoplastics is compared to the material behavior of metals [2].

Figure 4: Depiction of the effect of different test speeds and temperatures on the stress-strain behavior of thermoplastics
a) Dependency on the test speed,
b) Dependency on the temperature.

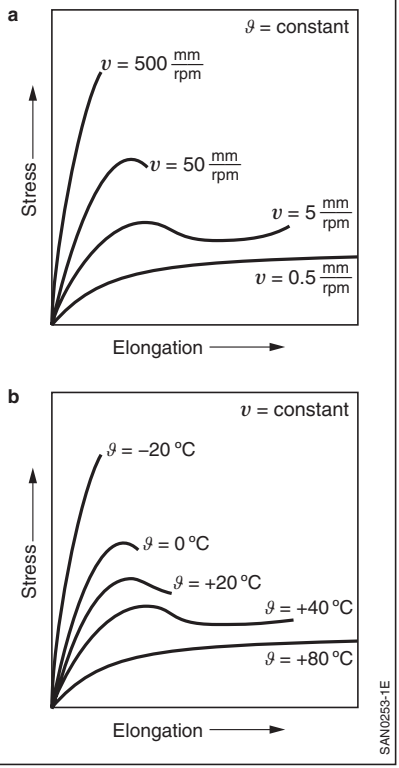


Table 2 and Table 3 show the mechanical properties of amorphous and semicrystalline materials. The values reproduce reference values from literature ([2] and [4]). The values may differ depending on the manufacturer and composition of filler or reinforcing material.

Chemical properties of thermoplastics
The chemical behavior of thermoplastics is determined by the structure of the macromolecules from which they are built. Polar plastics are attacked by polar solvents; non-polar plastics are attacked by non-polar solvents. Substances with a low molecular weight can migrate through solid thermoplastics (permeation).

Permeation of materials with a low molecular weight can trigger formation of stress cracks, much like with metals (referred to here as stress corrosion cracking). Suitable thermoplastics can be selected for a large number of application areas by selecting the right type of thermoplastic, appropriate shaping for the material and article, and optimum production parameters. Table 4 shows the chemical properties of some thermoplastics. The values are reference values from literature ([2], [4], [6]). Since the chemical behavior is difficult to estimate in some cases, consulting the plastics manufacturer or conducting your own measurements is advised.

Durability and aging of thermoplastics
Aging includes all irreversible changes to a material over time [7]. Aging processes change the properties of thermoplastics during a certain period of time. The causes of aging are distinguished between inner (such as residual stress, limited miscibility of additives) and external (energy input from heat and radiation, temperature change, mechanical loading, chemical influences). These causes lead to aging processes that manifest themselves in signs of aging and have a visible or measurable effect on thermoplastics. Examples of this are swelling, aftershrinkage, discoloration and alteration of the mechanical properties, such as brittleness.

More physical properties of the thermoplastics

Thermoplastics have good insulation properties against electricity and heat. Compared to other materials, thermoplastics have significantly larger and anisotropic coefficients of thermal expansion ([2], [4], [5]). Some thermoplastics, above all polyamides, absorb a significant amount of water, which results in changes to the mechanical and physical properties as well as the component dimensions.

Processing of thermoplastics

Thermoplastics are usually made available by raw material producers in granular form as sacked goods and can be processed in commercially available injection molding machines and extruders. Since thermoplastics are deformable, they can also be processed using deep-draw or compression methods. Since thermoplastics are meltable and solidify again, they can be also be welded during the production process and can be recycled to a certain extent.

Raw material producers usually provide recommendations for processing thermoplastics.

Use of thermoplastics

Thermoplastics are used in a wide variety of industries and in very diverse applications. Thermoplastics are used in the packaging industry, construction industry, consumer goods area (household appliances, toys, sports equipment), medical technology and aerospace technology. In the automotive industry, thermoplastics are being used very successfully in the interior, exterior and powertrain areas.

Thermoplastic elastomers
Thermoplastic elastomers (TPE) form their own plastic material class between thermoplastics and elastomers. They can be processed in a purely physical process that combines high shear forces, heat effects and subsequent cooling (for example, during injection molding or extrusion). Although no chemical cross-linking is required by a time-consuming and high-temperature vulcanization process such as with elastomers, the manufactured parts do in fact have rubber-elastic properties due to their special molecular structure. Renewed influence of heat and shear force causes the material to melt and deform. At the same time, however, this means that the thermoplastic elastomers can withstand far less thermal and dynamic loads than standard elastomers. The thermoplastic elastomers are not a "successor product" of conventional elastomers, but rather an interesting supplement, which combines the processing benefits of thermoplastics with the material properties of the elastomers ([2], [5], [8], [9], [10]).

Types of thermoplastic elastomers
"Thermoplastic elastomers" is the umbrella term for a whole series of different materials. They are always created through blends or block copolymers.

The blends are alloys made of a plastic matrix and a soft elastomer material. Block copolymers are molecular chains with different segments that congregate into hard and soft areas during cooling. Based on DIN EN ISO 18064 [11], the following subdivision can be made.

– TPO: Thermoplastic elastomers on an olefin basis, primarily PP/EPDM, such as Santoprene (Exxon Mobil).
– TPV: Cross-linked thermoplastic elastomers on an olefin basis, primarily PP/EPDM, such as Sarlink (DSM) and Forprene (SoFter).
– TPU: Thermoplastic elastomers on a urethane basis, such as Desmopan (Bayer) and Elastollan (BASF).
– TPC: Thermoplastic copolyester elastomers, such as Hytrel (DuPont) and Riteflex (Ticona).
– TPS: Styrene block copolymers (SBS, SEBS, SEPS, SEEPS and MBS), such as thermoplastic (Kraiburg TPE).
– TPA: Thermoplastic copolyamides, such as PEBAX (Arkema).

Properties of thermoplastic elastomers
The number of diverse commercial types with different properties on the market is very large. They, like thermoplastics, are usually made available by raw material producers in granular form as sacked goods.

Thermoplastic elastomers can be processed very well using injection molding and extrusion processes, since they pass through the plastic, molten state. They can be manufactured in all hardnesses from 5 Shore A to over 70 Shore D. The hardness and the compression set (DVR) are essential characteristics when using thermoplastic elastomers as sealants. Their thermal stability in particular is usually lower than that of elastomers. The maximum continuous service temperatures that can currently be attained for thermoplastic elastomers are approximately 150 °C.

Adhesion to nearly all technical thermoplastics can be achieved through modification. Their flowability as well as density, optics, scratch resistance and other properties can also be adjusted through compounding with a wide variety of fillers and additives.

Application of thermoplastic elastomers
Thermoplastic elastomers find a wide variety of applications in various industries while fulfilling the industry-standard requirements. Thus they are used in the automotive industry for control elements in the interior as well as for window trim in the exterior and for seals close to the engine. Furthermore, they are used in the industrial sector, for example, for tool handles or cable jackets. In the consumer sector, thermoplastic elastomers are found in toys, sports equipment, packaging, and personal care supplies such as toothbrushes and shavers. There are special compounds that satisfy the high requirements even for medical applications. They are used, for example, for drip chambers, seals and medical hoses.

Elastomers
Elastomers (or rubber compounds) are dimensionally stable, but elastically deformable plastics. The essential characteristic of these materials is that they can be stretched to at least twice their length. However, when the tensile load or compressive load is removed, they return to their initial state. This unique ability to reset is also referred to as rubber elasticity.

Elastomers are created from loose, wide-meshed and three-dimensional cross-linking of amorphous preliminary products (rubber). This loose fixation of polymer chains through chemical bonds leads to typical elastic behavior above the glass transition temperature T_g. This value usually lies significantly below 0 °C, and therefore below the service temperature of rubber compounds.

On the other hand, if the cross-linking is made solid and close-meshed, we speak of a thermoset. Cross-linked elastomers (just like thermosets) cannot be melted; that is, they decompose at high temperatures without melting.

The starting point for manufacturing elastomer materials is either natural or synthetic rubber. The rubber is mixed with various additives such as fillers, plasticizers, cross-linking chemicals, anti-aging agents and processing aids; then they are cross-linked under the influence of temperature.

During the cross-linking (vulcanization) a chemical reaction is underway, which usually takes place during the molding process under the influence of temperature (150 to 210 °C) and pressure. Not until after the vulcanization does the material have its rubber-elastic and mechanical properties, such as the desired hardness, tensile strength and elongation at break ([9], [12], [13], [14], [15]).

Classification of elastomers
Elastomers is an umbrella term for a whole material class whose individual materials can have widely differing properties. They can be classified into groups; based on the DIN ISO 1629 standard [16], the following subdivision can be made.
- R class: Rubbers with an unsaturated carbon chain, such as NR, NBR and SBR.
- M class: Rubbers with a saturated carbon chain, such as ACM, EPDM and FKM.
- O class: Rubbers with carbon and oxygen in the polymer chain, such as ECO.
- U class: Rubbers with carbon, oxygen and nitrogen in the polymer chain, such as polyurethane elastomers AU and EU.
- Q class: Rubbers with silicon and oxygen in the polymer chain, such as silicone elastomers VMQ.

Here, note that the ISO name (for example, NR for Natural Rubber) merely refers to the base rubber.

Properties of elastomers
General basic properties such as thermal and media resistance are already largely determined by the base rubber being used. These can be changed only within certain (very limited) boundaries. Yet within an elastomer class, such as NBR, there is a wide variety of different mixtures that can have significantly different specific properties such as hardness, strength behavior and elasticity. In addition, component suppliers often use their own recipes for their materials and the rubber compounds are often specially designed for the requirements of an application. Unlike thermoplastics or thermoplastic elastomers, non-cross-linked elas-

tomer mixtures are available on the free market only in a few cases and are not offered also in granular form as sacked goods or the like.

Tables 5 and 6 provide an overview of the names, application examples and some important properties of the most common kinds of elastomers. Please note: The data specified there can serve only as inexact guideline values and must be verified in each individual case of an intended application.

Use of elastomers

Elastomers have the property of being able both to absorb large deformations reversibly and to absorb mechanical energy. Ultimately, this results in diverse

Table 5: Name and application examples of elastomers

Code	Designation	Application examples
M-group		
ACM	Acrylate rubber	Oil circuit (for example, O-rings, radial shaft seal)
AEM	Ethylene acrylate rubber	Oil circuit, dampers, absorbers
EPDM	Ethylene-propylene-diene rubber	Coolant circuit, brake parts, body seals
FFKM	Perfluorinated rubber	Little use (special applications)
FKM	Fluorcarbon rubber	Standard for fuel applications (gas and diesel)
O-group		
ECO	Epichlorhydrin rubber	Fuel hoses, membranes
Q-group		
FVMQ	Fluorosilicone rubber	Membranes, fuel applications
VMQ	Silicone rubber	Turbocharger hoses, exhaust suspension, airbag coating
R-group		
CR	Chloroprene rubber	Bellows, grommets, windshield wipers, V-belts
HNBR	Hydrogenated (acrylo)nitrile-butadiene rubber	Seals in the engine compartment, hoses, drive belts
IIR	Isobutene-isoprene rubber (butyl rubber)	Gas-tight elastomer parts (inner layer of tires), dampers, membranes
NBR	(Acrylo)nitrile-butadiene rubber	Seals, dampers, absorbers, membranes, valves
NR	Natural rubber	(Truck) tires, engine suspensions, chassis mounts
SBR	Styrene butadiene rubber	Passenger car tires, brake parts
U-group		
AU / EU	Polyurethane rubber (polyester / polyether)	Gear wheels, wipers, damping elements (such as foamed material), interior

1 Very good resistance (no or little effect)
2 Good resistance (moderate effect)
3 Limited resistance (significant effect)
4 No resistance (unsuitable)

[1] Special materials with better cold resistance are possible
[2] Sulfur cross-linked
[3] Peroxide cross-linked
[4] Cold resistance, depending on the composition of the polymer
[5] Materials with better resistance to heat and hydrolysis are possible
[6] Materials with better ozone resistance are possible

applications for this material class. Thus rubber compounds are used to manufacture products that bridge tolerances, permit movement between various components, constitute static and dynamic seals, diminish vibrations and act as springs.

Typical technical applications include tires, seals (see also Elastomer materials, Seals), V-belts, hoses, flexible couplings, cable jackets, bearing elements, retaining elements, shock absorbers, windshield wipers, conveyor belts, roofing foils and shoe soles. But elastomers are also used to manufacture items for everyday use such as rubber boots, erasers, rubber bands, balloons, condoms, rubber gloves, pacifiers and wet suits.

Thermosets

Thermosets are the first plastics to have been manufactured for industrial production using a synthetic method. As early as 1910, Bakelite, a resin made of formaldehyde and phenol, came into use. In the 1920s and 1930s, molding resin masses with urea and melamine jointed it on the market. Polyester and epoxy resins were used for the first time after the end of World War II [17].

In general, thermosets refer to plastics with close-meshed molecular chains that are tightly cross-linked to each other. This results in the typical properties of thermosets:

– High strengths and rigidities with simultaneously low density,
– High dimensional stability under heat and thermal resistance,
– Good resistance to chemicals,
– High brittleness.

The varied types of thermosets find application in a wide variety of areas in the automotive industry. In addition to structural components, which will be covered in more detail below, this includes paint and adhesive systems, sealing compounds and substrates for interconnect devices in electronics.

The good thermal properties of thermosets make them particularly suitable for use in thermally stressed areas. This specifically relates to applications in the engine compartment of automobiles. Typical examples of components made of thermoset include water pump housings, belt pulleys and impeller wheels [18]. New developments in the area of tribologically modified PF molding compounds also open up further use options, such as for bearing elements, sliding elements and guide elements [19].

Due to the large number of thermosetting resin systems, the section below only covers the technically relevant materials (Table 7).

Unsaturated polyester resins

Unsaturated polyester resins (UP resins) fully cure through radical polymerization under the influence of heat. They can be adjusted with almost no shrinkage, which leads to very good dimensional stability. This is why components with special requirements for precision, such as headlamp reflectors, are manufactured from these kinds of materials. Furthermore, components made of UP resins feature good electrical properties, which helped them find increased usage earlier in ignition systems of motor vehicles (ignition distributors).

Epoxy resins

Epoxy resins (EP resins) cure in a polymerization reaction and therefore, unlike the phenol-formaldehyde resins, do not split off any volatile reaction products. Compared to other thermosetting materials, EP resins have a particularly low viscosity, which simplifies the procedure for processing them. Due to the high material prices, however, use of epoxides is limited. EP resins are used, for example, for encapsulating electronic components (special low-pressure EP is used for this). Moreover, EP resin is increasingly being used in continuous-fiber-reinforced (mostly carbon fiber-reinforced) structural lightweight components as matrix materials in the automotive industry.

Table 7: Thermosets

Type	Type of resin	Filler	t_G [1] °C	σ_{bB} [2] min. N/mm²	α_n [3] min. kJ/m²	CTI [4] min. grade	Properties, application examples

[8] Do not use types 13 to 83 (purely organically filled compounds) for new applications (availability no longer guaranteed).
[9] Barely used any more in new applications. Supply not guaranteed in the long term.

Phenol-formaldehyde resins
Phenol-formaldehyde resins (PF resins) are manufactured from phenol and formaldehyde using polycondensation. They have high mechanical rigidities and strengths and feature high chemical resistance, thermal resistance and dimensional stability under heat. In addition, there are tribologically modified forms that, however, cost significantly more because carbon fibers are added. PF resins are inherently flame retardant, which makes them ideal for applications in engine compartments.

Extenders
Filler are classified in accordance with DIN EN ISO 1043-2 [20]. A distinction is made here between material (such as carbon, glass, mineral), the form and structure (such as fibers, balls, powder) and special properties (such as flame retardant, thermal resistance) [4]. Technically relevant fillers primarily include glass fibers and glass balls as well as mineral fillers. Particularly in the aerospace industry, but also increasingly in the automotive industry, carbon fibers are also being used as reinforcement materials for thermosets.

Processing method
Thermosetting molding compounds are primarily processed using compacting or injection molding. There is also a wide variety of other processes in which the listed variants are combined or further developed.

Compacting
For compacting, pressure and temperature simultaneously act upon the molding compound. The mass is fed into the mold either without a form or in tablet form. Pressure brings the mass into the desired form, while the temperature cross-links the material. Due to the low machine-based effort, compacting is the least expensive processing method. However, this method can be used to manufacture only simple, large-format components. Above all, the manufactured components feature low level of orientation and the need for large amounts of finishing.

Injection molding
Here it is necessary to distinguish between easy-flowing granulate material and polyester bulk molding compound. Exceptionally high productivity is achieved when processing easy-flowing granulate material where the length of cycle times is largely dependent on component thickness. The barrel temperatures during injection molding are between 80 and 100 °C, while the mold temperatures range from 160 to 190 °C. While the injected mass is curing in the mold, new material for the next cycle is already being plasticized in the screw.

When processing polyester bulk molding compound (UP BMC), it is important to note that a stuffing unit is required in addition to the conventional machine equipment to convey the material into the screw. Then the material is homogenized in the injection barrel. Melting is not necessary; the barrel temperatures are usually around 25 to 35 °C.

Insulating materials
Electrical insulation plays a critical role in the proper functioning and service life of items such as alternators, engines and electrical devices, not just in motor vehicles.

Unfilled polymers have the best electrical insulation properties. Each addition of fillers reduces the dielectric strength of a polymer material by forming interfaces between the filler and polymer matrix as well as by excessive stress due to different dielectric properties.

The electrical insulation in motor vehicles not only has to reliably prevent disruptive electrical breakdowns, it also has to dissipate heat losses that arise, absorb mechanical loads and be resistant to liquids commonly used in motor vehicles. These properties typically have to be ensured in a temperature range from –40 to +180 °C. For this reason, a system of several materials is usually used as an insulating system; a single material is rarely used.

As an example here we will discuss surface insulators. These are usually used as more or less flexible combined insulation materials in electrical machines such as starters, alternators, hybrid engines and traction motors.

Plastic foils are flexible combined insulation materials that are bonded to pressboard, nonwoven materials or paper made of polymers. Flexible combined insulation materials often have a three-ply design with plastic foil as the middle layer. Depending on the combination of materials, they have different continuous service temperatures, tensile strengths and elongations at break, dielectric strengths, rigidities and impregnabilities.

The combination of plastic foils with fiber or nonwoven materials has technical advantages. Plastic foil made of unfilled polymers provides excellent electrical properties. The fiber or nonwoven materials, by contrast, have good impregnability and protect the foil against mechanical and thermal loads.

Foils made of polyester or polyimide are predominantly used as initial components as well as fiber or nonwoven materials made of organic fibers, polyester or aramide.

Flexible combined insulation materials are standardized as DIN EN 60626-1 ([21], definitions, general requirements), DIN EN 60626-2 ([21], test methods) and DIN EN 60626-3 ([21], properties of individual combinations of materials). In addition, there are standards for other surface insulators.

- Insulating foils: DIN EN 60674-1 ([22], definitions, general requirements), DIN EN 60674-2 ([22], test methods), DIN EN 60674-3-1 to -3-8 ([23], [24], properties of individual materials).
- Panel and roller pressboard: DIN EN 60641-1 ([25], definitions, general requirements), DIN EN 60641-2 ([26], test methods), DIN EN 60641-3-1, -3-2 ([26], properties of individual materials).
- Laminates: DIN EN 60893-1 ([27], definitions, general requirements), DIN EN 60893-2 ([27], test methods), DIN EN 60893-3-1 to -3-7 ([27], properties).

Sealing compounds

Sealing compounds (or cast resins) refer to reactive synthetic resins that are processed as a liquid for the finished product and solidify as this or a component part of it. While still a liquid, the resin is poured into a reusable or disposable mold. This results in either pure cast resin bodies with free form surfaces or other parts are included ([28], [29], [30], [31], [32]).

Unlike with meltable plastics (thermoplastics), the solidification occurs through a chemical cross-linking reaction and is irreversible (thermoset). They are usually poured in

- To cover and protect parts against penetration of moisture, dust, foreign matter, water, etc.
- To fix parts into place with respect to each other
- To increase the mechanical stability and the vibration and shock resistance
- To provide electrical insulation, that is, to increase the dielectric strength and contact protection
- To dissipate any heat losses that arise.

The range of applications for sealing compounds is broad and multi-faceted. As a result, the functions and requirements are also multi-faceted, ranging from processing and curing to the properties of the later application area. Selection criteria include:

- For application of liquid, not yet hardened sealing compound: viscosity, pot life, available systems engineering (manual, metering or molding system).
- The requirements that are placed on the cured molding compound in later use, such as hardness, elasticity, stretchability or pliability, thermal, mechanical, electrical and chemical loads of the molded components.

Due to their mechanical and electrical properties (Table 8), sealing compounds are ideal for use in electrical engineering and electronics. Typical applications of sealing compounds include:

– Molding and manufacturing electrotechnical components (such as ignition coils, transformers, insulators, capacitors, semiconductors, assemblies)
– Molding of open contact points for cables and lines

Different material classes are used depending on the requirements profile (such as service temperatures, chemical resistance, mold geometry). The sealing compounds used most frequently in electronics potting belong to the epoxide, polyurethane and silicone material classes. Less widespread, for example, are polyester and hot melt sealing compounds (hot melts, hot melt adhesives).

Table 8: Properties of different sealing compounds (examples)

Properties	Standard	Unit	Epoxy resin, unfilled	Epoxy resin, filled (quartz powder)	Unsaturated polyester resins	Polyurethanes	Silicone
Tensile strength	ISO 527-1 [38]	N/mm^2	60 to 90	80 to 100	30 to 80	3 to 80	0.3 to 10
Elongation at break	ISO 527-1 [38]	%	3 to 8	0.8 to 1.1	2 to 4	0.5 to 80	50 to 700
Flexural strength	ISO 178 [39]	N/mm^2	60 to 140	110 to 120	60 to 140	40 to 140	n/a
Impact strength	ISO 179-1 [40]	kJ/m^2	15 to 30	10 to 12	8 to 15	40	n/a
Glass transition temperature T_G		°C	+70 to +200	+70 to +200	+70 to +150	−40 to +130	−120
E module		N/mm^2	2,000 to 4,000	5,000 to 8,000	3,500	250 to 3,000	0.005 to 5
Continuous temperature resistance	DIN EN 60216-1 [41]	°C	110 to 200	110 to 200	120 to 140	90 to 140	150 to 250
Specific volume resistance		Ω cm	10^{14} to 10^{16}	10^{14} to 10^{16}	10^{13}	10^{13} to 10^{16}	10^{15} to 10^{17}
Exothermy during curing			High	Medium	Very high	Very low	Very low
Coefficient of thermal expansion		$K^{-1}\ 10^{-6}$	80 to 100	30 to 70	60 to 80	50 to 150	300
Shrinkage		%	0.5 to 2	0.1 to 1	3 to 9	0.2 to 1	0.1 to 2

+ = Good resistance
O = Limited resistance
– = No resistance
n/a = Not applicable

There are also extensive means of using chemicals and formulas to adapt the sealing compounds to the typical requirements for an application:
– Variations in chemicals provide different resin and curing systems
– Variations in formulas provide fillers, pigments, accelerators, toughness modifiers, wetting agents, degassing agents and anti-sedimentation agents

The chemical resistance of sealing compounds depends on the components of the cast resin, the cross-link density and the degree of cross-linking. As a rule of thumb, hard sealing compounds are more resistant than soft ones.

The final properties of the cured sealing compounds largely depend on the kind and quantity of ingredients used (hardeners, diluents, fillers) and the curing conditions. Therefore generally applicable specifications about physical properties are not possible.

Epoxide systems
Epoxides have been widely used for many years. They are generally hard and capable of carrying loads, their volume shrinkage during curing is rather low.

Characteristics include their excellent mechanical properties, good temperature tolerance, good adhesive strength on a wide variety of surfaces, and likewise good chemical resistance. The cross-linking or curing process is generally slow, particularly if only small volumes react with each other. More reactive hardeners could be used, but that can cause a substantially stronger exothermic reaction, creating stress for components and the printed circuit board.

Fillers are an essential component of epoxy resin formulations. They reduce costs and improve mechanical properties. At the same time, they lead to an increase in the crack resistance and rigidity, as well as to a reduction in thermal shrinkage, lowering lower inner stresses. Quartz powder is a standard filler in electronic applications.

Epoxide systems are frequently used, for example, as a thermally conductive sealing compound for all kinds of solenoids.

Polyurethane systems
Even after curing, polyurethane sealing compounds can still expand and flex (even if only somewhat), which is particularly important when sensitive components (such as ferrite on printed circuit boards) are cast.

The curing reaction for polyurethane systems is less exothermic than for epoxide sealing compounds. The volume shrinkage after the hardening is low and a broad spectrum of hardness and/or elasticity is available. The chemical and mechanical resistances are good.

Silicone
Silicone-based sealing compounds are usually significantly more expensive than epoxide or polyurethane sealing compounds, but they are used where typical continuous service temperatures are above 180 °C. The exothermic heat buildup during the hardening is also only very low.

Polyester systems
These systems have very good resistances to a wide variety of media, but a very strong heat buildup during hardening and a high degree of shrinkage after the hardening as a result. Under certain circumstances this leads to thermomechanical damage to the cast components, even to the point of having components tear away from the substrate.

Heat treatment of metallic materials

Hardness

Hardness is a property of solid materials that defines the resistance of a materials against penetration by a harder solid body. In metallic materials the hardness is used to assess mechanical properties such as strength, machinability, malleability, and resistance to wear. DIN EN ISO 18265 [1] defines guidelines for converting hardness to tensile strength.

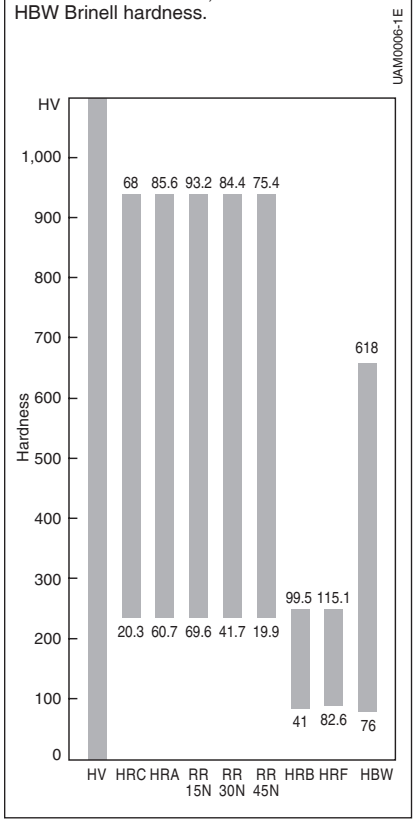
Hardness testing

Hardness testing is a nondestructive way of obtaining information about the mechanical properties of a material in a relatively short time.

The test data are generally derived from the size or depth of the deformation produced when a specified indentor is applied at a defined pressure. A distinction is made between static and dynamic testing. Static testing is based on measurement of the permanent impression left by the indentor. Conventional hardness tests include the Rockwell, Vickers and Brinell procedures. Figure 1 compares the fields of application of hardness testing based on these different procedures.

Dynamic testing monitors the rebound height of a test tool accelerated against the surface of the test specimen.

Another option for obtaining an index of surface hardness is to scratch the surface with a harder test tool and then measure the groove width.



Hardness-testing methods

Rockwell hardness (DIN EN ISO 6508, [2])
This method is particularly suitable for fast, automated testing of metallic workpieces, but places specific demands on clamping the workpiece in the test equipment. It is unsuitable for workpieces which as a result of their geometry give in the test equipment (e.g. pipes).

This method involves a test tool (indentor) of defined size, shape (tapered or spherical) and material (steel, hard metal or diamond) being pressed in two stages into the test specimen. In this process, after the preliminary test force is applied, the additional test force is exerted for a defined period. Initially, the factor e is calculated from the remaining penetration depth h for the HRA, HRB, HRC and HRF methods:

$$e = \frac{h}{0.002}.$$

Figure 1: Comparison of hardness ranges for different test methods for unalloyed and low-alloy steels and cast steel
The figures at the range extremities indicate the hardness data for the respective method.
HV Vickers hardness,
HR Rockwell hardness,
HBW Brinell hardness.

For the HR..N and HR..T methods the factor e is calculated from the penetration depth h with the equation:

$$e = \frac{h}{0.001}.$$

With the factor e the Rockwell hardness HR can now be calculated for the HRA, HRC, HR..N and HR..T methods:

$$HR = 100 - e.$$

If the HRB and HRF methods are used, the Rockwell hardness HR is calculated according to the of following equation:

$$HR = 130 - e.$$

The test specimen's surface should be smooth and as flat as possible. When testing on convex-cylindrical or spherical surfaces, the value determined must be corrected as a function of the hardness.

The abbreviation for the selected test method should be appended to the numerical value when specifying hardness (e.g.: 65 HRC, 76 HR45N). The designations provide an indication of the indentor used (diamond cone or ball), the preliminary test force and the total test force.

Table 1: Application of the Brinell hardness test

Material	Brinell hardness	Load factor $0.102\ F/D^2$
Steel; nickel and titanium alloys		30
Cast iron (nominal diameter of ball must be 2.5, 5 or 10 mm)	< 140 ≥ 140	10 30
Copper and copper alloys	< 35	5
	35 to 200	10
	>200	30
Light metals and their alloys	< 35	2.5
	35 to 80	5 10 15
	> 80	10 15
Lead and tin		1
Sintered metals	see DIN EN ISO 4498 [4]	

Depending on the indentor used and the total test force applied, different hardness scales with the abbreviations HRA, HRB, HRC, HRD, HRE, HRF, HRG, HRH, HRK, HR15N, HR30N, HR45N, HR15T, HR30T and HR45T are used.

Advantages of the Rockwell test method include minimal specimen preparation and rapid measurement. This test process can also be fully automated. Any tester vibration, or shifting and movement of either the test specimen or the indentor can lead to testing errors, as can an uneven support surface or a damaged indentor.

Brinell hardness (DIN EN ISO 6506, [3])
This method is used for metallic materials of low to medium hardness. The test tool (indentor) is a hard-metal ball with the diameter D. It is pressed with test force F vertically into the surface of a specimen. After the test force has been removed, the Brinell hardness is calculated from the remaining indentation diameter d:

$$HBW = 0.102\ \frac{2F}{\pi D^2 (1 - \sqrt{1 - d^2/D^2})},$$

with load F in N, ball diameter D in mm, and mean indentation diameter d in mm.

Test loads range from 9.81 N to 29,420 N. Results obtained using balls of different diameters are only conditionally comparable, and any comparisons should be based on testing at identical force levels. Testing should always be performed using the largest possible ball, while load factors should be selected to obtain an indentation diameter of between 0.24 D and 0.6 D. Table 1 lists the recommended load factors and ball diameters for a variety of materials as laid down in DIN EN ISO 6506-1 [3].

In the Brinell-hardness designation, the numeric value is accompanied by the abbreviation for the method, the ball diameter in mm and the test force in N multiplied by a factor of 0.102 (e.g. 600 HBW 1/30).

High test loads producing deformations extending over a relatively wide surface area can be employed to gather data on materials with inconsistent structures. An advantage of the Brinell method is the relatively high degree of correlation between the Brinell hardness factor and the steel's tensile strength.

The required preparations and ensuing test procedures are more complex than those used for Rockwell testing.

Vickers hardness (DIN EN ISO 6507, [5])
This test method can be used for all metallic materials, regardless of hardness. It is especially suitable for testing minute and thin specimens, while the potential application range extends to include surface and case-hardened parts, as well as nitrided workpieces and parts carburized in nitrogen-based atmospheres.

The test tool is a square-based diamond pyramid with an apical angle of 136°. This is applied to the surface of the test specimen at an individually specified force F. The diagonals d_1 and d_2 of the indentation remaining on the test surface after test force F has been removed are measured. The Vickers hardness is obtained from the arithmetic mean value d of the two diagonals:

$$\text{HV} = \frac{2F \sin\frac{136}{2}}{d^2} \approx 0.1891 \frac{F}{d^2},$$

with test force F in N and arithmetic mean value d of diagonal lengths d_1 and d_2 in mm.

In the formula for Vickers hardness data, the actual test figure is accompanied by the abbreviation HV, the force in N (multiplied by a factor of 0.102) and, following a slash, the force application period (if other than the standard 15 seconds) in seconds (e.g.: 750 HV 10/25).

The test specimen's surface should be smooth and flat. DIN EN ISO 6507 [5] stipulates that correction factors be used to compensate for any error stemming from surface curvature. Test-load levels are selected with reference to either the thickness of the workpiece to be tested or the layer to be tested.

A major advantage of this test method is that there are virtually no limitations on using it to assess thin parts or layers. It allows the use of extremely small force levels to determine the hardness of individual structural sections. The Brinell and Vickers numbers correlate well up to approximately 350 HV. However, a certain minimal degree of surface consistency is necessary to ensure accurate results.

Knoop hardness (DIN EN ISO 4545, [6])
This process closely resembles the Vickers method. The equal-sided diamond tip in the Vickers test has a rhombic shape in the Knoop test. The test tool is designed to leave an impression in the form of a thin, elongated rhombus. The long diagonal d of the indentation remaining on the test surface after test force F has been removed is measured. The hardness value HK is calculated as follows:

$$\text{HK} = 1.451 \frac{F}{d^2},$$

with test force F in N and length d of the long diagonal in mm.

In the Knoop-hardness designation, the numeric value is accompanied by the abbreviation HK for the method, the test force in N multiplied by a factor of 0.102 and – if necessary separated by a slash – the application period of the test force in s (e.g. 640 HK 0.1/20).

The penetration depth is roughly 1/3 less than in the Vickers method, allowing evaluation of surface hardness in thin parts and layers. However, the test method also places heightened demands on the surface: The test must be performed on a polished, smooth and flat surface.

Knoop testing is often used on brittle materials such as, for example, ceramic or sintered materials.

Martens hardness (DIN EN ISO 14577, [7])
In this method, the penetration of a pyramid-shaped test tool into materials is recorded, in the course of which both the force and the travel during plastic and elastic deformation are measured. Martens hardness is defined as the ratio of test force F to surface A_S of the indentor calculated from penetration depth h, and given in N/mm^2.

Martens hardness is denoted by the abbreviation HM, to which is appended the test force in N, the application time of the test force in s and the holding time of the test force in s (e.g. HM 0.5/20/20 ≙ 8,700 N/mm^2).

Scleroscope hardness
This dynamic measurement method is specially designed for heavy and large metal pieces. This process is based on the measurement of the rebound height of a steel indentor (hammer) featuring a diamond or hard metal tip. This is dropped from a stipulated height onto the surface of the test specimen. The rebound serves as the basis for determining the hardness.

The method is not standardized and there is no direct correlative relationship with any other hardness-testing method.

Heat-treatment processes

Heat treatment is employed to adapt the technological material properties of metallic components and tools to the relevant requirements. Such requirements can be processing properties to suit manufacturing and usage properties to suit function.

According to DIN EN 10052 [8], heat treatment involves "subjecting a workpiece in whole or in part to time and temperature cycles in order to bring about a change in its properties of its structure. If necessary, the chemical composition of the material can be changed during the treatment".

The process modifies the microstructure to achieve the hardness, strength, ductility, wear resistance, etc. required to withstand the stresses associated with static and dynamic loads. The most significant industrial processes are summarized in Table 2 (see DIN EN 10052, [8] for terminology).

Hardening
Hardening procedures produce a martensitic microstructure of extreme hardness and strength in ferrous materials such as steel and cast iron. These procedures consist of the individual stages known as austenitizing and cooling or quenching.

Through hardening
The workpiece being treated is heated to the austenitizing, or hardening temperature (Table 3), at which it is maintained until an austenitic structure emerges, and until an adequate quantity of carbon (released in the decay of carbides, such as graphite in cast iron) is dissolved in the treated material. After austenitizing, the workpiece is cooled or quenched at a rate sufficient for hardening, which can also occur in temperature stages. A complete conversion to the martensitic microstructure should be completed as quickly as possible. The necessary cooling process is determined by the chemical composition, the austenitizing conditions, the shape and dimensions, and the desired microstructure. Reference values for the required cooling rate can be found in the time-temperature transformation chart for the steel in question.

Table 2: Overview of heat-treatment processes

Hardening	Austempering	Draw tempering	Thermo-chemical treatment	Annealing	Precipitation hardening
Through hardening cross section Surface hardening Hardening of carburized parts (case-hardening)	Isothermic transformation in the bainite stage	Tempering of hardened parts Tempering above 540 °C for quenching and drawing	Carburizing Carbonitriding Nitriding Nitro-carburizing Boron treatment Chromating	Stress-free annealing Recrystallization annealing Soft annealing Spheroidization Normalizing Homogenizing	Solution treatment and aging

The austenitizing temperature varies according to the composition of the material in question (for specific data, consult the DIN Technical Requirements for Steels). Table 3 above provides reference data. See DIN 17022 [9] Part 1 and Part 2 for practical information on hardening procedures for tools and components.

Not all types of steel and cast iron are suitable for hardening. The following equation describes the hardening potential for alloyed and unalloyed steels with mass carbon contents of between 0.15 % and 0.60 %, and can be applied to estimate the hardness levels achievable with a completely martensitic microstructure:

Table 3: Standard austenitizing temperatures

Type of steel	Quality specification [10, 11, 12]	Austenitizing temperature in °C
Unalloyed and low-alloy steels	DIN EN 10083-1 10083-2 10083-3	
< 0.8 % by mass of C	10085	780...950
≥ 0.8 % by mass of C	–	750...820
Cold- and hot-working tool steels	DIN EN ISO 4957	780 to 1150
High-speed tool steels		1150 to 1300

$$\text{Max. hardness} = (35 + 50x \pm 2)\,\text{HRC}, \text{ (eq. 1)}$$

where the carbon content in % by mass is to be applied for x here. If the microstructure does not consist entirely of martensite, then the maximum hardness will not be achieved.

When the carbon content exceeds 0.6 % by mass, it may be assumed that the material's structure contains untransformed austenite (residual austenite) in addition to the martensite. Greater amounts of residual austenite can have a deleterious effect on achievable hardness and reduce wear resistance. In addition, residual austenite is metastable, i.e. there exists a potential for subsequent transformation to martensite at temperatures below room temperature or under stress. This can give rise to unwanted changes in the workpiece's dimensions and shape. Prompt low-temperature follow-up procedures or draw-tempering operations at over 230 °C can be useful in cases where residual austenite is an unavoidable product of the hardening procedure.

Temperature differences occur between the edge and core of the workpieces during cooling and quenching. With greater cross-sections, the reduced cooling rate in the core can give rise to a decrease in hardness as the distance to the surface increases. There is a hardness progression or gradient. The hardness

gradient is obtained from the material composition and the hardenability dependent on the austenitizing conditions (testing described in DIN EN ISO 642, [13]). In this case, it is necessary with regard to the required hardness to use material with sufficient hardenability. Information on choice of steel based on hardenability can be found in DIN 17021 [14].

DIN EN ISO 18265 [15] defines the method for using hardness as the basis for estimating tensile strength R_m. This method can only be applied in cases whether the surface and core hardnesses are virtually identical.

During hardening, the transformation of the microstructure to the martensitic state is combined with an increase in volume. With regard to the initial state, the volume increases by approximately 1 %. This equates to a change in length of approximately 0.3 %.

The changes in volume associated with rearrangements of the structure and thermal gradients during cooling give rise to stresses, which in turn result in distortion in the form of changes in dimension and shape. The stresses that remain in the workpiece after hardening are called internal stresses. The edge of a hardened workpiece tends to be subject to internal tensile stress, while the core tends to be subject to internal compressive stress.

Table 4: Comparison of power densities when heating with different sources

Energy source	Normal power density in W/cm^2
Laser beam	10^3 to 10^4
Electron beam	10^3 to 10^4
Induction (with medium- or high-frequency alternating current, or high-frequency pulses)	10^3 to 10^4
Flame heating	$1 \cdot 10^3$ to $6 \cdot 10^3$
Plasma beam	10^4
Molten saline solution (convection)	20
Air, gas (convection)	0.5

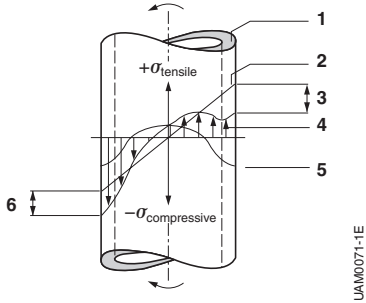
Surface hardening

This process is especially suited for integration within large-scale manufacturing operations, and can be adapted to fit the rhythm of the production line.

Heating and hardening are restricted to the surface, thereby minimizing alterations in shape and dimensions. Heating is generally provided by high- or medium-frequency alternating current (induction hardening) or by a gas burner (flame hardening). Friction (friction hardening) and high-energy beams (e.g. electron or laser beams) can also provide the heat required for austenitizing. Table 4 provides an overview of the specific heat energies for the individual procedures.

These methods can be used to treat both linear and flat surfaces, meaning that the parts can be heated either while stationary or in motion. The heat source itself can also be moved. Rotation is the best way of dealing with radially symmetrical parts, as it ensures concentric hardening. Either immersion or spraying arrangements can be applied for quenching. Information on performing surface hardening can be found in DIN 17022-5 [9].

Heat rise is rapid, so the temperatures must be 50 to 100 °C higher than those used in furnace heating so as to compensate for the shorter dwell period. The procedure is generally employed with low-alloy or unalloyed steels with mass carbon contents of 0.35 to 0.60 %. However, surface hardening processes can also be applied with alloyed steels, cast iron and rolling-bearing steels. The parts can be heat-treated to provide a combination of improved base strength and high surface hardness, making them suitable for high-stress applications (recessed edges, bearing surfaces, cross-sectional transitions).



Surface hardening generally results in internal compression stresses along the edge. This leads to increased fatigue resistance, especially when notched parts are exposed to inconstant vibration stress. The stress in Figure 2 corresponds to bending stress. The higher stressability results from the fact that the stress state (resulting stress) is reduced from the superposition of bending stress and internal stress.

The relationship defined in equation 1 can be employed to estimate the potential surface hardness. There is a substantial reduction in hardness between the surface and the unhardened core region. The surface hardness depth SHD – the depth at which 80 % of the minimum Vickers surface hardness is found – can be derived from the hardness progression curve (see DIN EN 10328, [16]).

Austempering
The object of this process is to achieve a bainite microstructure. This microstructure is not as hard as martensite, but does display greater ductility, as well as smaller changes in specific volume.

After austenitizing (see hardening), the parts for austempering are first cooled to a temperature of 200 to 350 °C (depending upon the exact composition of the material) at the required rate. The parts are then held at this temperature until the microstructure's transformation into bainite has been completed. Cooling to the transformation temperature is usually performed in molten saline solutions (a typical salt is a mixture of potassium nitrate and sodium nitrite). Following the microstructure transformation the parts can be cooled to room temperature (no special procedure required).

Figure 2: Cyclically alternating stress according to surface-layer hardening
$+\sigma$ Tensile, $-\sigma$ Compressive.
1 Case layer, 2 Bending stress,
3 Reduction of tensile stress,
4 Resulting stress, 5 Internal stress,
6 Increase in compressive stress.

Austempering is an excellent alternative for parts whose geometrical configuration makes them sensitive to distortion or cracks, or in which high ductility is required together with substantial hardness, or which should combine hardness with a low level of residual austenite.

Application
Cylinder heads in modern diesel high-pressure pumps for common-rail systems which must be able to withstand high wear and internal compressive stresses are austempered.

Draw tempering
Draw tempering of hardened components and tools is employed to increase their deformability and to reduce their risk of cracking. According to DIN EN 10052 [8], draw tempering involves heating the part in question once or repeatedly to tempering temperature, holding the part at this temperature, and then allowing it to cool appropriately. Draw tempering is performed between room temperature and Ac_1 temperature, i.e. the temperature at which austenitic structural constituents would be created.

Tempering at temperatures as low as 180 °C is enough to reduce the hardness of unalloyed and low-alloy steels by approx. 1 to 5 HRC. The individual materials respond to higher temperatures with specific characteristic hardness loss. Figure 3 shows a characteristic tempering curve for typical types of steel. This graph illustrates the fact that the hardness of steels which are alloyed with special carbide-forming elements (Mo, V, W) – such as, for example, hot-working or high-speed tool steel – is increased by tempering in a temperature range between 400 and 600 °C to values which can be above the quenching hardness (secondary hardening).

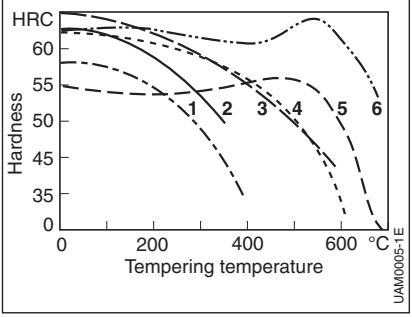
The mutual relationships between tempering temperature on the one side, and hardness, strength, yield point, fracture contraction and elongation at fracture on the other, can be taken from the tempering diagrams for the various steels (see e.g. DIN EN 17021, [17]).

Generally speaking, draw tempering reduces hardness and strength and increases deformability. Internal stresses

can also be reduced at tempering temperatures in excess of 300 °C.

The specific volume decreases when structures which are free of residual austenite are tempered. In the case of structures containing residual austenite, however, an increase in volume occurs during the transformation from residual austenite to martensite. Hardness increases, deformability is reduced, and new internal stresses can be created. The risk of cracking also increases.

It must be remembered that steels alloyed with manganese, chromium and nickel, or combinations of these elements, should not be tempered at temperatures of 350 to 550 °C, as brittleness could result. When these types of materials are cooled from tempering temperatures above 550 °C, the transition through this critical range should also be effected as rapidly as possible (see DIN 17022 Parts 1 and 2, [9] for additional information). This tempering sensitivity can be avoided by adding molybdenum or tungsten by alloying.



Quenching and drawing

Quenching and drawing involves a combination of hardening and tempering at a temperature which is generally between 540 °C and 680 °C. This procedure is designed to achieve an optimal relationship between strength and ductility. It is applied in cases where extreme ductility or malleability is required.

Particular care must be devoted to avoiding brittleness in the quench and draw operation (see above).

Figure 3: Tempering response of various types of steel

1 Unalloyed tempering steel (C45),
2 Unalloyed cold-working tool steel (C80W2),
3 Low-alloy cold-working tool steel (105WCr6),
4 Alloyed cold-working tool steel (X165CrV12),
5 Hot-working tool steel (X40CrMoV51),
6 High-speed tool steel (S6-5-2).

Annealing

Annealing can be applied to optimize certain operational or processing characteristics of parts. With this method, the parts are heated to a specific temperature and maintained there for an adequate period before being cooled to room temperature. The most important annealing processes in terms of technology are described in the following.

Stress-free annealing

Depending on the precise composition of the parts, stress-free annealing is carried out at temperatures ranging from 450 °C to 650 °C. The specific object is to achieve a reduction in internal stress in components, tools and castings.

Recrystallization annealing

Recrystallization annealing is applied with cold-form parts. The goal is to restructure the grain pattern in order to prevent increased hardening, thereby facilitating subsequent machining work.

The temperature requirement depends upon the composition of the material and the degree of deformation: it lies between 550 °C and 730 °C for steel.

Soft annealing and spheroidization

The purpose of soft annealing is to improve the machinability of material states which are difficult to cut or difficult to cold-form. The process involves heating the material in question to temperatures in excess of 600 °C, as briefly as possible above the Ac_1 temperature for the relevant steel, holding at this temperature, and slowly cooling to room temperature.

The temperature requirement is determined by the material's composition. It ranges from 650 °C to 850 °C for steel, and lower for nonferrous materials.

Spheroidization of cementite is applied when a microstructure with a granular

carbide pattern is desired. The cementite loses strength as a result of the annealing temperature and can pursue its striving for a body with as small a surface as possible (of the ball). If the initial structure is martensite or bainite, the result will be an especially homogeneous carbide distribution.

Normalizing
Normalizing is carried out by heating the parts to austenitizing temperature and then allowing them to gradually cool to room temperature. In low-alloy and unalloyed steels, the result is a structure consisting of ferrite and perlite. This process is essentially employed to reduce grain size, reduce the formation of coarse grain patterns in parts with limited reshaping, and to provide maximum homogeneity in the distribution of ferrite and perlite.

Precipitation hardening
This process combines solution treatment with aging at ambient temperature. The parts are heated and then maintained at a temperature to bring precipitated structural constituents into a solid solution, and quenched at room temperature to form a supersaturated solution. The aging process comprises one or several cycles in which the material is heated and held at above-ambient temperatures ("hot aging"). In this process, one or several phases, i.e. metallic bonds between certain base alloys, are formed and precipitated in the matrix.

The precipitated particles enhance the hardness and strength of the base microstructure. The actual characteristics are determined by the temperature and duration of the aging process (option of mutual substitution). Exceeding a certain maximum will usually reduce the strength and hardness of the final product.

Precipitation hardening is mostly applied for nonferrous alloys, but some hardenable steels (maraging steels) can also be processed.

Application
Steels which can be precipitation-hardened are used for example in rail-pressure sensors in common-rail systems.

Thermochemical treatment

In thermochemical treatment, the exchange of substances with suitable agents effects a change in the chemical composition of the base material. Specific function properties can be adapted by the diffusion of specific elements into the surface layer. Of particular importance for this process are the elements carbon, nitrogen and boron.

Carburizing, carbonitriding and case hardening

Carburizing increases the carbon content in the surface layer, while carbonitriding supplements the carbon enrichment with nitrogen. This process usually takes place at temperatures ranging from 750 to 1,050 °C in gases which give off carbon or nitrogen as a result of their disintegration by heat or excited in the plasma. The actual hardening is performed subsequently, either by quenching directly from the carburizing or carbonitriding temperature (direct hardening), or by allowing the parts to cool to room temperature (single hardening), or by allowing them to cool to a suitable intermediate temperature (e.g. 620 °C) prior to reheating (hardening after isothermic conversion). This process produces a martensitic surface layer, while the degree of martensite at the core is a function of hardening temperature, hardenability and part thickness.

Specific temperatures can be selected for either surface hardening in the upper layers with higher carbon content (case refining), or for the non-carburized core (core refining) (see DIN 17022 Part 3, [9]). Carburizing and carbonitriding produce a characteristic carbon declivity, with levels dropping as the distance from the surface increases (carbon curve). The distance between the surface and the point at which the mass carbon content is still 0.35 % is normally defined as the carburization depth.

The length of the carburizing or carbonitriding process depends upon the required carburization depth, the temperature and the atmosphere's carbon-diffusion properties.

Typical surface carbon contents during case hardening range between 0.5 and 0.85 % carbon by mass in order to achieve sufficient surface hardness. The carbon concentration essentially determines the surface hardness.

Excessive concentrations of carbon can lead to residual austenite or carbide diffusion, which could have negative effects on the performance of case-hardened parts in actual use. Control of the atmosphere's carbon level is thus extremely important in process management.

The most common carburizing processes used today are gas carburizing and vacuum carburizing. In the case of gas carburizing, the carbon level of the furnace atmosphere is regulated in such a way that the surface layer of the workpiece assumes the desired carbon content. A state of equilibrium is established with the surrounding furnace atmosphere. In the case of vacuum carburizing, on the other hand, the carbon content cannot be regulated. Here, the defined surface carbon content is adjusted by means of multistage carburizing. In a first stage, carburizing is performed to a very high surface carbon content in the range of material saturation. In the subsequent stage, this high carbon content is reduced by diffusion to the desired level. In practice, vacuum-carburizing processes consist of several consecutive carburizing and diffusion stages.

The gradient defining the relationship between hardness and depth corresponds to the carbon concentration curve. The case-hardening depth CHD can be taken from this. DIN EN ISO 2639 [18] defines this as the vertical distance to the surface to the layer which has a Vickers hardness of 550 HV 1.

The case-hardened part generally exhibits compression tension at the surface, and tensile stresses at the core. As with surface-hardened materials, this distribution pattern provides enhanced resistance to vibration loads.

In carbonitriding, nitrogen is also absorbed; it serves to improve the material's tempering properties, increase its durability and enhance its wear resistance. The positive effects are especially pronounced with unalloyed steels.

For additional, more detailed information on case hardening procedures, consult DIN 17022 Part 3 [9], and Information

Sheet 452 of the Steel Information Center, Düsseldorf [19].

Application
Injection nozzles subject to wear for Bosch common-rail systems which must be able to withstand high wear and internal compressive stresses are case-hardened by vacuum carburizing.

Nitriding and nitrocarburizing
Nitriding is a thermal treatment process (temperature range: 400 to 600 °C) which can be used to enrich the surface layer of virtually any ferrous material with nitrogen. In nitrocarburizing, a certain amount of carbon is diffused into the material to form nitrogen at the same time.

Molecular nitrogen, as is present in this temperature range in gaseous nitrogen, cannot diffuse into metallic materials. It is therefore necessary to offer diffusible nitrogen via suitable donor media. In practical applications, nitriding and nitrocarburizing processes are performed in gas atmospheres containing ammonia, in plasma containing nitrogen, or even in molten saline solutions containing cyanate. While ammonia gas releases diffusible nitrogen during its thermal disintegration, nitrogen is ionized in the plasma in order to split the molecules and facilitate the diffusion of nitrogen atoms.

The enriching nitrogen in the surface layer causes the precipitation of nitrides, in response to which the surface layer hardens. In the final analysis, this results in greater resistance to wear and corrosion, and in greater endurance strength.

As the process employs relatively low temperatures, there are no volumetric changes of the kind associated with transformations in the microstructure, so that changes in dimensions and shape are minute.

The nitrided region consists of an outer layer, several millimeters in depth, and a transitional white layer, the hardness of which may be anywhere from 700 HV to over 1,200 HV, depending on the composition of the material. Still deeper is a softer diffusion coating extending several tenths of a millimeter in which the nitrogen content decreases as the distance from the surface increases. The thickness of the individual layers is determined by the temperature and duration of the treatment process. The process produces a hardness gradient (similar to that which results from surface and case hardening); this gradient furnishes the basis for determining the nitriding hardness depth NHD. DIN 50190 Part 3 [20] defines this as the vertical distance from the surface to the point where the hardness corresponds to a defined limit. This limit hardness is usually actual core hardness + 50 HV 0.5.

The material's resistance to wear is essentially determined by the white layer, which contains up to 10 mass components of nitrogen in %. The nitriding hardness depth and the surface hardness determine the material's resistance to alternating cyclic stress (for additional details, see DIN 17022 Part 4, [9], and Information Sheet 447 from the Steel Information Center, Düsseldorf, [21]).

The corrosion resistance of nitrided or nitrocarburized workpieces can be significantly increased by postoxidation in water vapor or other suitable gases, or in molten saline solutions at temperatures ranging between 350 °C and 550 °C.

Application
Injection nozzles which are used, for example, in Bosch common-rail systems and which must be able to withstand extreme operating temperatures are gas-nitrided.

Components for windshield and rear-window wiper systems are nitrocarburized and postoxidized to increase their resistance to corrosion and wear. This is how these components get their typical black color.

Boron treatment
Boron treatment involves enriching the surface layer of ferrous materials with boron. Depending upon duration and temperature (normally 850 to 1,000 °C) of the treatment, a white layer of 30 µm to 0.2 mm in depth with a hardness of 2,000 to 2,500 HV is produced. It consists of iron-boron.

Boron treatment is particularly effective as a means of protecting against abrasive wear. However, the comparatively high process temperature leads to relatively

large changes in shape and dimensions, meaning that this treatment is only suitable for applications in which large tolerances can be accepted.

Application
Partly boron-treated tool holders with high wear resistance are used in Bosch hammer drills.

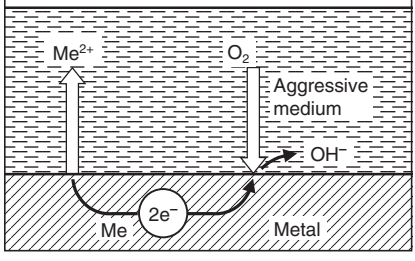
Corrosion and corrosion protection

Corrosion processes

Corrosion is the damage to a metal as a result of a reaction with substances in the environment. Corrosion processes always contain interphase reactions. An example of this type of reaction is metal scaling, i.e. oxidation in hot gases. As it proceeds, metal atoms oxidize to form nonmetallic compounds in a process emanating from the affected material's surface. In thermodynamic terms, the process can be viewed as an entropic transition from an ordered, high-energy state into a less-ordered state of lower energy, and consequently greater stability. The process takes place of its own accord.

The following deals exclusively with the corrosion that occurs at the phase boundary between the metal and aqueous phases (electrolyte), generally referred to as electrochemical corrosion.

Corrosive attack



Anodic subprocess

Two essentially distinct reactions occur in electrochemical corrosion: in the anodic subprocess, the directly visible corrosion process, the metal passes into the oxidized state as described in the reaction equation

$$Me \rightarrow Me^{n+} + n\ e^-$$

freeing an equivalent number of electrons (Figure 1). The metal ions thus formed can either be dissolved in the electrolyte, or can precipitate out on the metal as corrosion products (e.g. rust) after reacting with constituents in the attacking medium [1].

Figure 1: Free corrosion at the metal/corrosive-medium phase boundary.
In an aggressive medium (neutral or alkaline) oxygen is reduced at the corroding metal. Corrosion products are formed simultaneously.

Cathodic counter-reactions

This anodic subprocess can continue only as long as the electrons it produces are consumed in a second process. This second subprocess is a cathodic subreaction. In neutral or alkaline media oxygen is reduced in accordance with

$$O_2 + 2\ H_2O + 4\ e^- \rightarrow 4\ OH^-$$

to hydroxyl ions, which in turn are able to react with the metal ions. In acidic media the hydrogen ions are reduced via the formation of free hydrogen, which escapes as a gas according to the following formula:

$$2\ H^+ + 2\ e^- \rightarrow H_2\ .$$

Electrochemical series of metals

Metals are often ranked in "electrochemical series of metals" corresponding to consecutively higher standard potentials (see also Electrochemistry). As the value of standard potential increases the metals are referred to as "more noble", and as the value decreases as "more base".

It should be emphasized that the table ("Standard electric potentials of metals") is limited to thermodynamic values, and does not reflect the effects of corrosion kinetics, for example as encountered in the formation of protective layers. Most corrosion-resistant structural materials, however, develop protective layers, which are crucial to corrosion resistance. Thus, for example the materials aluminum, zinc and titanium seem to be very base metals, but are highly resistant due to the formation of protective layers. The formation of protective layers is exploited in the field of electrochemical corrosion protection.

Types of corrosion

General surface corrosion
General surface corrosion is a type of corrosion with uniform attrition of material over the entire boundary surface between the material and the attacking medium. This is a very frequent type of corrosion in which the material penetration rate (removal depth) can be calculated per unit of time based on the corrosion current.

Pitting corrosion
Pitting corrosion is a limited localized attack by a corrosive medium which penetrates the material by forming holes, or pits, whose depth is almost always greater than their diameter. Practically no material is removed from the surface outside the pitted areas. Pitting corrosion is frequently caused by chloride ions (e.g. from table salt).

Contact corrosion
When two different metals moistened by the same medium are in mutual electrical contact, a cathodic subprocess occurs at the more noble metal, while the anodic subprocess progresses at the baser material. This is called contact corrosion.

Crevice corrosion
Crevice corrosion is a corrosive attack primarily occurring in narrow crevices, caused by concentration differences in the corrosive medium, e.g. as a result of long oxygen diffusion paths. This type of corrosion generates potential differences between the crevice extremities, leading to intensified corrosion in more poorly ventilated areas.

Stress corrosion cracking
This is corrosion stemming from the simultaneous concerted action of a corrosive medium and mechanical tensile stress (which can also be present as internal stress in the object itself). Intergranular or transgranular fissures form, in many cases without the appearance of visible corrosion products.

Vibration corrosion cracking
Vibration corrosion cracking is corrosion caused by the simultaneous effects of a corrosive medium and mechanical fatigue stress, e.g. caused by vibrations. Transgranular cracks are formed, frequently without visible deformations.

Intergranular and transgranular corrosion
This involves types of corrosion characterized by selective formation along the grain boundaries or roughly parallel to the deformation plane in the grain interior.

Dezincification
Selective dissolution of zinc from brass, leaving behind a porous copper structure.

Corrosion testing

Electrochemical testing procedures
The primary tool for electrochemical corrosion testing is the potentiostat. Here metals or other electrically conductive materials are analyzed in different corrosive media. The typical setup with three electrodes is shown in Figure 2. This arrangement is essentially used to determine – as well as the corrosion potentials of the corroding materials – primarily the corrosion currents. In the case of uniform surface corrosion, the corrosion-current parameters are then used for the definition of the attrition mass and removal depth per unit of time.

The electrochemical testing procedures are a valuable supplement to the non-electrochemical methods, because they provide an understanding of corrosion mechanisms that occur. In addition to the small amount of corrosive medium required, another advantage of electrochemical procedures over non-electrochemical methods is that they provide quantitative data on attrition rates.

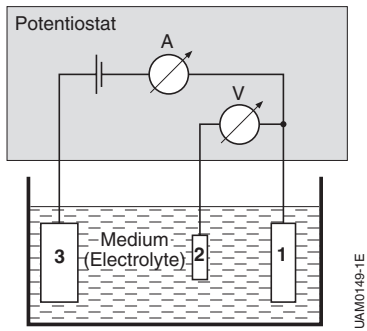
The potentiostat is used to alter the potential of the material to be analyzed and measure the flowing current. Evaluation enables reaction mechanisms and above all corrosion current densities to be determined.

Polarization-resistance measurement
In the case of free corrosion the corrosion current is determined from the polarization resistance (slope of the cumulative current-density/potential curve); testing entails subjecting the metal to minimal, alternating anodic and cathodic pulses.

Impedance spectroscopy
Electrochemical Impedance Spectroscopy (EIS) is employed to examine corrosion mechanisms. This alternating-current technique determines the AC resistance (impedance) of an electrochemical test object as a function of frequency. A low-amplitude sinusoidal alternating voltage is superimposed on the working electrode's potential, and the current response is measured. To interpret the measurement the system is approximated in the form of an equivalent network. By way of example, Figure 3 shows the equivalent network for the system, consisting of metal, coating, and medium.

Impedance elements (resistances, capacitances, inductances) are assigned to the sequences (e.g. electron transfer) at the phase boundary. In this simple example from Figure 3 the coating is – along similar lines to the phase boundary of material to corrosive medium – described as capacitor and resistor.

Figure 2: Schematic setup for measuring the current density/potential curves with a potentiostat
1 Working electrode,
2 Reference electrode,
3 Counter-electrode.



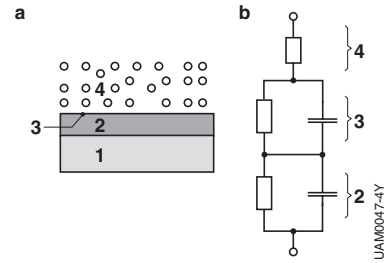


Figure 3: Evaluation of EIS data (electrochemical impedance spectroscopy)
a) Arrangement,
b) Equivalent network.
1 Metal,
2 Coating,
3 Phase boundary metal to medium,
4 Corrosive medium.

Direct conclusions can then be drawn from the equivalent networks and the impedance elements about various characteristics, such as the effectiveness of corrosion-protection measures, porosity, thickness, a coating's water-absorption ability, the effectiveness of inhibitors, the corrosion rate of the base metal, and so on.

Contact-corrosion current measurement
When contact corrosion is measured the two affected metals are immersed in the same corrosive medium. During measurement they are not directly contacted, but instead connected via the potentiostat. Here the contact-corrosion potential and the contact-corrosion current flowing between the two metals are directly measured and the curve plotted against the measurement period.

Non-electrochemical corrosion-testing procedures
In non-electrochemical testing procedures test specimens essentially are first exposed to a corrosive environment (exposure tests) and then the change in the test specimens is assessed.

Simple standard tests (e.g. corrosion load by neutral salt spray fog testing) are conducted with the aim of testing quality or comparing corrosion-protection measures and materials. The emphasis is placed on using tests that can uncover weak points in corrosion-protection measures and describe different qualities.

After corrosion load is completed, it is possible by comparing images in accordance with DIN EN ISO 4628-3 [2] to assign rust levels (degrees of rusting) which are defined according to rust coverage or surface perforation (Table 1).

Table 1: Rust level and rust surface acc. to DIN EN ISO 4628-3

Rust level	Rust surface in %
R_i0	0
R_i1	0.05
R_i2	0.5
R_i3	1
R_i4	8
R_i5	40...50

For the purpose of service-life assessment, testing procedures have evolved to reflect specific requirements, e.g. motor-vehicle testing. These are as a rule corrosion loads with cyclically alternating loading by salt spray fog, dry phase and moist phase. These tests provide reliable indices of projected service life under normal operating conditions by using short-term exposure in extremely harsh conditions to simulate long-term stresses in the real world (e.g. testing in accordance with Bosch standard N42AP 226 “Climatic tests – Tightened life – Corrosion testing”).

For a further adaptation of corrosion load to practical operation products are operated under tightened conditions (e.g. vehicle tests of the different automobile manufacturers).

In addition to the corrosion loads for life testing the focus is on assessing the function of the products.

Corrosion protection

The manifestations and mechanisms of corrosion are many and varied, so widely differing methods can be adopted to protect metals against corrosion attack. Corrosion protection means intervening in the corrosive process with the object of reducing the rate of corrosion in order to prolong the service life of the components.

Corrosion protection can be achieved by applying four basic principles:

– Measures in planning and design: the choice of suitable materials and the suitable structural design of components.
– Measures that intervene in the corrosive process by electrochemical means.
– Measures that separate the metal from the corrosive medium by protective layers or coatings.
– Measures that influence the corrosive medium, for example, the addition of inhibitors to the medium.

Corrosion protection by means of suitable structural design

Material selection

Selecting suitable materials which feature optimum resistance to corrosion under the expected conditions can be of considerable assistance in avoiding corrosion damage. When the costs that would otherwise be incurred for upkeep and repair are factored into the long-term cost of ownership equation, a more expensive material can often be the more cost-effective alternative.

Design

Design measures, too, are of major importance. A great deal of skill and expertise goes into design, particularly regarding the connections between parts that are made of the same material or different materials.

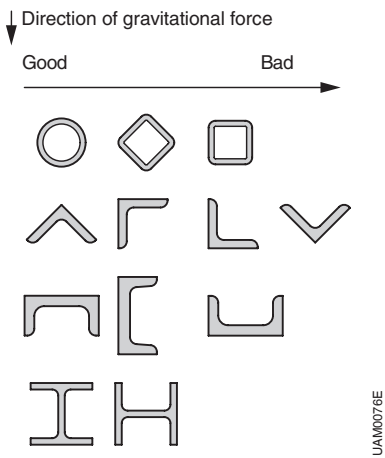
Corners and edges of sections are difficult to protect, and this is where corrosion can easily attack. A favorable installation position can avoid corrosion (Figure 4).

Beads and welts can trap dirt and moisture. Suitable surfaces and drain openings can help avoid this problem (Figure 5).

In the case of welds the structure is altered in a detrimental way. In order to avoid crevice corrosion, welds have to be smooth and free of gaps (Figure 6).

Contact corrosion can be avoided by joining same or similar metals, or by installing washers, spacers, or sleeves to ensure that both metals are electrically insulated (Figure 7).

Figure 4: Good and bad installation positions for profile sections



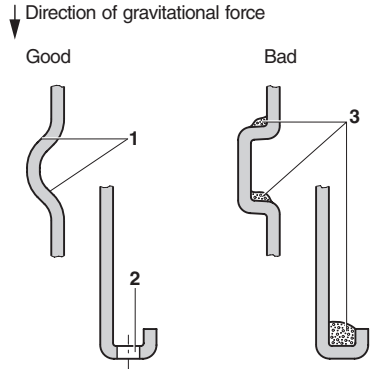


Figure 5: Design of beads and welts

1 Sloping faces (foreign matters slide off),
2 Wide gap with drain,
3 Deposits of dirt and moisture.

Electrochemical processes
The schematic current-density/potential curves for a metal suitable for passivation coating (e.g. by oxide layer on stainless steel) show how these processes work (Figure 8). The current-density values arranged in ascending order on the y-axis represent anodic currents corresponding to the corrosion reaction defined in the equation

$Me \rightarrow Me^{n+} + n\ e^{-}$.

In contrast, the descending current-density values represent cathodic currents.

As can be seen from the diagram, corrosion only occurs when potentials $E_a \leq E \leq E_p$ and $E \geq E_d$. Therefore corrosion can be suppressed by applying an external voltage. There are two basic ways of doing this.

Cathodic protection
For cathodic protection, the potential is shifted so far toward the left that no anodic currents flow, leading to $E < E_a$. As an alternative to applying voltage from an external source, it is also possible to shift the potential by contacting a base metal to act as a "sacrificial" reactive anode.

Anodic protection
Another option is, by applying an external voltage, to shift the potential of the threatened electrode into the passive range, i.e. into the potential range between E_p and

Figure 6: Design-related crevices in welds and how they can be avoided

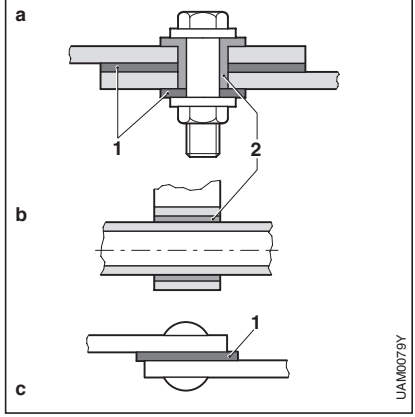

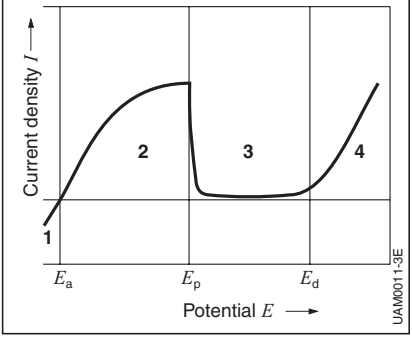

Figure 8: Schematic curve of current density as a function of the potential for a metal which can be passivated
1 Cathodic protection, occurs when $E < E_a$,
2 Corrosion without protection,
3 Anodic protection, occurs when $E_p < E < E_d$,
4 Transpassive range.
E_a Free corrosion potential of the metal in an active state,
E_p Passivating potential,
E_d Breakthrough potential.

E_d. This is called anodic protection. The anodic currents, which flow in the passive range, are less than those in the active range by exponential powers of between three and six, depending on the type of metal and the corrosive medium. The result is excellent protection for the metal.

However, the potential should not exceed E_d, as oxygen would be produced in this transpassive range, potentially leading to higher rates of oxidation. Both of these effects would cause the current to increase.

Coatings

Coatings inhibit corrosion by forming protective films which are applied to the surface of the metal to be protected, where they resist attack by the corrosive medium (see also Deposits and coatings).

Inhibitors

Inhibitors are substances added to the corrosive medium in low concentrations (up to a maximum of several hundred ppm) for absorption at the surface of the protected metal. They drastically reduce the rate of corrosion by blocking either the anodic or the cathodic subprocess (frequently blocking both subprocesses simultaneously). Organic amines and amides of organic acids are the most frequent inhibitors. In automotive applications, for example, inhibitors are used in fuel additives. They are also added to antifreeze in order to inhibit corrosion damage in the coolant circuit.

Vapor-phase inhibitors

Vapor-phase inhibitors (VPI), or volatile corrosion inhibitors (VCI), are organic substances of moderate vapor pressure. They are frequently enclosed in special-purpose packing materials or as solvents in liquids or emulsions with oil. The inhibitors evaporate or sublimate over the course of time, and are adsorbed as monomolecules on the metal, where they inhibit (i.e. slow down or stop) either anodic or cathodic corrosion subreactions, or both at once. Dicyclohexylamin nitrite is a typical example.

For optimal effectiveness, the inhibitor should form a sealed coating extending over the largest possible surface area. Standard commercial vapor-phase inhibitors are generally a combination of numerous components capable of providing simultaneous protection for several metals or alloys; exceptions: cadmium, lead, tungsten and magnesium.

Vapor-phase inhibitors provide only temporary protection for metallic products during storage and shipping. They must be easy to apply and remove. The drawback of vapor-phase inhibitors is that they are potentially injurious to health.

Deposits and coatings

Deposits and coatings are used to adapt the surface properties of components to particular requirements ("surface engineering", Table 1). It is thus possible, for example, for a component to be made from a tough, low-cost material which still has a hard and wear-resistant surface. The main applications for deposits and coatings are

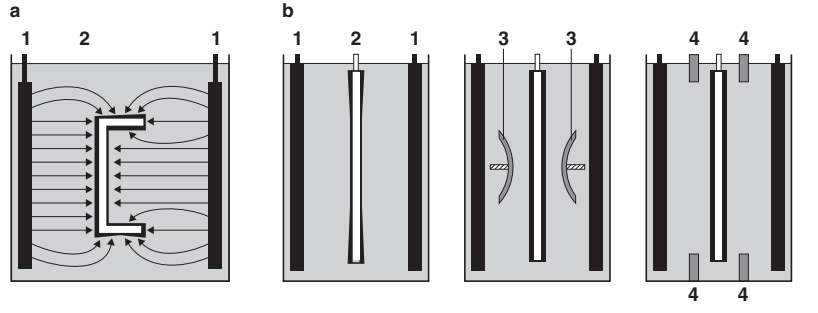
– Corrosion protection (as well as functional retention, often for decorative reasons)
– Wear protection
– Joining and bonding techniques (plug-in, welded, soldered, bonded, and crimped contacts).

In coating systems, distinctions are made between the following types of coating:

– Deposits in which one layer is applied
– Conversion coatings in which the functional coating is produced by chemical or electrochemical conversion of the base material, and
– Diffusion coatings in which the functional coating is produced by diffusion of atoms or ions into the base material.

Deposits

Electrodeposits



Electrodeposits are deposited using an external power source. The workpieces to be coated are immersed into an electrolyte (Figure 1) which contains ions of the metal to be deposited. The metal ions consumed during the deposition process are either supplied by the anode solution or added to the electrolyte (when inert anodes are used). The progression and distribution of the field lines influence the liner-thickness distribution. A uniform layer thickness can be achieved by means of an optimized configuration of anodes and screens.

Electrodeposits are widely used in corrosion protection, in wear protection and for electrical contacts. Some important deposits are described below.

Zinc and zinc alloys

Electrolytically deposited zinc coatings are widely used as corrosion protection for steel components and are a cathodically effective means of corrosion protection (sacrificial effect). To increase the corrosion-protection effect, zinc deposits are passivated in a chrome(VI)-free solution. Zinc alloys, such as zinc-nickel with

approx. 15 % nickel offer a significantly higher degree of corrosion protection.

Nickel
Electrolytically deposited nickel coatings offer limited corrosion protection with an attractive visual appearance. One area of automotive engineering in which this is chiefly used is the nickel-plating of spark-plug shells.

Chrome
In the case of chrome deposits, a distinction is made between hard chrome and bright chrome. Bright chrome is used as a deposit approx. 0.3 µm thick with a nickel or copper/nickel intermediate deposit. In the past, bumpers and molding strips were provided with bright-chrome deposits for decorative reasons. Decorative chrome deposits have become an important element in vehicle design.

Hard-chrome deposits are chrome deposits with a thickness greater than 2 µm. Owing to the high level of hardness of the electrolytically deposited chrome coating, it is ideally suited for use as a wear-protection coating. In the past, hard-chrome deposits were often applied in strong thicknesses and then mechanically reworked. Due to further developments in process engineering, components today are increasingly custom-coated with coating thicknesses ranging from 5 to 10 µm, and then used without reworking (e.g. components for fuel injectors).

Tin
Electrolytically deposited tin coatings are mainly used as contact surfaces for plug-in and switch contacts, and as solder contact surfaces. A coating thickness of 2 to 3 µm is ideal for plug-in contacts. Greater coating thicknesses are required for solder applications in order to ensure solderability even after extended storage periods.

Gold
Gold deposits are normally used for contacts subject to stringent requirements. They are characterized by good conductivity, low contact resistance, and good resistance to corrosion and pollutant gases. This ensures contact stability. Hard-gold deposits (with approx. 0.5 % alloying constituents, predominantly cobalt) are harder and more abrasion-resistant than pure-gold deposits and are suitable for contacts subject to mechanical load.

Chemically deposited coatings (no external current)
In contrast to electrodeposits, chemically deposited coatings are characterized by a more uniform coating-thickness distribution on the component, since deposition in a coating bath does not occur under

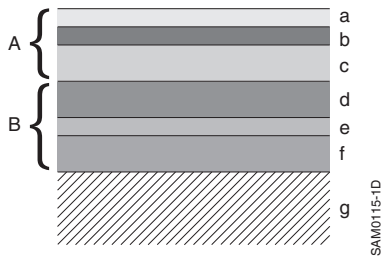
Table 1: Areas of application for coatings

Coating system	Coating material	Main application
Electrodeposits	Zn, ZnNi, Ni Cr Sn, Ag, Au	Corrosion protection Wear protection Decorative Electrical contacts
Chemical deposits	NiP, NiP dispersions Cu, Sn, Pd, Au	Wear and corrosion protection Electronic applications
Hot-immersion deposits	Zn, Al Sn	Corrosion protection Electrical contacts
Paints (wet and powder-based paints)	Organic polymers Pigments (color particles)	(Decorative) corrosion protection Wear reduction Electrical insulation
PVD and CVD coatings (plasma technology)	TiN, TiCN, TiAlN DLC i-C(WC), a-C:H	Wear protection of tools Reduction of friction and wear of components

the influence of an external electric field. Owing to the slow deposition rate and the costly chemicals in the coating bath, they are more expensive than electroplated liners. The following have become widespread in industry:

– "Chemical nickel" (nickel-phosphorus, NiP) as a corrosion- and wear-protection deposit, used for example in electric fuel pumps or in high-pressure pumps for gasoline direct injection.
– "Chemical copper" and "Chemical tin" in printed-board technology.

Hot-immersion deposits



Hot-immersion coatings are deposited by immersing the substrates in a molten metal bath. Cathodically effective hot-immersion deposits are used to protect low-alloyed steels against corrosion. Zinc, zinc/aluminum alloys and aluminum are used. Coating start material such as sheet and strip is a cheap and widely used practice. However, free punch edges must be accepted here.

Tin and tin-alloy coatings deposited in hot-immersion priming are primarily used as surfaces for plug connectors and as soldering surfaces.

Zinc-lamella deposits

Zinc-lamella deposits are coatings based on zinc and aluminum lamellas in an inorganic binder. They are applied by immersion centrifuging or electrostatic spraying and thermal hardening. Zinc-lamella deposits are low-cost corrosion-protection coatings for mass-produced steel parts (e.g. screws/bolts).

Paints

Paints have a wide variation range because of their broad chemical bases and numerous means of application, such as brushing, spraying, and immersing, even with the use of current (CD: cathodic deposition).

Paint coatings can also fulfill a multitude of different functions. In motor vehicles, the primary function fulfilled by paint coatings is corrosion protection accompanied by a decorative effect, but other functions include wear protection, soundproofing or electrical insulation.

The very high demands imposed on corrosion protection and visual appearance over the service life of a vehicle are guaranteed by a complex, elaborate layered structure (Figure 2 and Table 2). The assemblies in the engine compartment, on the other hand, are usually only given one or two coats of paint. Less importance is placed here on decorative properties.

Low-solvent systems, above all water-based paints, are almost always used in automotive engineering. Where possible, powder-based paints and UV-hardening paints which are completely solvent-free are used.

Table 2: Structure of solid-color and metallic coatings

Layer	Layer thickness	Structure	Composition

PVD and CVD coatings
PVD and CVD coating systems are generally deposited in a vacuum supported by plasma or heat treatment on components and tools (Figure 3). There are two different procedures, depending on whether the coating-forming material is obtained from the solid (PVD, physical vapor deposition) or gaseous (CVD, chemical vapor deposition) phase. Most modern procedures combine the two categories.

Hard-material coatings
Tools are coated with hard material to increase their service life and their performance. A typical example of the tool coatings widely introduced onto the market is the gold-colored titanium nitride (TiN), which is produced, for example, by the cathodic sputtering or arc evaporation of titanium in a reaction with nitrogen. More recent coating systems, such as titanium carbonitride (TiCN) or titanium aluminum nitride (TiAlN), can be used for high-speed cutting or for dry machining.

○ Argon,
● Metal/carbon,
● Nitrogen/hydrogen.

Superhard materials, such as diamond, are increasingly used to coat carbide tools.

DLC coatings
Protecting components against wear is subject to special conditions. Here, the coating should establish a low coefficient of friction for the components that come into contact with and move relative to each other and minimize the wear for the entire layout. DLC (diamond-like carbon) coatings protect not only the coated component against wear, but also the uncoated opposed body. They have a very low coefficient of friction of 0.1 to 0.2, both in a dry friction pairing against steel and under media. DLC layers are media-resistant and have a corrosion-inhibiting effect. Due to these advantages, DLC coatings are very important in the field of coating components. However, it must be noted that coatings containing hydrogen will degrade in an oxidizing atmosphere at a local temperature of 350 °C and higher. Hard-material coatings, such as TiN, can withstand considerably higher temperatures and are also used in component coating.

Different coating compositions and processes allow materials to be adapted to different wear loads or combinations of abrasive, vibration, sliding, seizure, and adhesive wear. The term DLC therefore describes not a layer but a class of materials within which there exists a multitude of coating variants with all manner of properties and with manufacturer-specific nomenclature.

Plasma-assisted PVD and CVD processes are conducted in such a way that the tempering temperature of the component is not exceeded during coating. This avoids impairing the hardness of the steel base material.
Low-friction carbon coatings containing metal carbide i-C(WC) are electrically conductive and have a microhardness of approx. 1,800 HV at a modulus of elasticity of 150 to 200 GPa.

In comparison, metal-free carbon coatings (a-C:H) offer increased hardness of approx. 3,500 HV and significantly improved wear resistance, but this is ac-

companied by an increase in brittleness. They are electrically insulating.

The greatest coating hardness and wear resistance for DLC coatings is currently achieved with metal- and hydrogen-free ta-C (tetrahedral amorphous carbon). For all DLC coatings, in view of their high internal compression stress, it is important to ensure a stable connection to the substrate, which is achieved for the most part with a metallic adhesive coating system.

With thicknesses of 2 to 4 µm, diamond-like carbon coatings offer very good wear protection and are especially suitable for precision components subject to high mechanical loads. There is no rework needed after coating.

Thermal spray-coating
In thermal spraying metals or alloys are melted thermally or in a plasma flame and sprayed onto the surface to be coated. There are a multitude of ways in which the procedure is modified in which ceramic surfaces can be created as well as metallic coatings. By choosing the relevant procedure, it is possible to create tightly sealed coatings for example for wear or corrosion protection or porous, permeable coating systems.

Coatings

Diffusion coatings
Surface treatment can be selectively combined with surface hardening by using the diffusion process to thermochemically carburize, carbonitride, or chromate the metal, or treat it with boron or vanadium (see Heat treatment of metallic materials, Thermochemical treatment). The metal can also be oxidized, nitrided, or sulfided without hardening.

Conversion coatings
Conversion coatings are formed not exclusively by the application of a material, but by in part the chemical or electrochemical conversion of the base material.

Browning coatings
Browning coatings consist of thin iron-oxide layers (predominantly Fe_3O_4) which are formed by the oxidation of the iron in steel in an alkaline, aqueous solution containing nitrite at temperatures greater than 100 °C. With subsequent oiling, they offer temporary corrosion protection for low-alloy steels.

Phosphating coatings
Phosphating coatings are formed on steel, galvanized steel, and aluminum in solutions containing phosphoric acid by immersion or spraying. Zinc-phosphate coatings are predominantly used as a wash primer for paint coatings or in combination with anti-corrosion oil. Manganese phosphate serves as a wear-protection coating with anti-seizure properties, and as a wash primer for other coatings to improve component antifriction properties.

Anodized coatings
Anodized coatings are formed by the electrochemical conversion of metal into metal oxide in aqueous electrolytes. Aluminum, magnesium, and titanium can be anodized. Anodized coatings on aluminum materials are widely used for corrosion and wear protection.

Tolerances

Form deviations

No component can be manufactured with absolute precision, i.e. with an ideal geometry. A whole range of causes is responsible for this, e.g., deformations as a result of machining forces, the play in guides of machine tools, tool wear, vibrations, and much more. The consequence of this is that every component exhibits dimensional, geometrical and surface deviations. To guarantee the function it is necessary that all the permissible deviations be indicated in the drawing.

Dimensional deviations
Each dimension can only be manufactured between an upper and a lower limit dimension. The difference between these two limits is called the dimensional tolerance.

Geometrical deviations
Geometries also exhibit deviations from the ideal geometry. A distinction is made between form and positional deviations.

Surface deviations
The surface of a workpiece likewise cannot be manufactured to the ideal smoothness levels. The description of the surface texture can be specified with the aid of the primary, waviness and roughness profiles.

Geometrical Product Specifications

Geometrical Product Specifications (GPS) refers to all the indications in a CAD model or a drawing which are required to manufacture and check (verify) a product. Product specifications must be carried out in such a way that the component to be manufactured performs its function without limitations.

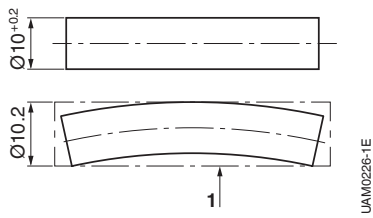
The aim of Geometrical Product Specifications is to provide a clear and complete description of the product in accordance with standardized rules. These rules are laid down in the form of GPS standards. In addition, the design intent, i.e. what is important for the function, must be apparent from a drawing.

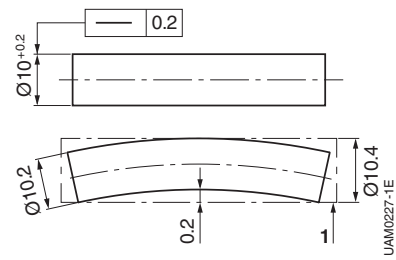
Important standards which are important for the correct interpretation of tolerances are set out in ISO 8015 [1]. These include among others the standard tolerancing principle.

Tolerancing principles
The relationship between the dimensional and geometrical tolerances is defined by the tolerancing principle. According to GPS there are two possibilities for this.

1. The envelope principle
Until 1985 no tolerancing principle was indicated on drawings, but was instead interpreted according to the Taylor principle. This corresponds to the envelope requirement at which the maximum

Figure 1: Envelope requirement
1 Envelope with maximum material size.





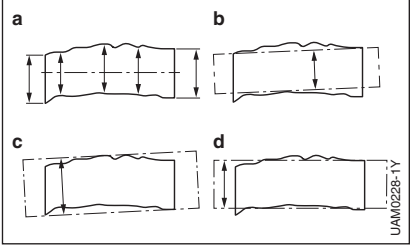


Figure 2: Independence principle
1 Envelope with maximum material virtual size.

material size forms an ideal envelope (Figure 1). All dimensional, form and parallelism deviations must be within this envelope. This requirements can be applied to cylinders and parallel, opposing surfaces. The envelope requirement was described in 1987 in DIN 7167 [2] and established this principle as standard if nothing different was indicated in the drawing.

2. The independence principle
In 1985 ISO 8015 defined the independence principle for the first time. According to this, dimensional and geometrical tolerances are independent of each other. Adding the two tolerances produces an envelope with a maximum material virtual size (Figure 2). The entry "Tolerancing acc. to ISO 8015" is absolutely necessary for drawings to which the independence principle should apply. This principle has been the GPS standard since 2012 (after DIN 7167 was withdrawn) and is also valid without a corresponding entry in the drawing. If the envelope requirement is to apply to an individual dimension element, an Ⓔ must be entered after the dimension. The independence principle can be canceled with the drawing entry "Dimensions acc. to ISO 14405 Ⓔ". In this case the envelope requirement applies to the entire drawing.

Figure 3: Dimensions acc. to ISO 14405
a) Two-point dimension (local point) LP,
b) Maximum inscribed dimension GX,
c) Minimum circumscribed dimension GN,
d) Averaged dimension (acc. to Gauss) GG.

Dimensional tolerances
Dimension definition
Although dimensions are as old as the technical era, dimension characteristics were defined for the first time in 2010 in ISO 14405 [3]. According to this, different dimension characteristics can be assigned to a dimension element, e.g., a cylinder, by indicating the corresponding modification symbol after the dimension. Four different dimension characteristics and the associated modification symbols are indicated in Figure 3. The two-point dimension (local point) does not have to be indicated since without drawing indication all the dimensions have to be measured accordingly (GPS standard).

ISO tolerance system
A special tolerance system has been defined for the pairing of two dimension elements in ISO 286 [4]. It applies to cylinders (cylindrical fits) and two parallel, opposing surfaces (flat fits). A special example of this is given in the chapter "Roller bearings" for bearing seats (see Roller bearings).

The tolerance class is identified by a combination of letters and code numbers. Capital letters are used for bores, lower-case letters for shafts. In this way the fundamental deviation, which indicates the position of the tolerance interval relative to the zero line, is defined (Figure 4). The code number (01 through 18) defines the fundamental tolerance degree (size of the tolerance). Both the fundamental deviation and the tolerance degree are indicated in ISO 286 in tables.

All combinations from A through z and from a through Z and all code numbers from 01 through 18 are possible as fits (e.g., $30^{H7}/30_{e6}$). Clearance, transition and interference fits can be defined in this way. To limit the multitude of possible fits, only bores with the fundamental deviation zero (code number H) are paired with different shaft tolerances. This produces the system of fits "Unit bore" (Figure 5). This is used whenever expensive tools (e.g., reamer) are used to produce bores. ISO 286 also defines a system of fits "Unit shaft". Only shafts with the fundamental deviation zero (code number h) are used. Clearance, transition and inter-

ference fits can be achieved with these combinations.

Geometrical tolerances

Since a two-point dimension cannot define geometry properties, it additionally requires an indication with regard to the permissible form or positional deviations.

A form tolerance only defines how far the real form may deviate from the ideal form and therefore requires no reference. A surface must for example be flat within a specified tolerance, regardless of the position of this surface.

Positional tolerances limit the permissible deviations of an element from the ideal position relative to one or more elements, the so-called reference elements. A reference is always required to define a position in space. Since references are derived from real elements, they should be as precise as possible and therefore always require a form tolerance.

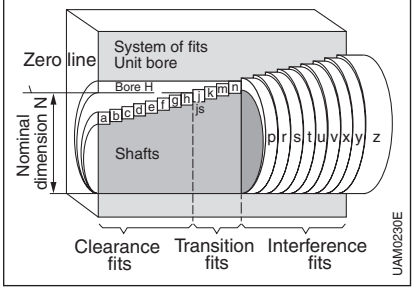
Six form and eleven positional tolerances (Table 1) are defined in ISO 1101 [5]. The specification for parallelism is shown in Figure 6.

General tolerances

General tolerances are used to make drawings more simple. Standard workshop precision is sufficient for all dimensions and geometry elements which are not directly important to the function or exchangeability. It can be maintained without any special effort and applies to all the dimensions and geometries which are not individually toleranced. The general tolerances are dependent on the different manufacturing processes, e.g., machining (ISO 2768, [6], [7]), metal castings (ISO 8062-3, [8]) or plastic castings (DIN 16742, [9]).

ISO 2768 is the most frequently used general tolerance and therefore indicated

Figure 5: Unit bore



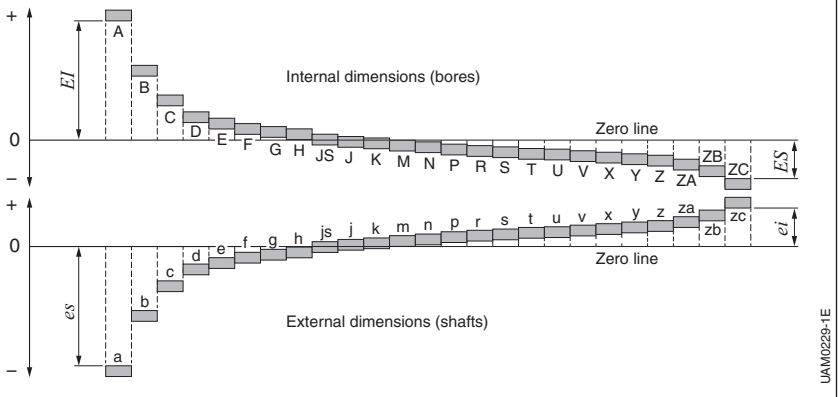


Figure 4: Position of the tolerance intervals

EI Lower limit dimension for internal dimensions, *ES* Upper limit dimension for internal dimensions,
ei Lower limit dimension for external dimensions, *es* Upper limit dimension for external dimensions.

in many drawings. The indication is provided either in or near the title block. Four tolerance classes (f, m, c, v) are available for dimensional tolerances, while only three tolerance classes (H, K, L) are available for geometrical tolerances. The following entry is required for the tolerance class "middle" (m): ISO 2768 – mH.

Surface parameters

The surface texture can dramatically influence the function of a product. Thus, the surfaces of guides and bearings should be as smooth as possible to limit wear and friction losses. However, smooth surfaces are a disadvantage to frictional joints (e.g., driving fits) since these reduce the coefficient of friction and hence also the transmittable force.

Profile meters record the profiles of the real surfaces and evaluate them according to the drawing indications. According to ISO 4287 [10] and ISO 1302 [11] the following surface parameters can be indicated and evaluated:

– primary profile, unfiltered (parameter P),
– waviness profile, without roughness profile (parameter (W),
– roughness profile, without waviness profile (parameter (R).

Primarily roughness profiles are used in practice. The parameters most commonly used in drawings are Rz and Ra (Figure 7).

Average peak-to-valley height Rz

The average peak-to-valley height Rz is the mean value of five Rz values from five adjacent individual measured lengths l_r.

$$Rz = \frac{1}{5}\sum_{i=1}^{i=5} Rz_i \ .$$

The greatest Rz value from the five individual measured lengths is designated $Rz1$max. Rt is the distance between the highest peak and the lowest valley of the profile of the overall measured length l_n. These two parameters can also be specified to describe the surface.

Arithmetic roughness average Ra

The roughness average Ra is the arithmetical mean of the absolute amounts of the deviations from the surface center line over the measured length l_n.

$$Ra = \frac{1}{l_n}\int_0^{l_n} |Z(x)|\, dx.$$

Ra was the standard characteristic value for surface texture until the 1990s. But since Ra reacts with a lack of sensitivity in respect of peaks and furrows, its informative value is minimal. In other words, Ra

filters very strongly so that for example a single scratch is not evaluated. This is the reason why Ra is used increasingly less and Rz increasingly more for this purpose.

Axles and shafts

Function and application

The purpose of axles and shafts is to absorb forces and torques and transmit them to the casing. But they differ with regard to their function. Thus, an axle never transmits a torque, but a shaft always transmits a torque. While an axle can be stationary or rotate, a shaft is always rotatory. While most shafts rotate (e.g., crankshaft), they can however also perform smaller angular movements (e.g., slewing drives).

Axles
Axle serve exclusively to accommodate wheels, rollers, drums, etc. Rotating machine parts are seated on stationary axles. A rotating axle rotates in bearings about itself, while for example a wheel is permanently mounted on it. Figure 1a shows a fixed axle customary in vehicle manufacturing, while Figure 1b features a rotating axle for a railroad car. The purpose of axles is therefore confined to bearing and supporting. In practice, however, this definition is not always applied consistently, as the example of final drive shows (see Final drive).

Shafts
Shafts must not only accommodate elements and support forces, but also transmit power. Power P is calculated with torque M_t and angular frequency ω or rotational speed n as

$$P = M_t\,\omega = M_t \cdot 2\pi\, n.$$

Machine parts such as gears, belt pulleys, clutch hubs and many more are used for input and output. Shafts can be found in every rotating drive system, e.g., the crankshaft in the engine (see Crankshaft) or a shaft in the transmission (Figure 2).

Dimensioning

It is possible to observe in axles and shaft three failure causes, according to which they must then be designed and configured:
– exceeding the load capacity,
– impermissible deformation,
– operation in the resonant range (dynamic response).

Figure 1: Axles
a) Fixed vehicle axle,
b) Rotating railroad axle.

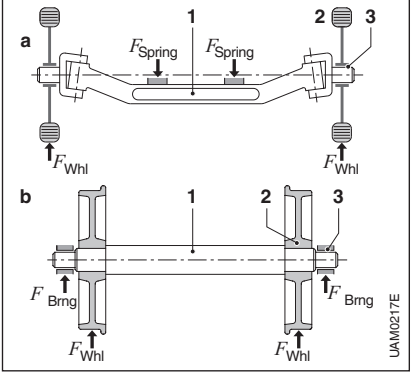
F_{Brng} Bearing force.



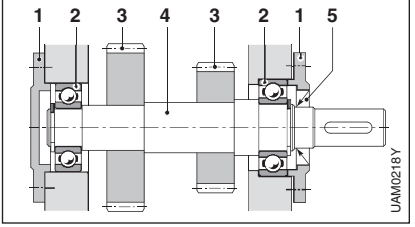


Figure 2: Transmission shaft with locating/ floating bearing arrangement
1 Bearing cap, 2 Roller bearing,
3 Gears, 4 Shaft,
5 Shaft seal.

Load capacity
Axles and shafts fail when the existing stresses are greater than the sustainable stresses. The load cases are important as well as the magnitude of the stresses. In other words, whether the stress involved is static or dynamic.

The essential differences between axles and shafts with regard to stresses are set out in Table 1. It can be seen from this that the bending stress is always alternating for axles and shafts. An exception is the eccentric shaft, where the centrifugal force rotates as a result of imbalance with the shaft and hence gives rise to a static bending stress.

In the case of a stationary axle, the bending stress can, depending on the application, be steady, cyclic or alternating.

Shafts are additionally subjected by the torque to torsional stress. Because bending and torsional stresses occur at the same time, a strength hypothesis is required to calculate the existing stress since these stresses cannot simply be summarized by addition. A precise re-calculation based on the state of the art can be performed in accordance with DIN 743 [1]. The results are for the most part good, but the work involved is correspondingly high. With less work the load capacity of a shaft can be roughly calculated with the aid of the yield criterion [2].

Table 1: Stresses

	Movement	Stress	Load case
Axle	stationary	Bending	steady, cyclic, alternating[1]
	rotating	Bending	alternating
Shaft	rotating	Bending	alternating
		Torsion	steady, cyclic, alternating[1]
Eccentric shaft	rotating	Bending	steady
		Torsion	steady, cyclic, alternating[1]

[1] Depending on the application.

Deformation
If the permissible deformation is exceeded, axles and shaft can impair the function even when the load capacity is sufficient. Transverse forces give rise to deflections, to which bearings and gears react with great sensitivity (Figure 3). Both the edge loads on the bearings and the engagement faults at the gears generate noises and the service life is greatly reduced as a result. The maximum deflection can be easily calculated for a constant cross-section. However, axles and shafts usually have complex geometries such that deflection lines are determined by means of FEM calculations.

Shafts are additionally twisted by the torsional moment, which can have a negative impact on the transmission behavior of shaft/hub connections. Therefore the torsion angle φ should not exceed 0.25° per meter length. The two ends of a shaft section with constant shaft cross-section at distance l are twisted by the torque M_t through the angle φ:

$$\varphi = \frac{M_t l}{G I_p} \cdot \frac{180°}{\pi}.$$

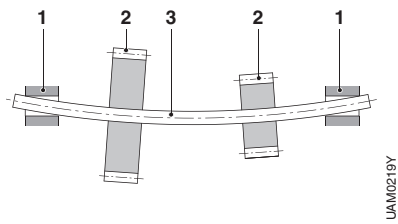
G is the shear modulus and can be taken for steel with sufficient accuracy as 80 GPa. I_p is the polar planar moment of inertia, for solid shafts with diameter d the following applies:

$$I_p = \frac{\pi}{64} \cdot d^4.$$

Dynamic response
Shafts are elastic components which have mass and are additionally subjected to masses such as gears, belt pulleys, etc. Therefore rotating axles and shafts are oscillating systems which are excited by centrifugal forces or by rhythmic force or torque fluctuations to forced oscillations. Resonance occurs when the excitation frequency coincides with the natural frequency. The amplitudes are in this case theoretically of infinite magnitude. In other words, an axle or a shaft can already be destroyed under very small loads if the system has enough time to oscillate in the resonant range.

Design

Axles and shafts should be able to be produced cost-effectively. In terms of design, this means providing for the fewest possible machined surfaces, using large tolerances, and permitting large peak-to-valley heights. As well as low manufacturing costs, operational reliability must also be guaranteed. The design requirements result from the functions to be performed and the mountability, the required load capacity, the permissible deformation, and the dynamic response.



Function and mountability
A shaft as pictured in Figure 2 must perform a number of functions: directing torque via shaft/hub connections, supporting forces via bearings, preventing axial displacement of the bearing rings, defining axial positions of the gears, and sealing lubricant. A seal makes other demands on the shaft surface than a bearing seat or a shaft/hub connection. It follows from this that as a rule each function has a separate shaft diameter. Securing the axial position of bearing inner rings and hubs can be performed by means of shaft shoulders and retaining rings. When installing the bearings it is important to ensure that no sealing surfaces are damaged. This necessarily results in a stepped shaft with different diameters.

Load capacity
Shaft shoulders, which are required to ensure the function, give rise to stress concentrations as a result of the notch effect and thereby reduce the load capacity. Notches are also created by parallel keys and grooves for retaining rings. Since rotating axles and shafts are dynamically stressed by rotating bending, they are particularly notch-sensitive. Notches must therefore be avoided in highly stressed zones. If this is not possible, the notch effect must be reduced as much as possible by design measures such as small shaft shoulders and larger radii on the inside edge.

Deformation
Deformability is essentially dependent on the moment of resistance. Rigid axles and shafts with large moments of resistance are required for small deformations. It is to be noted here that hollow shafts have much better material utilization than solid shafts. Weight savings of up to 50 % are readily possible.

Dynamic response
High torsional and bending stiffness result in high natural frequencies. Therefore rotating axles and shafts are designed to be as stiff as possible so that the resonant speed is sufficiently removed from the operating speed. As with deformations, hollow shafts here too present the advantage that they offer maximum stiffness with minimum mass.

Springs

Basic principles

Functions

All elastic components to which forces are applied are spring elements. However, springs in the narrower sense mean only those elastic elements that can absorb, store, and release work over a relatively long distance. The stored energy can also be used to maintain a force. The most important applications of industrial springs are:

- Absorbing and damping shocks (shock absorbers and vibration dampers),
- Storing potential energy (spring motors),
- Applying a force (coupling springs),
- Vibrating systems (vibrating table),
- Force measurement (spring balance).

Spring characteristic

The spring characteristic shows the behavior of a spring or spring system. This means the dependency of spring force F or spring torque M_t on deformation. Metal springs have linear characteristics (Hooke's law), rubber springs have progressive characteristics, and disc springs have degressive characteristics (Figure 1a). The gradient of the characteristic is called the spring rate R.

For translational motion: $R = \frac{dF}{ds}$.

For rotary motion: $R_t = \frac{dM_t}{d\alpha}$.

Spring duty

For frictionless springs under stress, the area under the characteristic represents the absorbed or released work (Figure 1b):

$$W = \int F\, ds\ .$$

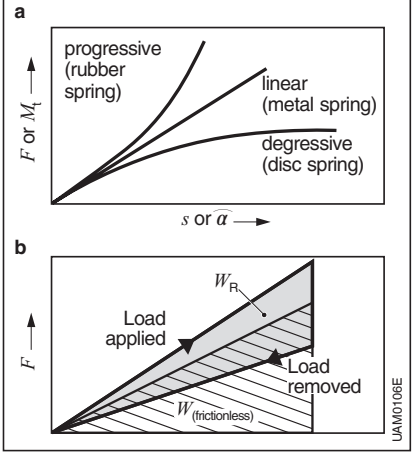
Spring damping

If friction occurs, the prevailing force when the spring is loaded is greater than when the load is removed. The area enclosed by the two characteristics represents frictional work W_R, and is thus a measure of the damping rate (Figure 1b):

$$\psi = \frac{W_R}{W}\ .$$

Damping due to internal friction can be very high with rubber springs ($0.5 < \psi < 3$). With metal springs, however, it is rather low ($0 < \psi < 0.4$). This means that metal springs have a notable damping rate that is only achievable by means of external friction, e.g. as occurs in layers of leaf and disc springs.

Table 1: Symbols and units



Quantity		Unit
b	Width of spring leaf	mm
d	Wire diameter	mm
D	Mean coil diameter	mm
E	Modulus of elasticity	MPa
F	Spring force	N
G	Shear modulus	MPa
h	Height of spring leaf	mm
h_0	Spring deflection (disc spring)	mm
i	Number of leaves (leaf spring)	–
i'	Number of leaves which continue to ends	–
k	Stress coefficient	–

σ_a	Permissible variable stress	MPa
σ_b	Bending stress	MPa
σ_m	Mean stress	MPa
τ_t	Torsional stress	MPa
ψ	Damping	–

Spring combinations

A very wide variety of spring characteristics can be achieved by combining several springs (Figure 2). In principle, springs can be combined in parallel or in series. A combination of parallel and series springs is also possible.

Figure 1: Spring characteristics and spring duty
a) Spring characteristics of different springs,
b) Spring duty.
s Spring deflection, $\widehat{\alpha}$ Twist angle,
F Spring force, M_t Spring torque,
W Spring duty,
W_R Frictional work.

Parallel combinations

If springs are arranged in parallel, the external load is distributed proportionally between the individual springs. However, the spring deflection (s) is equal for all springs. The spring rate of the spring system is the sum of individual spring rates:

$$R_{total} = R_1 + R_2 + R_3 + ... + R_n .$$

Accordingly, spring systems comprising parallel springs are harder than individual springs.

Series combinations

With series springs, the total external load acts on each individual spring. However, spring travel for each spring is different depending on the individual spring rates, and are added. The following applies to the resulting spring rate of the overall system:

$$\frac{1}{R_{total}} = \frac{1}{R_1} + \frac{1}{R_2} + ... + \frac{1}{R_n} .$$

Spring systems consisting of series springs are softer than the softest individual springs.

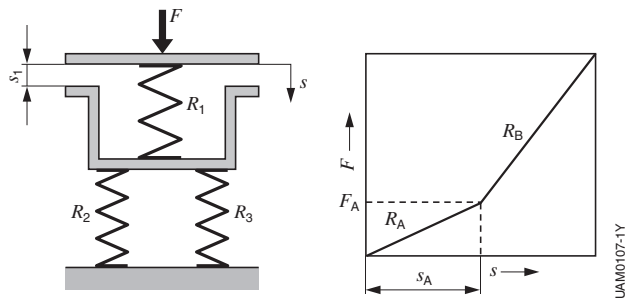

Figure 2: Spring combinations
Parallel combination of spring 2 and spring 3 in series with spring 1.

$$R_B = R_2 + R_3$$

$$\frac{1}{R_A} = \frac{1}{R_1} + \frac{1}{(R_2 + R_3)}$$

$$F_A = s_1 R_1$$

$$s_A = s_1 + \frac{F_A}{R_B}$$

Metal springs

Normally, metal springs are classified according to their stresses (Table 2). It should be noted that a loss of power occurs under permanent stress and at higher temperatures; this loss of power is called relaxation. This loss of power, which increases with rising temperature and load duration can be taken from material-dependent relaxation diagrams for compression springs in DIN EN 13906-1 [1]. From 120 °C, relaxation is no longer negligible. In unalloyed spring steels a loss of power can already occur from 40 °C.

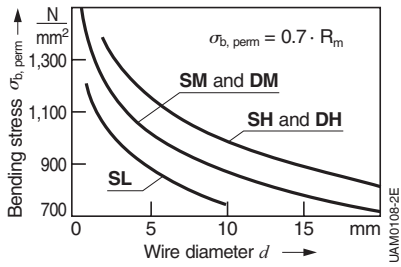

Table 2: Stress on springs

Stress	Construction
Tensile, compressive stress	Tensile test bar, ring spring

Torsional stress	Torsion-bar spring, helical spring

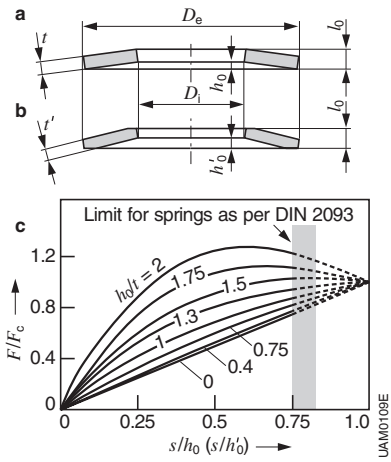
Table 3: Permissible bending stresses for leaf springs

Steel bands	Static stress $\sigma_{b,\,perm}$	Dynamic stress $\sigma_{b,perm}=\sigma_m \pm \sigma_A$
Hot-rolled	960 MPa	
Cold-rolled, hardened, and draw-tempered	1000 MPa	
Individual leaves ground		500 ± 320 MPa
Individual leaves with rolling skin		500 ± 100 MPa
Layered leaves with rolling skin		500 ± 80 MPa

Figure 3: Permissible bending stresses
R_m Tensile strength.

Springs subjected to tensile and compression stress

Due to their high spring stiffness (high spring rate), metal tensile and compression test bars are suitable only for very few special applications.

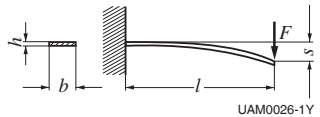


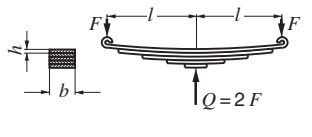
Springs subjected to bending stress

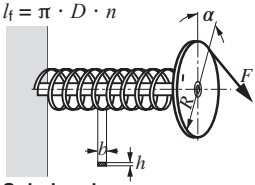
The calculation equations for leaf, coil and spiral springs subjected to bending stress are set out in Table 4.

Leaf springs

A simple leaf spring is used as a compression or guide spring. Layered leaf springs are used for suspension and wheel control in vehicles. They are usually made of spring steel in accordance with DIN EN 10089 [2] (hot-rolled) and DIN EN 10132 [3] (cold-rolled strip). The draft design may assume the permissible bending stresses specified in Table 3.







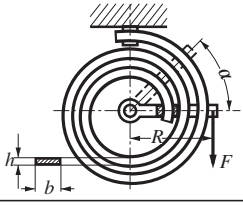


Figure 4: Disc springs according to DIN 2093
a) Without contact bearing surfaces,
b) With contact bearing surfaces,
c) Calculated spring characteristic of a disc spring to DIN 2092.

Torsion and spiral springs
During an excursion of the torsion or spiral spring (twist angle $\widehat{\alpha}$) aligning torques are generated about the rotational axis. Due to the clamping conditions, the bending stresses in the angle are almost uniform. The calculation equations for circular and rectangular sections, which apply to both torsion and spiral springs, are set out in Table 4. For the frequently used spring-steel grades (SL, SM or DM and SH or DH) it is possible, for design purposes in the case of static and quasi-static stress, when the increase in stress as a result of the wire curvature is disregarded, to calculate with the permissible bending stresses in accordance with Figure 3.

Disc springs
The cone-bowl-shaped disc springs (Figure 4) are primarily subjected to bending stresses. A wide variety of applications results from the large number of possible parallel and series combinations. Disc springs are mainly used where spring force and travel must be absorbed within confined spaces. They are used among other things in regular and

Table 4: Leaf spring, torsion spring, and spiral spring

Type		Spring force	Spring deflection
Simple straight leaf spring (constant cross-section)  UAM0026-1Y		$F_{max} = \frac{b \cdot h^2}{6 \cdot l} \cdot \sigma_{b,perm}$	$s = \frac{4 \cdot F \cdot l^3}{E \cdot b \cdot h^3}$
		Spring rate	Spring duty
		$R = \frac{F}{s} = \frac{E \cdot b \cdot h^3}{4 \cdot l^3}$	$W_{max} = \frac{\sigma^2_{b,perm}}{18 \cdot E} \cdot b \cdot h \cdot l$
Layered leaf spring  UAM0028-1Y		Spring force, spring torque	Spring deflection
		$F_{max} = \frac{i \cdot b \cdot h^2}{6 \cdot l} \cdot \sigma_{b,perm}$	$s = \frac{12 \cdot F \cdot l^3}{(2 \cdot i + i') \cdot E \cdot b \cdot h^3}$
		Spring rate	Spring duty
		$R = \frac{(2i + i') \cdot E \cdot h^3 \cdot b}{12 \cdot l^3}$	$W_{max} = \frac{\sigma^2_{b,perm}}{3 \cdot E} \cdot \frac{i^2}{(2i + i')} \cdot b \cdot h \cdot l$

		$M_{t,max} = \frac{b \cdot h^2}{6} \cdot \sigma_{b,perm}$	$\widehat{\alpha} = \frac{12 \cdot M_t \cdot l}{E \cdot b \cdot h^3}$
		Spring rate	Spring duty
		$R = \frac{M_t}{\widehat{\alpha}} = \frac{E \cdot b \cdot h^3}{12 \cdot l}$	$W_{max} = \frac{\sigma^2_{b,perm}}{6 \cdot E} \cdot b \cdot h \cdot l$

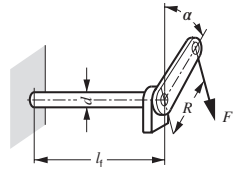
overload clutches and to pre-tension rolling bearings. Because friction occurs between the individual disc springs in spring assemblies layered in the same direction, they are also suitable for damping vibrations and shocks.

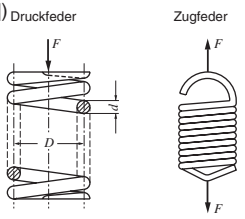
At h_0/t > 0.4, the nonlinearities of the springs are no longer negligible. Spring forces, spring travel, and spring rates can be calculated with sufficient precision according to DIN 2092 [4], or they can be taken from the manufacturer's data.

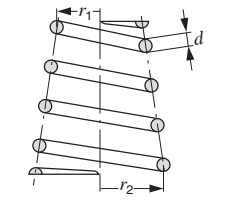
For disc springs subjected to static stress (< 10^4 stress reversals), fatigue-strength calculation is not required if the maximum spring force at $s = 0.75\ h_0$ is not exceeded. For dynamically stressed disc springs the maximum permissible tensile stress and the permissible stress range can be taken from DIN 2093 [5].

Springs subjected to torsional stress

The calculation equations for torsion-bar and helical springs subjected to torsional stress are set out in Table 5.







Torsion-bar springs

Circular sections are usually selected for torsion bars. They have a very high volume utilization factor, which means that they can absorb a lot of energy, but they occupy little space.

Helical springs

Cylindrical helical springs are manufactured as compression and extension

Table 5: Torsion-bar spring and helical springs

Type	Spring force, spring torque	Spring deflection
Torsion-bar spring Circular section (DIN 2091, [6]) 	$M_{t,\,max} = \frac{\pi \cdot d^3}{16} \cdot \tau_{t,\,perm}$	$\widehat{\alpha} = \frac{32 \cdot M_t \cdot l_f}{G \cdot \pi \cdot d^4}$
	Spring rate	Spring duty
	$R = \frac{M_t}{\widehat{\alpha}} = \frac{G \cdot \pi \cdot d^4}{32 \cdot l_f}$	$W_{max} = \frac{\tau^2_{t,perm}}{16 \cdot G} \cdot \pi \cdot d^2 \cdot l_f$
Cylindrical helical springs Circular section (DIN EN 13906, [1]) 	Spring force, spring torque	Spring deflection
	$F_{max} = \frac{\pi \cdot d^3}{8 \cdot k \cdot D} \cdot \tau_{t,\,perm}$	$s = \frac{8 \cdot D^3 \cdot n}{G \cdot d^4} \cdot F$
	Spring rate	Spring duty
	$R = \frac{G \cdot d^4}{8 \cdot D^3 \cdot n}$	$W_{max} = \frac{\tau^2_{t,perm}}{16 \cdot G} \cdot d^2 \cdot D \cdot \pi^2 \cdot n$
Tapered helical springs with circular section 	Spring force, spring torque	Spring deflection
	$F_{max} = \frac{\pi \cdot d^3}{16 \cdot k \cdot r_2} \cdot \tau_{t,\,perm}$	$s = \frac{16 \cdot (r_1 + r_2) \cdot (r_1^2 + r_2^2) \cdot n \cdot F}{G \cdot d^4}$
	Spring rate	Spring duty
	$R = \frac{G \cdot d^4}{16 (r_1 + r_2) \cdot (r_1^2 + r_2^2) \cdot n}$	$W_{max} = \frac{\tau^2_{t,perm}}{32 \cdot G} \cdot \frac{d^2 (r_1 + r_2) \cdot (r_1^2 + r_2^2) \cdot \pi \cdot n}{r_2^2}$

springs. The calculation equations are identical for both types. Compression springs in conical form can optimize the use of space if the individual coils can be pushed into each other.

Compression springs

To enable the force to be introduced as centrically as possible in the case of a compression spring, the spring ends are created and surface-ground vertically to the spring axis. Cold-formed springs consist of at least two active coils ($n \geq 2$) and two created, non-active end coils. In the case of hot-formed springs n should be ≥ 3 and as non-active end coils only ¾ coils are created in each case. This produces the total number of active coils as indicated in Table 6. Furthermore, the spring ends are arranged with an offset of 180° to each other so as to produce a total coil number of n_t = 2.5; 3.5; 4.5; 5.5; 6.5, etc.

In order to avoid plastic deformation in the spring, the active coils may not touch each under maximum load. In other words, a compression spring must never be compressed to the block (solid) length

d) For hot-formed springs.

L_c. The sum of the minimum distances between the individual coils is indicated with S_a and can be calculated in accordance with Table 6. Under dynamic load S_a must be doubled for hot-formed springs, whereas a factor of 1.5 should be used for cold-formed springs.

The effect of the wire curvature is taken into account by the stress coefficient k (Table 7). In the case of static stress, this effect can be disregarded, i.e. k = 1 is then set. The following applies to the stress range prevailing in the case of dynamic stress:

$$\tau_{kh} = k \frac{8\,D}{\pi \cdot d^3} \cdot (F_2 - F_1) \leq \tau_{kH} .$$

Extension springs

Extension springs are formed either with loops or with rolled-in or screwed-in end pieces. Since service life is determined primarily by the loops, it is impossible to give general fatigue limit values. Cold-formed extension springs hardened and tempered after drawing can be manufactured with an internal preload. This allows significantly higher stresses.

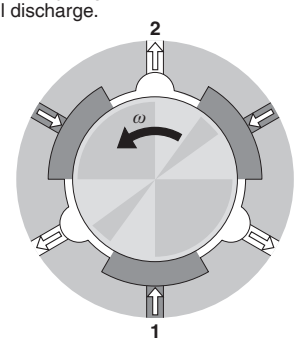
Friction bearings

Features

The task of bearings is to guide machine parts and support forces between surfaces that are moving relative to each other. In order to minimize the wear and power loss, the friction that occurs in the process must be kept as low as possible.

Friction (or plain or sliding) bearings are made of metallic (e.g. sintered metals) and non-metallic materials. A distinction is made between radial and axial (thrust) bearings based on the direction of the external load. Another distinguishing feature is lubrication. Hence, friction bearings can be either hydrostatically or hydrodynamically lubricated, or self-lubricating. A complete separation of the sliding surfaces is the optimal state. With full lubrication there is pure fluid friction with very low coefficients of friction. The lubricant layer has a shock-, vibration- and noise-absorbing effect.

Table 1: Symbols and units (DIN 31652 [1])



Description	Symbol	Unit
Axial bearing length	B	m
Inside bearing diameter (nominal diameter)	D	m
Shaft diameter (nominal diameter)	d	m
Eccentricity (displacement between shaft and bearing centers)	e	m
Bearing force (load)	F	N
Minimum lubricating film thickness	h_{min}	m
Local lubricating film pressure	p	Pa = N/m^2
Specific bearing load = $F/(B\,D)$	$\overline{p}$	Pa
Bearing clearance = $D - d$	s	m
Sommerfeld number	So	–
Sliding velocity	v	m/s
Relative eccentricity = $2\,e/s$	ε	–
Effective dynamic viscosity of lubricant	η_{eff}	Pa · s
Relative bearing clearance = s/D	ψ	–
Hydrodynamically effective angular velocity	ω_{eff}	s^{-1}

Hydrostatic friction bearings

In the case of hydrostatic bearings the lubricant is forced by an external pump at high pressure between the sliding surfaces. At any point in time there is a complete separation of the sliding surfaces on account of the thin lubricating film (Figure 1). Friction losses only occur on account of the shear forces in the lubricant. These forces are proportional to the speed at which the bearing surfaces move against each other. At low relative speeds hydrostatic friction bearings consequently operation with virtually zero friction. There is no stick-slip effect when starting and after-running due to the absence of slip resistance.

Hydrostatic friction bearings are therefore wear-and-tear-resistant and consequently have a very long service life. The drawbacks of these friction bearings are the high costs and the large installation space required. For these reasons they are used primarily in heavy machine construction.

Figure 1: Hydrostatic friction bearing.
1 Oil supply (high pressure),
2 Oil discharge.

Hydrodynamic friction bearings

Application

Most of the hydrodynamic friction bearings used in motor-vehicle engines are plain bearings (Figure 2) for holding the crankshaft drive, including the camshafts. They are usually designed as bearing shells with special clearance (oval clearance acc. to Figure 3).

Operating principle

In the case of hydrodynamic friction bearings the pressure is generated automatically. The following preconditions are required for this purpose:

– relative movement between the sliding surfaces,
– wedge-shaped gap,
– lubricant must adhere to the sliding surfaces,
– sufficient lubricant supply.

A friction bearing requires a bearing clearance in order to build up a lubricating gap that is capable of bearing. In the stationary state the shaft touches the bearing shell and consequently there is solid-body friction. The eccentric displacement of the shaft creates a wedge-shaped lubricating gap (Figure 3). As the rotational speed increases a lubricating film that is capable of bearing is built up as a result of the lubricant that adheres to the sliding surfaces being pumped into the wedge gap. Until the pressure has built up fully in the lubricating gap, i.e. until the sliding surfaces are completely separated, the shaft still partly touches the bearing shell. During this period the bearing is in the mixed-friction range. There is pure fluid friction only when the operating rpm exceeds the transition rpm.

Stribeck curve

The friction states in the hydrodynamic friction bearing were analyzed by Richard Stribeck. The curve named for him shows the dependence of friction on shaft speed (Figure 4, [2]).

Sommerfeld number

Depending on load and rotational speed, the eccentricity of the shafts is set within the system in such a way that the integral of the lubricant pressure of the external bearing force maintains equilibrium. The hydrodynamic pressure distribution in a convergent bearing gap is determined from the solution of Reynolds' differential equation. The integration of the pressure

distribution produces the load capacity of the lubricating film and is expressed in the dimensionless Sommerfeld number So [1] (for quantities, see Table 1):

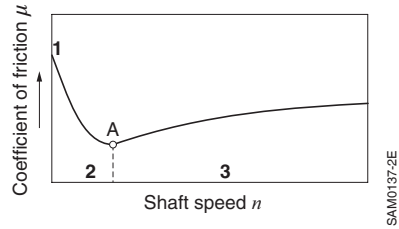
$$So = \frac{F\,\psi^2}{(D\,B\,\eta_{\text{eff}}\,\omega_{\text{eff}})}.$$

For stable operation $So > 1$ must be the case, bearings subjected to high load should be designed with $So > 3$. As the Sommerfeld number increases, so the relative eccentricity ε increases and the minimum lubricating-gap thickness h_{min} decreases. The following applies:

$$h_{\text{min}} = \frac{(D-d)}{2} - e = 0.5\,D\,\psi\,(1-\varepsilon).$$

The relative eccentricity is then:

$$\varepsilon = \frac{2e}{(D-d)}.$$



With the aid of the Sommerfeld number it is possible, in accordance with DIN 31652 [1] and VDI 2204 [2], to calculate the coefficient of friction μ in the bearing and thus also the friction loss and the thermal stress.

Table 2: Coefficients of friction for different types of friction

Type of friction	Coefficient of friction μ
Solid-body friction	0.1…>1
Mixed friction	0.01 to 0.1
Fluid friction	0.001 to 0.01

3 Fluid friction,
A Transition point (transition rpm).

Coefficient of friction $\mu = \frac{\text{Friction force}}{\text{Normal force}}$

Requirements

The coefficients of friction given in Table 2 are approximate values, and are intended only for comparison of the different operating states. As hydrodynamic bearings also operate with mixed friction some of the time, must be able to withstand a certain amount of contamination without loss of function, and are also subjected to high dynamic and thermal stress (particularly in piston engines), the bearing material must meet a number of requirements, some of which are mutually exclusive.

- Conformability: This is the property of a bearing material to adapt to necessary modifications of shape by local deformation without permanent damage.
- Embeddability: This is the ability to absorb dirt particles into the bearing surface without negative consequences.
- Resistance to wear: This prevents the separation of small particles in the event of mechanical load in the mixed-friction area.
- Run-in performance: This is the interaction of conformability, embeddability, and resistance to wear.
- Resistance to seizing: This prevents partial welding of the sliding surfaces under high compressive load.
- Mechanical loadability: This prevents plastic deformation under high compressive loads.
- Fatigue strength: This describes the slowly progressing material fatigue which under alternating load can result in failure even in the case of small bearing forces.

If a bearing (e.g. piston-pin bushing) is simultaneously subjected to high loads and low sliding velocities, high fatigue strength and wear resistance should take precedence over resistance to seizing. The bearing materials used in such cases are hard bronzes or special brass alloys.

Since they are subjected to dynamic loads with high sliding velocities, connecting-rod and crankshaft bearings in internal combustion engines must fulfill a number of different requirements. In these applications, multilayer bearings (Figure 5), above all trimetal bearings, have proved themselves in practice.

The service life of friction bearings in the crankshaft drive can be further increased through the use of special solutions such as the sputter bearing (Figure 6). It contains a highly wear-resistant AlSn running layer (sputter layer) which is applied in the PVD procedure (physical vapor deposition) to the bearing material underneath. Grooved sliding bearings (Figure 7) are also used in internal-combustion engines subjected to high load (e.g. turbocharged diesel engines). In this variant fine grooves, which are filled with a soft filler (e.g. PbSnCu), are incorporated in the circumferential direction of the bearing surface. The bearing surface therefore exhibits soft and hard areas next to each other.

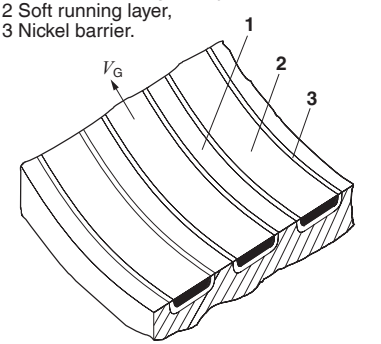
Bearing materials



Lead, tin, copper, and aluminum alloys are used as bearing materials. Values for the permissible specific bearing load are given in Table 3.

Lead and tin bearing metals, formerly called babbitt metals, are ideally suitable for higher sliding velocities and are characterized by good run-in and emergency-running properties. Tin bronzes

Table 3: Empirical values for permissible specific bearing load (acc. to DIN 31652-3)

Bearing materials	Permissible specific bearing load $\overline{p}_{lim}$ [MPa]
Pb and Sn alloys (babbitt metals)	5 to 15
Bronze, tin base	7 to 25
Bronze, lead base	7 to 20
AlSn alloys	7 to 18
AlZn alloys	7 to 20
Maximum values only apply for very low sliding velocities

3 Nickel barrier.

are suitable for high stresses and are very wear-resistant; run-in and emergency-running properties are however less good. Lead bronzes demonstrate better emergency-running properties with only slightly worse resistance to wear. Aluminum alloys have a higher corrosion resistance than babbitt metal and copper alloys (bronzes).

Standardized materials for friction bearings are listed in ISO 4381 [3], ISO 4382 [4], and ISO 4383 [5]. Some bearing materials contain lead. EU 2016/774 [6] prohibits the use of lead in passenger cars. Lead is currently still permitted in commercial vehicles and in general machine construction.

Self-lubricating bearings made of metal

Sintered bearings

Friction bearings made of sintered metal belong to the category of self-lubricating bearings. They consist of sintered metals which are porous and impregnated with liquid lubricants. For many small motors in motor automotive applications, this type of bearing is a good compromise in terms of precision, installation, freedom from maintenance, service life, and cost. They are used primarily with shaft diameters from 1.5 to 12 mm.

For motor vehicles sintered-iron and sintered-steel bearings are preferred to sintered-bronze bearings since they are cheaper and exhibit a smaller interaction with the lubricant (Table 4). The advantages of sintered-bronze bearings are higher permissible sliding velocities, lower noise, and lower friction coefficients (e.g. for record-players, office equipment, and data systems).

Sintered metals bearing the designation SINT-B (Table 4) have 20 % porosity. Aside from these there are also SINT-A with 25 % and SINT C with 15 % porosity.

The performance of sintered bearings over long periods of service is closely related to the use of optimum lubricants. Mineral oils are used; however, these exhibit insufficient cold-flow properties and moderate resistance to aging. Synthetic oils (e.g. esters, poly-α-olefins) on the other hand have good cold-flow proper-

Table 4: Materials for sintered-metal bearings (acc. to DIN 30910-3 [7])

Material group	Designation Sint- …	Composition [%]	Remarks

ties and can be subjected to high thermal loads. Furthermore, the evaporation tendency is low. Synthetic grease oils (oils which have metal soaps) are characterized by low starting friction and low wear. The most important properties of sintered bearings are set out in Table 5.

Metal-ceramic bearings

Metal-ceramic friction bearings consist of material manufactured by powder-metallurgy processes; in addition to the metallic matrix, the bearing material also contains finely distributed solid lubricant particles. Bronze, iron, and nickel are used as the material, graphite or molybdenum disulfide (MoS_2) for example are used as the lubricant. Ceramic bearings are particularly suitable for use under high loads, and are at the same time self-lubricating. However, they are very brittle and therefore sensitive to jolts and impacts.

Metal-ceramic bearings are used in motor vehicles, for example as steering-knuckle bearings.

[1] Value in parentheses applies to additional lubrication.

Self-lubricating bearings made of plastic

Different plastics can be used for friction bearings. The various properties of plastic bearings are set out in Table 5.

Solid polymer bearings made of thermoplastics

Features

Friction bearings made of thermoplastics are inexpensive and are suitable for low bearing forces and low operating temperatures. The danger of "seizing" is extremely small.

The most frequently used thermoplastic polymer materials are:
- Polyoximethylene (POM, POMC)
- Polyamide (PA)
- Polyethylene and polybutylene terephthalate (PET, PBT)
- Polyetheretherketone (PEEK)

The tribological and mechanical properties can be varied over a wide range by incorporating lubricants and reinforcements in the thermoplastic base material.

Lubrication additives
- Polytetrafluoroethylene (PTFE)
- Graphite (C)
- Silicone oil, and other liquid lubricants, recently also enclosed in microcapsules

Reinforcement additives
- Glass fibers (GF)
- Carbon fibers (CF)

Application examples
- Windshield-wiper bearings (PA and glass fiber)
- Idle actuators (PEEK + carbon fiber, PTFE and other additives)

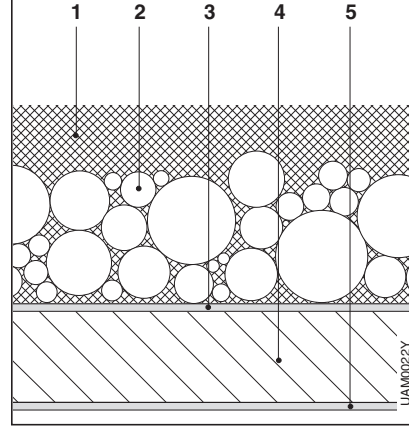
Polymer bearings made of duroplastics

These materials have high intrinsic friction and are seldom used as bearing materials in motor vehicles. Duroplastics which are used for friction bearings are:
- Phenolic resins (high friction)
- Epoxy resins (additives of PTFE or C, reinforcement by fibers required on account of their inherent brittleness)
- Polyimides (high thermal and mechanical loadability)

Application example

Polymer bearings made of duroplastics are used in wiper motors as axial startup blocks made of polyimide.

Metal-backed composite bearings



Composite bearings are combinations of polymer materials, fibers, and metals. The respective structure (Figure 8) deliver advantages over pure or filled polymer friction bearings with regard to load capacity, bearing clearance, heat conduction, and installation. They are also more suitable for oscillating motions.

Example of bearing structure

The bearing consists of a steel backing electroplated with tin; above this a

Figure 8: Section through a self-lubricating composite bearing

1 Polymer liner, 2 Porous bronze layer, 3 Copper layer, 4 Steel backing, 5 Tin layer.

0.2…0.35 mm thick bronze-bead layer with 30…40 % porosity in which a low-friction polymer material is rolled in as a liner is sintered on. The liner consists of
– acetal resin or polyvinylidene fluoride, either impregnated with oil or containing lubricating recesses, or
– PTFE + ZnS or molybdenum disulfide (MoS_2) and graphite as additive.

Metal-backed composite bearings are available in a number of different shapes and compositions. Metal-backed composite bearings with woven PTFE fiber inserts have unusually high loadability and are suitable for use in ball-and-socket joints.

Application examples for motor vehicles
– Piston-rod bearings for suspension struts
– Release-lever bearings for clutch pressure plates
– Brake-shoe bearings in drum brakes
– Ball-and-socket bearings
– Door-hinge bearings
– Bearings for winding shafts for seat belts
– Steering-knuckle bearings
– Gear-pump bearings

Composite bearings with specially modified liners are required for heavy-duty requirements in diesel high-pressure injection pumps. The liner is made of PEEK or PPS with additives (e.g. carbon fibers, ZnS, TiO_2, and graphite). The particle size is sometimes in the nanometer range.

Carbon-graphite bearings
Carbon-graphite bearings are members of the ceramic bearing family due to their method of manufacture and material properties. Powdered carbons are used as the base material, pitch and synthetic resins are used as binders. It is to be noted that carbon-graphite bearings are very brittle.

Advantages
– Thermal stability up to 350 °C (hard-burnt carbon) and up to 500 °C (electro-graphite)
– Low friction
– Good corrosion resistance
– Good thermal conductivity
– Good thermal shock resistance.

Application examples for carbon-graphite bearings
– Fuel-pump bearings
– Bearings in drying ovens
– Adjustable guide vanes of compressors in exhaust-gas turbochargers

Rolling bearings

Application

Rolling bearings are some of the most important components in machines. Great demands are made on their load capacity and operational reliability. Rolling bearings are widely used in motor vehicles. Passenger cars and commercial vehicles are fitted with a large number of rolling bearings in bearing arrangements for alternator, starter, wheel bearing, transmission, suspension strut, drive shaft, water pump, tension pulley, steering, windshield-wiper motor, fan, and fuel-injection pump.

Figure 1: Design of rolling bearings

c) Needle bearing,
d) Cylindrical rolling bearing,
e) Tapered rolling bearing,
f) Self-aligning rolling bearing.
1 Outer race, 2 Inner race,
3 Cage, 4 Rolling element.

General principles

Type
Rolling bearings are generally made up of two races (Figure 1, outer race and inner race), a cage, and a rolling-element assembly. The rolling elements guided by the cage roll on the raceways. Balls, cylindrical rollers, needle rollers, tapered rollers, and self-aligning rollers are used as rolling elements. A rolling bearing can be lubricated with grease. It is fitted with sheet-steel cover plates or rubber gaskets to prevent grease discharge and to provide a seal against dirt.

The rolling bearing transfers the outer force from one bearing race to the other via the rolling elements. A distinction is made between radial bearings and axial (thrust) bearings, depending on the main direction of load.

Structural dimensions
The rolling bearing is a ready-to-install machine part. Various ranges of outside diameters and widths are available for a hole diameter. Standardized abbreviation codes are used to identify the diameter and width ranges of a rolling bearing. The designations are recorded in the standard DIN 623-1 [1].

The external dimensions are indicated in the catalogs of rolling-bearing manufacturers.

Tolerances
Dimensional and form tolerances of rolling bearings are standardized in ISO 492 [2] and DIN 620 ([3], [4], [5], [6], [7]) according to precision. Rolling bearings of normal precision, i.e. tolerance class P0 (also called PN), generally satisfy all the demands which are made by mechanical engineering on bearing quality. For more stringent requirements, the standard provides for more precise tolerance classes P6, P5, P4, and P2.

Bearing play and bearing clearance
The bearing play of an uninstalled rolling bearing refers to the distance through which the bearing races can be moved against each other. A distance is made between radial play and axial play.

Radial play is defined in the standard DIN 620 Part 4 [6]. The normal radial play category is CN. In accordance with operating conditions – e.g. fits with conversion parts and temperatures – it is possible also to use the other radial-play categories C2 (< CN) or C3 and C4 (> CN).

Axial play is derived from the radial play and raceway and rolling-element geometries, and is always given as a reference parameter.

When bearings are installed the term used is bearing clearance. During operation the bearing clearance is determined by the original bearing play, fits and material of the conversion parts such as shaft and housing, and the temperature difference between the bearing races. As a rule a perfectly running bearing should have a very small bearing clearance.

Materials
Bearing races and rolling elements are primarily composed of chrome-alloy special steel 100Cr6 (DIN EN ISO 683-17, [8]) or 52100 (ASTM A295, [9]) with a high degree of purity and hardness in the range of 58 to 65 HRC. For special applications the races and rolling elements can be made of other materials, e.g. ceramic.

Rolling-bearing cages are made of metal or plastic. The metallic cage in small rolling bearings is primarily composed of sheet steel. Polyamide 66 (PA66) is used for the majority of plastic cages. This material, especially when reinforced with fiberglass, is characterized by its favorable combination of strength and elasticity.

Other thermoplastics and duroplastics are also used as cage materials for special applications subject to extremely high thermal loads.

Selection of rolling bearings

It is necessary to take into account many external factors in order to choose the right bearing from the wealth of options.

Selection criteria
Load
The size and direction of the load acting on the rolling bearing normally determine the type and size of the bearing. Deep-groove ball bearings are usually used in the case of low to medium loads. Rolling bearings have one advantage in the case of high loads and limited installation space. With the exception of only purely radially loaded needle bearings, cylindrical rolling bearings and axial bearings, rolling bearings can simultaneously accommodate radial and axial loads (combined loads).

Deep-groove ball bearings transfer axial loads in both directions, while angular-contact ball bearings and tapered rolling bearings can only be axially loaded in one direction.

Cylindrical rolling bearings and self-aligning bearings are particularly suitable for radial loads, but less so for axial loads.

Speed limit
Ball bearings with point contact between rolling elements and raceways have a higher speed limit than rolling bearings of the same size. The permissible speed of a rolling bearing is dependent above all on the type of construction, the size, and also the lubricating process. A bearing lubricated with oil usually has a higher speed limit than a bearing lubricated with grease.

Mounting
A distinction is made between locking bearings (completely assembled) and non-locking bearings (can be disassembled). Non-locking bearings include tapered rolling bearings, angular-contact ball bearings, cylindrical rolling bearings, and needle bearings. These bearings are for the most part easier to assemble and disassemble than locking bearings such as deep-groove ball bearings and self-aligning bearings. During mounting on the shaft and in the housing, tapered rolling bearings and angular-contact ball

bearings must be adjusted to the required bearing clearance and preload, which always calls for great care.

Further selection criteria
In addition to the previously mentioned main criteria, it is also necessary to take into account – when choosing a rolling bearing – angular adjustability to compensate for misalignment between the bearing points, running smoothness, friction, and costs.

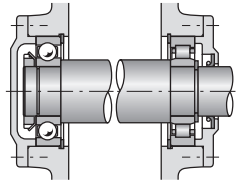
Layout of bearing arrangement
As a rule, two bearings arranged at a specific distance from each other are required to guide and support a rotating machine part. There are two important variations of bearing arrangement: The locating/floating bearing arrangement and the preloaded bearing arrangement.

Locating/floating bearing arrangement
Two radial bearings are seated on the shaft and in the housing (Figure 2). The distance between the two bearing points is determined by manufactured conversion parts within the framework of the tolerance. In addition, the shaft, when heated to different temperatures or when made from different materials, does not expand in the same way as the housing. These differences must be compensated for in the bearing points. For this reason, one bearing is to be axially secured as a locating bearing on the shaft and in the housing and one bearing is to be movable in the axial direction as a floating bearing. Typical applications of the locating/floating bearing arrangement can be found in alternators and steering motors.

Single-row deep-groove ball bearings are frequently used as locating bearings. Cylindrical rolling bearings, needle bearings, and deep-groove ball bearings are usually used as floating bearings.

Double-row angular-contact ball bearings and tapered rolling bearings are also used, e.g. as wheel bearings, in the case of high radial and axial loads.

Figure 2: Locating/floating bearing arrangement



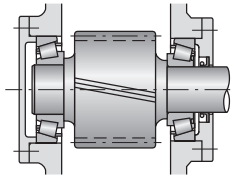


Figure 3: Preloaded bearing arrangement

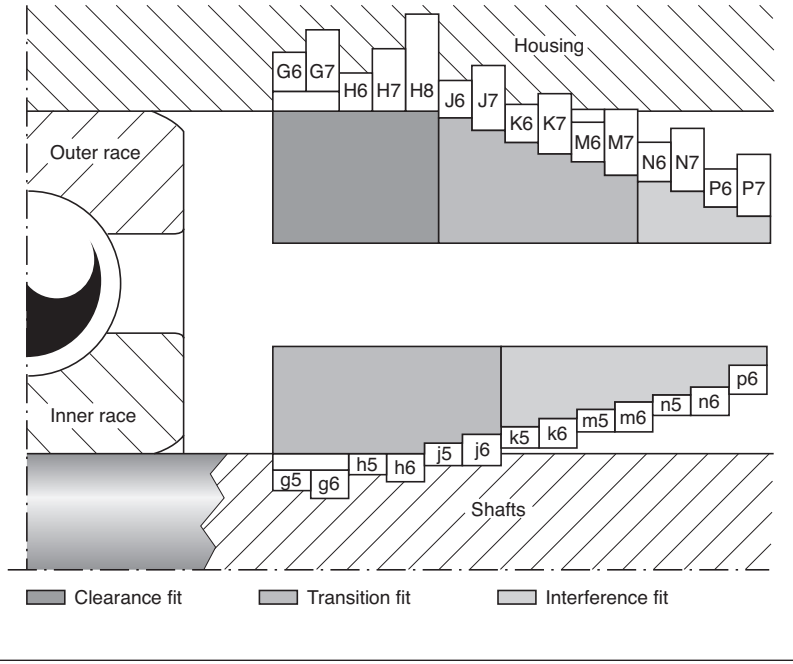

Preloaded bearing arrangement
A preloaded bearing arrangement is predominantly formed from two angular-contact ball bearings or tapered rolling bearings arranged in mirror-image fashion (Figure 3). During assembly, a bearing race is displaced on its seat surface until the bearing arrangement has attained the desired or required play or preload. Because of the possibility of play regulation, a preloaded bearing arrangement is particularly suitable for applications with close guidance, e.g. bearings in transmissions.

Tolerances and fit of bearing points
Rolling bearings essentially have negative tolerances for hole diameter, outside diameter and width, i.e. the nominal size is always the maximum limit of size.

Mounting the races on the bearing points (shaft and housing bore) is important for the installation of rolling bearings. The rolling bearings must not twist, above all tangentially, under load on the counterparts. The safest and easiest way of ensuring mounting is to make the correct choice of fit and tolerances so that the load capacity of the bearing can be fully utilized. Depending on the tolerance band of the bearing seat, the fit is referred to as clearance fit, transition fit, or interference fit (Figure 4).

Figure 4: Fits of bearing seat

The load conditions of the bearing races are of great importance to the choice of fit. A distinction is made between two loads, based on the load direction and the rotation of the bearing races.

– Rotating load: The race rotates relative to the load direction, and must be firmly seated.
– Concentrated load: The race is stationary relative to the load direction, and can have a close clearance fit to interference fit with its counterpart.

Because of the small thicknesses of the bearing races, the form variations of the seats are transferred to the raceways. The counterparts should therefore demonstrate as much form quality as possible, such as concentricity, cylindricity, and runout.

Calculation of load capacity

It is necessary to distinguish between static and dynamic load capacity when calculating the load capacity of a rolling bearing. The basic principles for calculating the static and dynamic load capacities are set out in ISO 76 [10] and ISO 281 [11].

Static load capacity
If a rolling bearing is subjected to load while stationary or while rotating at low speed, i.e. $n\,d_m \le 4{,}000\,\text{mm} \cdot \text{min}^{-1}$ (n rotational speed, d_m mean value of bore and outside diameters), it is considered under static load.

If a bearing is subjected to load in both the radial and the axial directions, the static equivalent bearing load P_0 is formed from this:

$$P_0 = X_0\,F_r + Y_0\,F_a \text{ in N}$$

where
X_0 Radial factor; X_0 = 0.6 for single-row deep-groove ball bearing.
Y_0 Axial factor; Y_0 = 0.5 for single-row deep-groove ball bearing.
F_r Radial load in N.
F_a Axial load in N.

At $P_0 < F_r$, $P_0 = F_r$ must be reckoned on. For other bearing types, refer to the specifications in the catalogs of rolling-bearing manufacturers for the factors X_0 and Y_0.

As the measure of the static load capacity, a ratio

$$f_S = \frac{C_0}{P_0}$$

is formed, where C_0 is termed the static load rating. C_0 is the load at which permanent total plastic deformation of rolling elements and raceways at the contact point subject to greatest load amounts to 0.0001 of the rolling-element diameter. Catalogs specify C_0 for all rolling bearings. The calculation of the static load rating C_0 is shown in the standard ISO 76.

In the case of normal requirements, the characteristic figure $f_s = 1$ can be approved. The requirement of lower deformation (< 0.0001) corresponds to a greater characteristic figure $f_s > 1$.

Dynamic load capacity
Calculating the dynamic load capacity is based on the method of the standard ISO 281. This refers to the service life of a rotating rolling bearing under load, where the running surfaces can be subject to material fatigue. The important characteristic figure of load capacity is the dynamic load rating C. This specifies the load of the rolling bearing for a nominal bearing service life of one million revolutions.

For the purpose of calculating the nominal service life, the following applies in accordance with ISO 281:

$$L_{10} = 10^6 \left(\frac{C}{P}\right)^p \quad \text{in revolutions,}$$

$$L_{10h} = \frac{10^6}{60n}\left(\frac{C}{P}\right)^p \quad \text{in hours.}$$

L_{10} Nominal service life achieved or exceeded by 90 % of a larger batch of identical bearings.
C Dynamic load rating in N – specified in rolling-bearing catalogs.
P Dynamic equivalent bearing load in N.
p Exponent, p = 3 for ball bearings, p = 10/3 for rolling bearings.
n Rotational speed in min^{-1}.

The dynamic equivalent load P is defined as the imaginary load constant in size and direction which influences the service life, such as the actually acting radial load and axial load. It is calculated from:

$$P = X\,F_r + Y\,F_a \text{ in N}$$

where
F_r Radial load,
F_a Axial load,
X Radial factor,
Y Axial factor.

The radial factor X and axial factor Y are dependent on bearing type, size, bearing clearance, and load ratio, and are specified in ISO 281 and in rolling-bearing catalogs.

Modified service life

In addition to the nominal service life, an extended modified service life L_{na} has been introduced in the standard ISO 281, for which operating conditions can also be included in the calculation:

$$L_{na} = a_1 \, a_2 \, a_3 \, L_{10} ,$$

where

a_1 Coefficient for survival probability, e.g.:
90 %: $a_1 = 1$;
95 %: $a_1 = 0.62$.

a_2 Coefficient for special bearing design such as internal construction and materials.

a_3 Coefficient for operating conditions, such as bearing lubrication and operating temperature.

The coefficients a_2 and a_3 are not mutually independent, and are frequently combined as coefficient a_{23}:

$$L_{na} = a_1 \, a_{23} \, L_{10} .$$

Numerous systematic examinations and experiences from practice make it possible to quantify the influences of bearing materials and operating conditions on the achievable service life of rolling bearings. Diagrams and computing programs are provided by rolling-bearing manufacturers to calculate the coefficients a_2, a_3 and a_{23}.

Seals

Seal technology

Function

The function of a seal is to separate two different media from each other. For economic reasons it is necessary to seal existing sealing points with simple geometries. The O-ring assumes the simplest of these geometries.

Classification

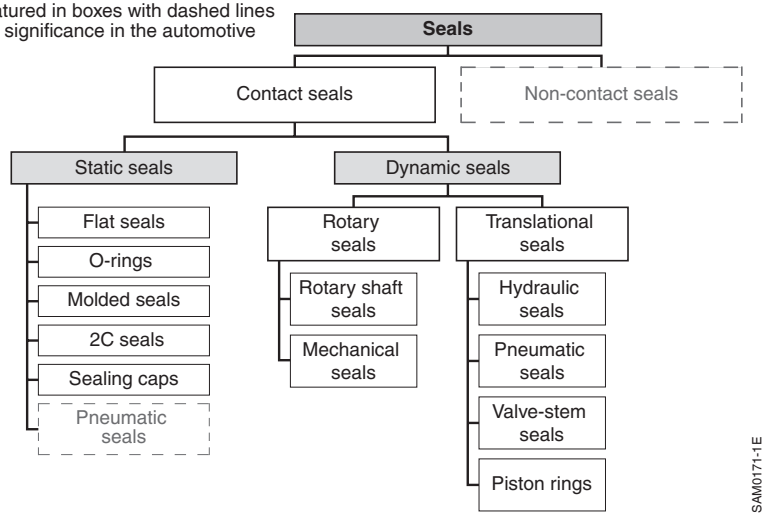
A distinction is made between static and dynamic seals (Figure 1). In the case of a static seal there is no relative movement between seal and machine parts; in the case of a dynamic seal there is relative movement between seal and machine parts. This can exist both between seal and shaft and between seal and housing.

100 % tightness can be achieved with static seals, but this for the most part cannot be achieved with dynamic seals. A “leakage rate”, which may not be exceeded, is defined for dynamic seals. When a seal complies with this rate, it is said to be subject to technical tightness.

Materials for seals

In the main elastomers but also other materials are used for seals in automotive applications. Elastomers are used in a diverse range of applications – as tires, in door seals, as axle boots, in fuel hoses, or as assorted seals in the engine compartment.

Requirements



Elastomers, like all organic-chemicals, are not subject to unlimited use. External influences, e.g., different media, oxygen or ozone as well as pressure and temperature, alter the material properties and hence their behavior. Elastomers can swell, shrink, harden, crack, or even break.

The complete sealing system must always be taken into consideration in the design of a new seal. This comprises the following seven points:

– seal geometry,
– system pressure (averaged pressure and short-time peak pressures),

Figure 1: Types of seals

Seals featured in boxes with dashed lines are of no significance in the automotive sector.

– system temperature (averaged temperature and short-time peak temperatures),
– gap to be sealed,
– roughness of the mating face,
– medium to be sealed,
– relative speed between seal and machine part.

Applications
The matching sealing system is designed in line with the prevailing requirements. An overview of the existing solutions and where they are used is provided in Figure 2.

O-ring

With the O-ring, design engineers are provided with an efficient and economic sealing element for a huge variety of different applications. It is used primarily as a static sealing element, but can also be used in dynamic applications. Cost-effective manufacturing processes and easy handling make the O-ring the most commonly used seal.

A large selection of elastomer materials for standard and special applications enables virtually all liquid and gaseous media to be sealed.

Description

O-rings are continuously vulcanized in molds. They are characterized by their ring shape with a circular cross-section. The O-ring is defined in its dimensions by the inside diameter d_1 and the cross-section d_2 (Figure 1).

Thanks to its simple geometry the O-ring has many benefits:
- symmetrical cross-section,
- simple, compact design,
- self- and double-acting,
- simple calculation and definition of the groove,
- continuous groove design,
- large choice of materials,
- wide range of applications.

Applications

O-rings are used as primary sealing elements, as tensioning elements for rubber-energized hydraulic seals, and as wipers (secondary sealing element). They therefore cover a huge range of applications.

Whether it be as an individual seal for a repair or as a quality-assured sealing element in automobile manufacturing or mechanical engineering – there is today no field in industry in which the O-ring is not used. The O-ring is used mainly in static seals
- as radial-static sealing, e.g., in bushings, covers, pipes, and cylinders (Figure 2),
- as axial-static sealing, e.g., in flanges, plates, and plugs (Figure 3).

Dynamic use is only possible at low load levels. It is limited by the speed and the pressure to be sealed
- to sealing e.g. back- and forward-moving pistons, rods, and plungers,
- to sealing e.g. slowly slewing, rotating or screw-like movements on shafts, spindles, and rotary transmission leadthroughs.

Operating concept

O-rings are self- and double-acting sealing elements. The pressure forces caused by installation in the radial or axial direction produce the initial tightness. They are

Figure 1: O-ring dimensions

b) Pressure p from outside.
d_7 Groove outside diameter,
d_8 Groove inside diameter.

superimposed by the system pressure. This creates a total sealing pressure, which increases as the system pressure increases (Figure 4). The O-ring behaves under pressure similarly to a liquid with high surface tension. In this way, the pressure is uniformly transmitted to all sides.

Figure 4: Pressure forces on the O-ring
a) Without pre-pression,
b) Pressure forces with pre-pression,
c) Pressure forces with pre-pression, with system pressure.
1 Pressure path in the O-ring.
p System pressure.

Materials

Equipment manufacturers and operators expect sealing systems to function without leaks and to have long service lives. In the interests therefore of finding the ideal seal solution in an individual application, the choice of materials is, as well as the correct design, of crucial importance. The specific material properties will be discussed elsewhere (see Elastomers), since this apply equally to all seals.

Sealing gap

Excessively large sealing gaps run the risk of gap extrusion (Figure 5), which can cause the O-ring to be destroyed.

The permissible radial sealing gap S between the parts to be sealed is dependent on the system pressure, the cross-section, the media temperature, and the Shore hardness of the O-ring. Table 1 sets out recommendations for the permissible gap dimension S as a

Figure 5: Sealing gap

function of the O-ring cross-section and the Shore hardness. The table applies to elastomer materials, except polyurethane and FEP- or PFA-sheathed O-rings. In the case of pressures greater than 5 MPa for inside diameters larger than 50 mm and pressures greater than 10 MPa for inside diameters smaller than 50 mm, it is necessary to provide back-up rings (Figure 6).

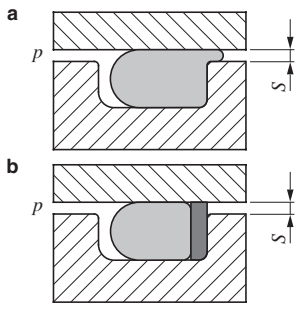
p System pressure,
S Sealing gap.



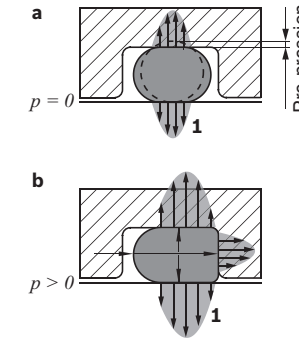


Figure 7: Sealing-pressure path in the O-ring
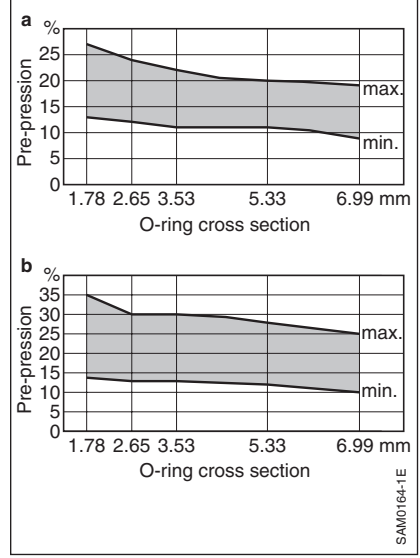
a) System pressure $p = 0$,
b) System pressure $p > 0$.
1 Sealing-pressure path.



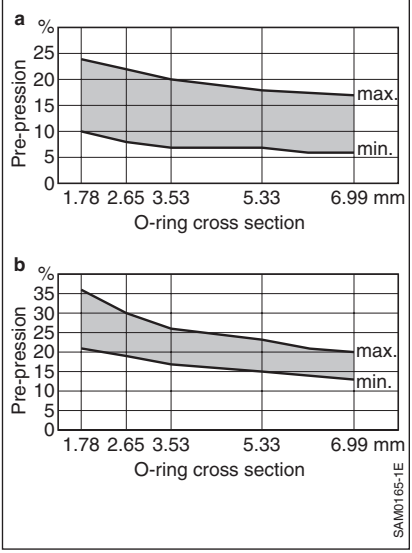
Groove filling
To avoid damaging effects on the sealing function, it is important to take into consideration the groove filling for an installed O-ring. It should in the installed state where possible not exceed 85 % so as to accommodate any thermal expansion of the O-ring, volume swelling due to media contract, and influences of tolerances.

Pre-pression
The pre-pression (Figure 7) serves among other things
– to achieve the initial tightness,
– to bridge production-related tolerances,
– to ensure defined frictional forces,
– to compensate the compression set,
– to provide compensation for wear.

Depending on the application, the following values, referred to the cross-section (d_2), are recommended for the pre-pression: for dynamic use 6 to 20 %, for static use 15 to 30 %.

For the design of grooves the guide values for pre-pression can be taken from the

Figure 8: Permissible range of pre-pression as a function of cross-section
a) Hydraulic, dynamic load,
b) Hydraulic and pneumatic, static load.



diagrams in Figure 8 and Figure 9. These taken into account in accordance with ISO 3601-2 [1] the dependence on loads and the cross-section.

Surfaces

Elastomers adapt to irregular surfaces under pressure. For gas- or liquid-tight connections, however, minimum demands must be made of the surface quality of the surfaces to be sealed. Basically, for instance, scores, scratches, shrink holes, and concentric or spiral machining marks are not permitted.

Dynamic mating faces are subject in terms of surface quality to more stringent demands than static seals. There are as yet no standardized definitions for describing mating faces. The specification of the R_a value (roughness average) is in practice not sufficient to assess the surface quality. Manufacturer recommendations therefore contain different terms and definitions among others in accordance with DIN 4768 [2] and DIN EN ISO 4287 [3].

Figure 9: Permissible range of pre-pression as a function of cross-section
a) Pneumatic, dynamic load,
b) Axial-static load.

General technical data

O-rings can be used in a wide range of applications. Temperature, pressure and media determine the choice of suitable materials. To be able to assess the suitability of the O-ring as a sealing element for a given application, it is necessary to consider the interaction of all the operating parameters. Further information can also be obtained in the calculation program for O-rings of Trelleborg Sealing Solutions [4].

Usage criteria

Operating pressure

Static usage

In static usage the following values apply to the operating pressure:

– operating pressure < 5 MPa for inside diameters > 50 mm without back-up ring.
– operating pressure < 10 MPa for inside diameters < 50 mm without back-up ring (depending on material, cross-section and gap dimension).
– operating pressure < 40 MPa with back-up ring.
– operating pressure < 250 MPa with special back-up ring.

The permissible gap dimensions must be observed here.

Dynamic usage

In dynamic usage the following values apply to the operating pressure:

– operating pressure < 5 MPa in back- and forward-moving usage, without back-up ring.
– higher pressures with back-up ring.

Speed

In back- and forward-moving usage speeds of up to 0.5 m/s are permitted, in the case of rotating seals also up to 0.5 m/s. This applies in each case depending on material and application.

Temperature

Depending on material and media resistance, usage in the temperature range of –60 to +325 °C is permissible.

The short-time peak and continued-use temperatures and the operating time must be taken into account when assessing the

usage criteria. In the case of rotating usage the temperature increases caused by frictional heat must be observed.

Media
Virtually all liquids, gases and chemicals can be sealed with a large variety of materials with different properties. Details on the choice of suitable materials can be found elsewhere (see Elastomers). Further information can be found on the Internet, e.g, in the Chemical Compatibility database [5].

Notes on installation
Before starting installation, it is necessary to check the following points:
– Lead-in chamfers fashioned as per drawing?
– Internal bores deburred and rounded?
– Machining residues (e.g., swarf, dirt, foreign particles) removed?
– Thread crests covered?
– Seals and components greased or oiled? Media compatibility with elastomer must be ensured. It is recommended to use the medium to be sealed for lubrication. No lubricants with solid additives (e.g., molybdenum disulfide, zinc sulfide) may be used.

An installation-oriented design can eliminate potential causes of seal failure (examples in Figures 10, 11 and 12). Since O-rings are always installed with interference, lead-in chamfers and edge roundings must be provided.

Installation by hand
– Do not use any sharp objects.
– Look out for twisting, use aids and appliances for correct positioning.
– Use fitting aids wherever possible.
– Do not overstretch O-rings.
– Do not stretch O-rings made of extruded round cord over the joint.

Figure 10: Rod installation with O-ring

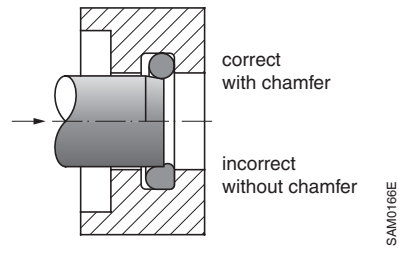


Figure 11: Piston installation with O-ring

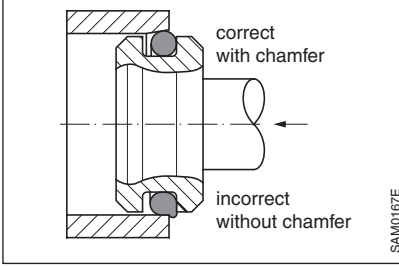

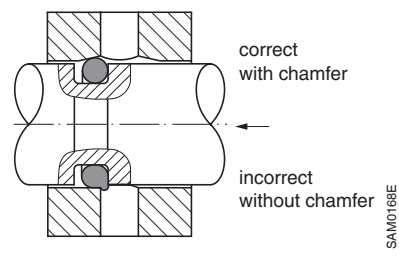

Figure 12: O-ring installation over cross-bores

Installation over threads, shafts, and similar
If the O-ring has to be guided during installation over threads, shafts, keyways or similar, a mounting sleeve will be required. This should not have any sharp edges or burrs and can be made of soft metal or plastic.

Lead-in chamfers
The minimum lengths of the lead-in chamfers are specified in Table 2 as a function of the cross-section d_2 (see also Figure 13 and Figure 14). The surface roughness of the lead-in chamfer is specified as:
$R_z \leq 6.3$ µm; $R_a \leq 0.8$ µm.

Installation types and information on installation-space design
Installation types
O-rings can be used in a variety of applications in components. The subsequent fitting situation must already be taken into account in the design. Sharp edges and bores should be circumvented so as to avoid damage during fitting. In the case of long sliding movements, the seal seat must if possible be stepped or the O-rings arranged in such a way that they only cover short mounting distances. Otherwise there is the risk of twisting.

Radial installation (static and dynamic)
The O-ring size in the case of rod seals (internally sealing) must be chosen in such a way that the O-ring outside diameter ($d_1+2\,d_2$) is at least equal to or greater than the installation-space outside diameter d_6 (Figure 2).

The O-ring size in the case of piston seals (externally sealing) must be chosen in such a way that the inside diameter d_1 is equal to or less than the groove-base diameter d_3 (Figure 2).

Axial installation (static)
In the case of axial-static installation, the pressure direction must be taken into account in the choice of the O-ring size (Figure 3). For internal pressure the O-ring outside diameter should chosen as being equal to or greater than the groove outside diameter d_7. For external pressure the O-ring inside diameter should be chosen as being less than the groove inside diameter d_8.

Elongation and upsetting
Radial installation of piston seal
When the O-ring is used as a piston seal (externally sealing), the nominal inside diameter d_1 of the O-ring (see Figure 2) should be elongated for dynamic applica-

Table 2: Lead-in chamfers

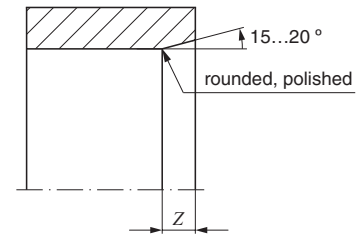

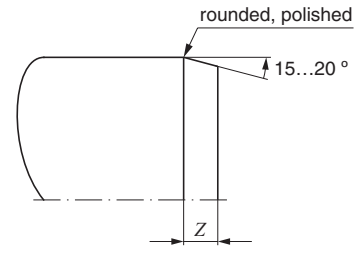

Figure 14: Lead-in chamfer for shafts and rods
Z Lead-in chamfer.

tions between 2 % and 5 % and for static applications between 2 % and 8 %. In the case of O-rings with an inside diameter d_1 < 20 mm it is not always possible to maintain this, which can result in a larger elongation range. To minimize the elongation range and the maximum stretching, it is necessary to minimize the diameter in the groove base d_3 (see Figure 2) and to impose less stringent demands on minimum stretching.

In dynamic applications it is important not to exceed a maximum elongation of 5 % so as to avoid detrimental effects on the sealing function. Basically, exceeding these recommended values will lead to a greater reduction of the O-ring cross-section, which as a result may impact on the service life of the O-ring.

Radial installation of rod seal
If the O-ring is used as a rod seal (internally sealing), the outside diameter of the O-ring (d_1+2d_2) should be at least equal to or greater than the outside diameter of the installation space (groove base) d_6 (see Figure 2) so as to achieve upsetting of the O-ring outside diameter. The outside diameter of the O-ring should for O-rings with a diameter d_1 > 250 mm not exceed 3 % of the groove outside diameter and 5 % for O-rings with a diameter d_1 < 250 mm. For O-rings with a diameter d_1 < 20 mm, this is not always possible on account of the tolerance position, which may result in greater upsetting of the outside diameter. Basically, exceeding these recommended values will lead to a marked increase in the O-ring cross-section, which as a result may impact on the service life of the O-ring.

Axial-static installation
If the O-ring is used as an axial-static seal, the pressure direction should be taken into account in the choice of the O-ring size (Figure 3). For O-ring pressurization the O-ring size should be chosen in such a way that prior to pressurization the O-ring fits closely on the groove flank on the non-pressure side. For internal pressure the O-ring should be chosen in such a way that the outside diameter (d_1+2d_2) of the O-ring is equal to or slightly greater (max. approximately 1 to 2 %) than the groove outside diameter d_7. For external pressure the O-ring should be approximately 1 to 3 % smaller than the groove inside diameter d_8.

Back-up rings
Back-up rings have no sealing functions, but, as the name suggests, are protective and supporting elements made of extrusion-resistant materials with a predominantly rectangular cross-section. They are installed together with an elastomer seal, as a rule with an O-ring, into a groove for static application. The close fit between back-up ring and bore or rod prevents the O-ring, which is under pressure, from extruding into the sealing gap.

Advantages
– Use of O-rings in high-pressure applications,
– use of O-rings of low hardness,
– compensation of large radial gap dimensions,
– externally and internally sealing application possible,
– used for static and back- and forward-moving or slowly rotating movements,
– compensation of gap enlargement by thermal expansion,
– static and dynamic applications.

Molded seal

Application

Downsizing and weight reduction in vehicles are imposing increasingly more stringent demands on the sealing systems. Engine components and add-on parts are increasingly being manufactured from plastics. Owing to the lower rigidity levels, plastic components are subject to greater deformation than metal components (e.g., axial and radial tolerances, tolerances due to high pressures).

Diecast metal components are as a rule not remachined, entailing greater component tolerances accordingly. These demanding requirements can be satisfied very well with elastomer sealing systems (Figure 1).

Sealing system

Influencing variables

Figure 2 shows the significant influencing variables for a sealing system. It depicts a molded seal for sealing between housing and cover. The system's requirements profile can be divided into the following stress types: mechanical (pressure, vibrations), chemical or physical (fluids or media), thermal, and electrical.

Design features

When it comes to the design features, the installation space (Figure 2, A1) is considered with its tolerances, flatness, the surface texture, the sealing gap, and the radius and flank angles. The installation space consists of the seals partners groove and counter-sealing face. The profile of the molded seal (Figure 2, A2) is matched under the criteria of compression and the clearance examination to the installation space.

Figure 1: Design examples
a) I-profile,
b) Double-I-profile,
c) T-profile.

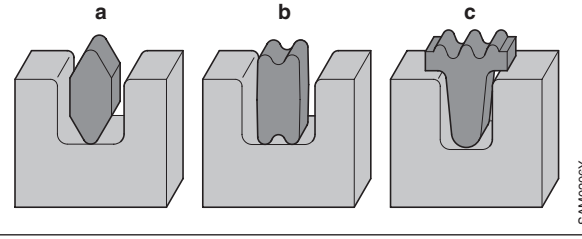

Figure 2: Significant influencing variables for a sealing system
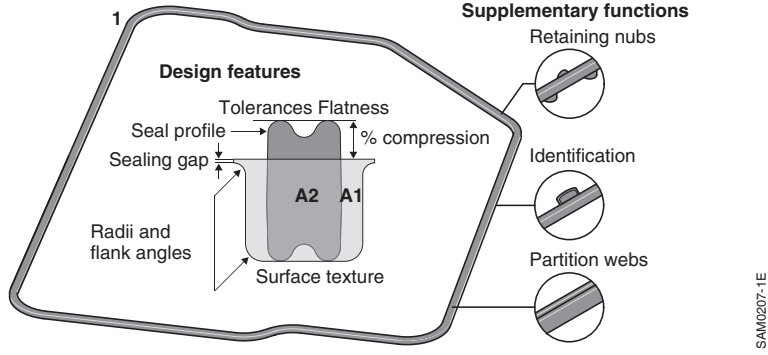
1 Molded seal (sealing between housing and cover).
A1 Installation space,
A2 Profile of molded seal.



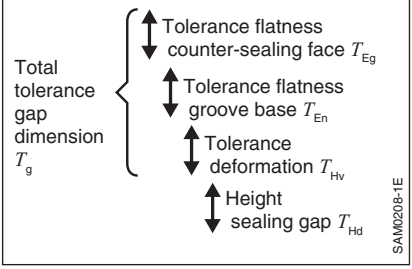


Figure 3: Relationship between gap dimension and sealing gap

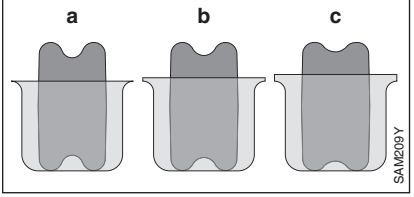


Additional functions can also be used on the molded part. Consequently, retaining nubs are used to provide transport retention for example during fitting, an identification for traceability, and partition webs for locating a leak.

The overview in Figure 3 shows the relationship between gap dimension and sealing gap. The gap dimension T_g is the sum of the component tolerances consisting of flatness of groove base T_{En} and counter-sealing face T_{Eg}, the bushing protrusion T_B and the entire widening and bending-up T_A (T_A and T_B are summarized in Figure 3 as Tolerance Deformation T_{Hv}). It is a theoretical dimension and is divided into three cases (Figure 4). If a sealing gap H_d is present in the design, this must be taken into account in the configuration of the compression.

Figure 4: Overview: minimum, nominal and maximum clearance

a) Maximum sealing, minimum installation, minimum clearance.
b) Nominal sealing, nominal installation, nominal clearance.
c) Minimum sealing, maximum installation, maximum clearance.

Finite-element method

The finite-element method is a numeric analysis method for obtaining estimates for complex technical problems (see Finite-element method). All FEM calculations are based on idealized input data. A calculation is expedient only if the input variables for the material model, the system's requirements profile (e.g., pressure, temperature, installation) and the geometry are known precisely. For example, the overall elongation of a seal can be determined after installation at room temperature and a defined overpressure. The results are shown in graphic form with the areas with differing elongation being colorized.

Flat seals

Application
Flat seals (gaskets) and their limits of use are very much dependent on the material used. Here, the applications vary in vehicle manufacturing from hot fluids, through strong chemical stress, to high pressures. Depending on the requirement, the flat seal can be sheathed in metal or even made up entirely of metal.

The different types of flat seal are as follows:
– Less hard-wearing: Paper, compressed fiber, elastomer, hard- and elastomer-bonded cork.
– Medium hard-wearing: Bonded glass-fiber, aramide-fiber, carbon-fiber and mineral-fiber seals (soft-material seals), elastomer-metal composite.
– Strongly hard-wearing: Expanded graphite, metal.
– Corrosion-resistant: Solid, expanded, filled PTFE; corrosion-resistant metal, elastomer-metal composite.

Variants
As the above list shows, there is a large variety of flat seals. Only the most important of this will be discussed in the following.

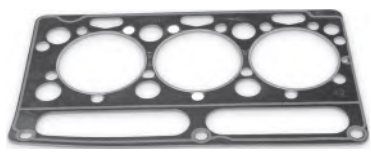
Cylinder-head gaskets
Cylinder-head gaskets (Figure 1) are fundamental static seals in the engine compartment. The complex flat seal as a rule consists of one or more coated metal layers with the possibility of having elastomer areas vulcanized on. The cylinder-head gasket not only seals against combustion gas, oil and coolant, but also acts as a power-transmission element between the cylinder head and the crankcase.

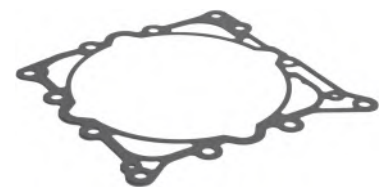
Soft-material seals
Soft-material seals made of elastomer-fiber composite materials are, in terms of their basic principle, some of the oldest seals. They depend first and foremost on the quality of their fibers and are very pressure- and temperature-resistant. They are used for example as intake-manifold seals and in exhaust-gas recirculation valves. Natural rubber, NBR, SBR, CR, HNBR and FKM are used (see Elastomers) as binders in elastomer-bonded soft-material seals. For higher stresses simply flat seals with expanded graphite or pure metal gaskets can be used.

Metal-bead gaskets
In the case of narrow sealing webs or low surface pressure, a good solution is to use metal-bead gaskets (used for example as cover gaskets in pressure applications). The surface pressure is reduced on account of the beads to a linear pressure. This allows a higher surface pressure with consistent screw force. An elastomer coating applied to the carrier plate also facilitates the micro-sealing effect.

Elastomer-metal flat seal
The flat seal made of an elastomer-metal composite is particularly suitable for preventing micro-leaks. This inherently sta-

Figure 1: Example of a cylinder-head gasket for a cylinder bank of a 6-cylinder engine with two exhaust and two intake valves





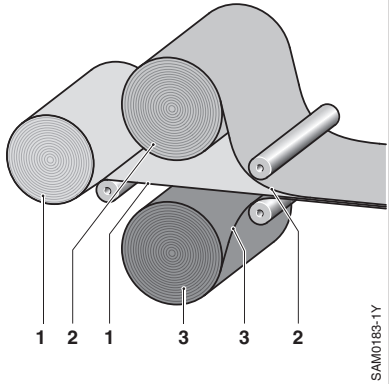


Figure 2: Flat seal in an electric-motor housing with integrated cooling

ble and at the same time adaptable seal consists of a thin metal layer with vulcanized-on elastomer layer (Figure 2). Stamped into complex geometries, the seal is ideal for use in primary frictional connection. With an elastomer-layer thickness of at least 0.2 mm, it also offers the opportunity of compensating for shrink holes and pores in the casting. The elastomer-metal flat seal is used in flange joints, pumps, automatic transmissions, and electric motors.

Figure 3: Coil production
1 Metal carrier,
2 First elastomer coil,
3 Second elastomer coil.

Sealing caps

Application
Sealing caps belong to the group of static seals. They facilitate the reliable sealing of assembly- or production-related bores at various points in the engine compartment. Design engineers can always choose between the standard solution according to DIN 443 [6] and other special types which meet the high requirements of the automotive industry.

The standard solution according to DIN 443 describes a cap made of metal which is generally pressed into the housing and provides secure sealing only by means of an additional adhesive connection. Set against these caps are sealing caps, which have an elastomer layer and do not required any additional adhesives. The elastomer layer furthermore facilitates installation without damaging the housing surface and thereby prevents micro-leak paths.

Technology
Metal sealing caps are worked in a deep-drawing process from the coil material into the finished product. The favorable elastomer-metal sealing caps can be manufactured in different ways. Possible production processes are compression molding, injection molding, lamination or vulcanization. One innovative production process involves the technology whereby multiple-layer rubber-metal connections are produced, and then stamped and deep-drawn as composite material (Figure 3).

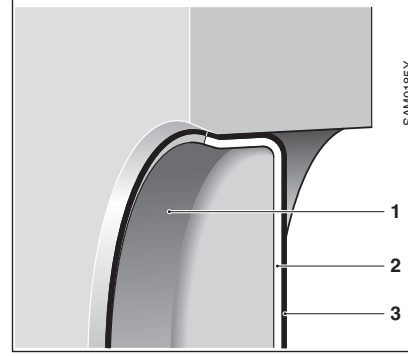
The process of applying a binder to metal carriers and vulcanizing elastomers on metal creates secure and solid connections which can be fashioned into complex seal geometries. In this way, flat seals, seals with metal frames for automated handling, friction-optimized guide bands, and housing gaskets and sealing caps can be specifically produced.

Often, as a result of the optimized rubber-metal connection, the surfaces of the sealing faces no longer have to be machined in a complicated process. The elastomer layer improves sealing performance and, furthermore, no adhesives or sealing compounds are required in

production, enabling the cycle times in assembly to be reduced and the production process to be fashioned in a more process-reliable way. Users gain cost advantages through simpler handling, the possibility of automation in assembly, and reduced logistics expenditure. There are cost-reduction potentials, particularly in respect of injection-molded sealing caps.

Examples in practice

Engine blocks are produced by sand casting. At the end of the production process, the engine block features a number of bore holes which cannot be avoided from a production standpoint, but must nevertheless be sealed. Rubber-metal sealing caps offer an ideal solution to this since they are easily mounted, not bonded, and rustproof. The installation situation is pictured in Figure 4.



There are further possible uses in the form of static sealing of bore holes in the transmission and in steering systems. But rubber-metal sealing caps are also used in practice in the camshaft housing and crankcase and in pumps.

Variants

Rubber-metal sealing caps can be manufactured from different materials. Steel, galvanized steel and stainless steel may be used as metal materials. Possible elastomer materials are NBR, EPDM and AEM, and hence provide for a temperature range of –45 to 150 °C and different media-resistance capabilities.

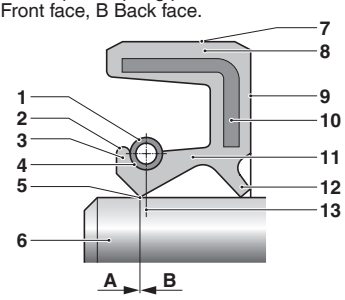
Radial shaft seal

Application

Radial shaft seals are ring-shaped sealing elements the purpose of which is to separate permanently and safely from each other oil or grease from the inside and, for example, dirt, dust or water from the outside. Radial shaft seals are used in drive systems (axles and transmissions, e.g., Simmer shaft seal), pumps, electric motors, and in machine-building.

Design

Radial shaft seals generally consist of a sealing lip of elastomer material and a strengthening ring of metal. A tension spring lends the sealing lip its constant pre-tension over the entire service life (Figure 1). The sealing lip is the end of the diaphragm (sealing cup). The sealing edge is the area of the sealing lip that touches the shaft and assumes the actual sealing function.



The sealing-lip geometry corresponds to today's state-of-the-art and is based on many years of application-technology experience. The sealing edge can be press-finished or manufactured at the face by mechanical cutting.

The entire radial force of the seal is created by the initial force of the elastomer sealing lip and the tensile force of the spring. The former is obtained depending on deformation from the elasticity of the material, the sealing-lip geometry, and the overlap between the shaft and the seal.

Specifically for the automotive industry the function and application-related information regarding radial shaft seals are described in DIN 3761 [7] and in ISO 6194 [8].

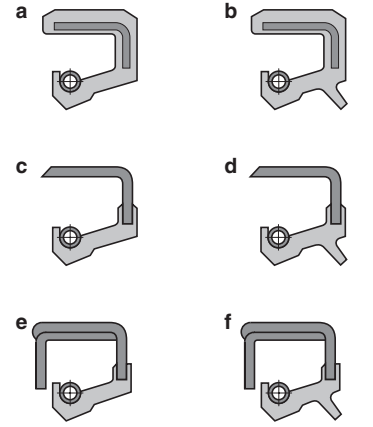
Seal design

Standard types



Radial shaft seals are available in standard types according to DIN 3760 [9] and DIN 3761 or ISO 6194. Figure 2 shows versions in which the strengthening ring is completely enclosed in elastomer and versions in which the strengthening ring is embedded in elastomer only in the area of the diaphragm and consequently forms the casing of the shaft seal (adhesion part to which the elastomer adheres).

Special types

Special types are used when application parameters are outside the scope of DIN 3760 and DIN 3761 or ISO 6194. This can be increased speed above 10 m/s, pressure above 0.05 MPa, grease used

Figure 2: Radial shaft seals in standard types

Standard types acc. to DIN 3760 and DIN 3761 or ISO 6194.
a) DIN 3760 Type A, b) DIN 3760 Type AS

e) DIN 3761 Type C, f) DIN 3761 Type CS

instead of oil as the medium to be sealed, or increased dirt accumulation. It is recommended to use a special seal in all these situations. Figure 3 shows some special types by way of example.

Main features

The main features to be observed in any choice of seal is the outer casing, the strengthening ring, the tension spring, and the material.

Outer casing

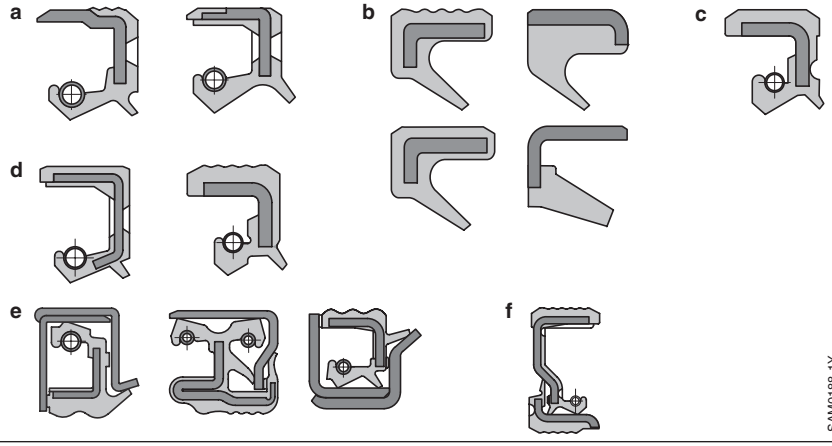
The outer casing can be either smooth or grooved; in both cases the seal can be pressed into bores in accordance with ISO fit H8. The outside diameter of the radial shaft seal is manufactured in accordance with ISO 6194-1 (Table 1).

Metal strengthening ring

Cold-rolled sheet steel in accordance with DIN EN 10139 [10] is used for the standard version. Depending on installation conditions and environmental conditions, however, other materials such as brass and stainless steel (steel grade 1.4301 in accordance with DIN EN 10088-3 [11]) may come into play.

The primary purpose of the strengthening ring is to stiffen and reinforce the radial shaft seal. Normally, this ring may not be subjected to axial load. Should this be necessary, a special version of the strengthening ring may also be used (e.g., metal version, partly rubberized version).

Tension spring



When rubber is exposed to heat, load or chemical stress, it gradually loses its original properties. This is called rubber aging. The original radial force of the sealing cup is lost. The primary purpose of the tension

Table 1: Tolerances acc. to ISO 6194-1

Outside diameter d_2 nominal [mm]	Diametrical tolerances [mm]	
	Metal housing	Rubber-coated
$d_2 <$ 50	+0.20 +0.08	+0.30 +0.15
50 < $d_2 <$ 80	+0.23 +0.09	+0.35 +0.20
80 < d_2 < 120	+0.25 +0.10	+0.35 +0.20
120 < d_2 < 180	+0.28 +0.12	+0.45 +0.25
180 < d_2 < 300	+0.35 +0.15	+0.45 +0.25
300 < d_2 < 500	+0.45 +0.20	+0.55 +0.30

Figure 3: Special types of radial shaft seals

a) Types with semi-rubberized outside diameter, b) Rotary seals without tension spring, c) Type for medium to high pressures, d) Types for medium pressures, e) Cassette seals, f) System-shaft seals.

spring therefore is to maintain the radial force.

Tests have shown that the radial force must be different depending on size range and sealing-ring type. It has also emerged from these tests that it is very important to keep the deviations of radial force during the life of the seal within tight limits. The radial force has been established by comprehensive laboratory tests.

The tension spring is coiled tightly and with pre-tension. The total force of the tension spring thus comprises partly the pre-tension and partly the force obtained from the spring rate. Using a tension spring with pre-tension offers the following advantages:
– In the event of sealing-lip wear, the part of the total radial force resulting from the spring pre-tension remains unchanged.
– Through partial softening of the spring (by heat treatment) the pre-tension can be regulated in such a way that the envisaged radial force is achieved for the respective shaft diameter.

Elastomer material of the seal

The main features for ensuring reliable functioning of radial shaft seals are both the correct design and the choice of the correct material. Therefore the choice of material must be taken into consideration as one of the most important decisions with regard to media compatibility and environmental conditions. Some material properties which are directly connected to the environmental conditions are:
– good chemical resistance,
– good resistance to heat and cold,
– good ozone and weather resistance.

Functional material requirements are among others:
– high resistance to wear,
– low friction,
– low deformation by compression,
– good elasticity.

For cost reasons, good workability is desirable as an additional property. None of the materials available today can satisfy all these requirements. The choice of material therefore always constitutes a compromise between the relative importance of the respective factors.

Table 2: Material recommendations

Materials for sealing conventional media		Material designation				
		NBR	FKM	ACM	VMQ	HNBR
		Material code				
		N	V	A	S	M
		Max. permissible continuous temperature [°C]

NBR Nitrile butadiene rubber, FKM Fluorine rubber, ACM Acrylate rubber, VMQ Silicone rubber. HNBR Hydrogenated nitrile butadiene rubber.

Materials and their designations are
– nitrile butadiene rubber (NBR),
– acrylate rubber (ACM),
– silicone rubber (VMQ),
– fluorine rubber (FKM),
– hydrogenated nitrile butadiene rubber (HNBR).

Hydrogenated nitrile butadiene rubber (HNBR) is a further development of conventional nitrile butadiene rubber (NBR). This material offers substantially improved heat and ozone resistance and can be used instead of acrylate rubber and in certain cases also instead of fluorine rubber. A special composition is developed for each rubber type in order to satisfy the requirements imposed on seals. In addition, still more compounds are available for some extreme conditions.

Table 2 sets out material recommendations for various applications.

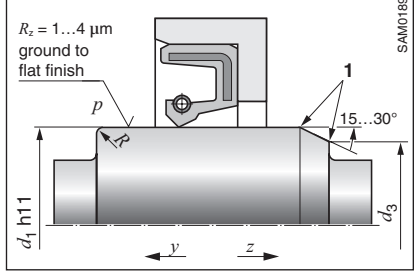
Design of shaft and bore

Surface texture, hardness and machining method

The shaft design is of crucial importance both to the seal and to the service life (Figure 4). Basically, the higher the circumferential speeds the greater the hardness of the shaft should be. It is established in DIN 3760 that the shaft must exhibit a hardness of at least 45 HRC. As the circumferential speed increases, the demand for hardness rises, and at 10 m/s a hardness of 60 HRC is required.

The choice of appropriate hardness is not only dependent on the circumferential speed, but also influenced by factors such as lubrication and particles that cause wear. Poor lubrication and difficult external conditions (e.g., high dust deposits on construction machinery) therefore require a higher shaft hardness. DIN 3760 and DIN 3761 lay down maximum values for the surface roughness; a surface roughness of R_t = 1 to 4 µm (maximum roughness) is recommended. It has, on the other hand, emerged from laboratory tests that the most favorable roughness is R_t = 2 µm (roughness average R_a = 0.3 µm). Both rougher and finer surfaces cause higher friction, which results in higher temperature and increased wear. Consequently, a roughness of R_t = 2 to 3 µm (R_a = 0.3 to 0.5 µm) is to be recommended.

Friction and temperature measurements have also shown that grinding the shaft is the best machining method. Spiral grinding marks can however cause a pumping effect and leakage, which is why plunge-cut grinding should be chosen. Whole-number conditions of wheel speed to workpiece speed must be avoided here. Polishing the contact surface with emery cloth produces a surface texture which causes higher friction and temperature build-up than plunge-cut grinding.



In some cases it is not possible to furnish a shaft with the hardness, surface quality and corrosion resistance required for the seal. However, this problem can be solved by fitting a separate sleeve on the shaft. In the event of wear, only the sleeve has to be replaced.

Radial run-out

Radial run-out of the shaft is to be avoided wherever possible or kept within the tightest limits. At high rotational speeds the sealing lip is at risk of not being able to follow the shaft due to its inertia. The shaft seal must be arranged in direct proximity to the bearing (e.g., roller bearing) and the bearing clearance kept as small as possible (Figure 5).

Figure 4: Shaft design

1 Edge rounded and polished, lead-in chamfer 15 to 30 °.
d_1 Diameter of shaft, tolerance h11,
d_3 Inside diameter of chamfer,
R Radius,
R_z Average peak-to-valley height,
p Pressure of medium,
y, z Direction of installation.

Deviation in concentricity
A deviation in concenticity between the shaft and the accommodating bore is to be avoided wherever possible so that the sealing lip is not subjected to load on one side (Figure 6). Depending on the direction of installation y or z, it is recommended to incorporate a chamfer or a radius. The dimensions for this are shown in Figure 4 and Table 3.

Properties of the shaft surface
The values of the moving surface are established for shaft seals in DIN 3760 and DIN 3761 or ISO 6194. The surface should exhibit the following properties:

Surface roughness
R_a = 0.2 to 0.5 µm (arithmetic roughness average),
R_z = 1 to 4 µm (average peak-to-valley height),
R_{max} (= R_t) = 6.3 µm.

Table 3: Chamfer length for the shaft end

Diameter d_1	Diameter d_3	Radius R
$d_1 <$ 10 mm	d_1 – 1.5 mm	2 mm
10 mm ≤ $d_1 \leq$ 20 mm	d_1 – 2.0 mm	2 mm
20 mm ≤ $d_1 \leq$ 30 mm	d_1 – 2.5 mm	3 mm
30 mm ≤ $d_1 \leq$ 40 mm	d_1 – 3.0 mm	3 mm
40 mm ≤ $d_1 \leq$ 50 mm	d_1 – 3.5 mm	4 mm
50 mm ≤ $d_1 \leq$ 70 mm	d_1 – 4.0 mm	4 mm
70 mm ≤ $d_1 \leq$ 95 mm	d_1 – 4.5 mm	5 mm
95 mm ≤ $d_1 \leq$ 130 mm	d_1 – 5.5 mm	6 mm
130 mm ≤ $d_1 \leq$ 240 mm	d_1 – 7.0 mm	8 mm
240 mm ≤ $d_1 \leq$ 500 mm	d_1 – 11.0 mm	12 mm

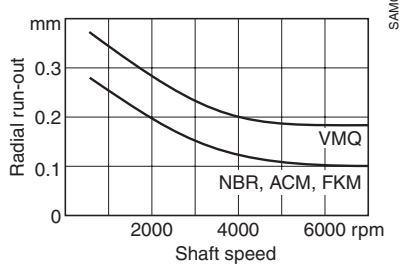
Hardness
55 HRC or 600 HV,
hardness penetration depth at least 0.3 mm.

Housing bore for the shaft seal
The housing dimensions are shown in Table 4 and Figure 7. The tolerances for the metric sizes comply with DIN 3761 or ISO 6194 so that a good press fit is achieved for a tolerance in the housing bore with ISO H8. For the imperial sizes (inches) the tolerances conform to the American standards. In installation cases where the housing bore has a different tolerance, the seal can be manufactured with a matching interference. A special fit between the seal and the bore may be required for housing bores of soft material, e.g., light alloy, in common with bearing housings with thin walls. The tolerances for seal and bore must in such cases by defined by practical tests.

If a part, e.g., a bearing, is pressed by the seal seat, this can be damaged. To avoid such damage, the seal must be chosen with a larger outside diameter than that of the bearing.

Surface roughness of the housing bore
The values for the surface roughness in the housing bore are specified in ISO 6194-1. The following values are recommended:
R_a = 1.6 to 3.2 µm,
R_z = 6.3 to 12.5 µm,
R_{max} (= R_t) = 16 to 25 µm.

Figure 5: Radial run-out



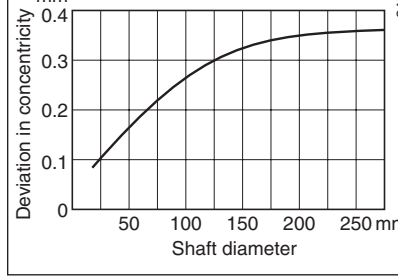


Figure 6: Deviation in concentricity

For metal-caged seals (not rubberized) or required gas tightness, a good scoring-free, flat-finish surface quality is required. If the radial shaft seal is glued in the housing, it must be ensured that no adhesive comes into contact with the sealing lip or the shaft.

Installation instructions

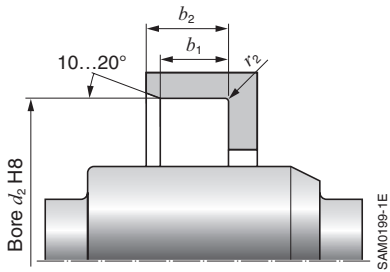
The following points must be observed in relation to installing radial shaft seals:

- The installation spaces must be cleaned prior to installation.
- In the case of rubber seals, shafts and seal must be greased or oiled.
- Sharp-edged transitions must be chamfered, rounded or covered.
- When pressing in, it is important to ensure that the seal is not tilted.
- The press-in force must be applied as closely as possible to the outside diameter.
- The seal must be seated centrically and perpendicularly to the shaft.
- The end face of the locating bore is usually used as the stop face; the seal can also be secured with a shoulder or a spacer.

Table 4: Housing dimensions

Width of seal b mm	b_1 min. (0.85 b) mm	b_2 min. (b + 0.3) mm	r_2 max. mm
7	5.95	7.3	0.5
8	6.80	8.3	
10	8.50	10.3	
12	10.30	12.3	0.7
15	12.75	15.3	
20	17.00	20.3	

Figure 7: Housing dimensions: installation depth and lead-in chamfer
Quantities, see Table 4.



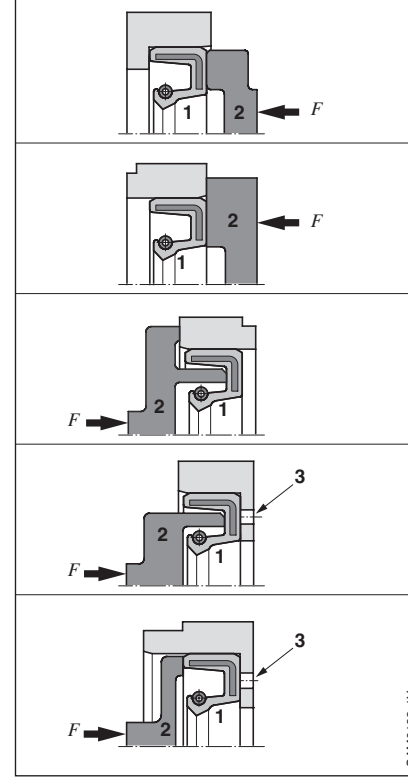


Figure 8 shows different press-in situations for the radial shaft seal with suitable mounting tools or devices.

Removal and replacement

Generally speaking, the removal of seals does not pose any difficulties. A screwdriver or similar is usually sufficient to remove them. The seal is damaged in this process. After a machine has been repaired or overhauled, new radial shaft seals should always be fitted, even if the old seals still appear to be intact.

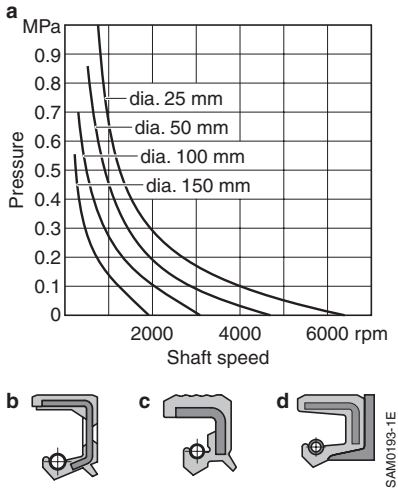
The sealing edge of the new ring should not rest on the old running point. This can be achieved by

Figure 8: Installation aids in the mounting of radial shaft seals
1 Radial shaft seal,
2 Mounting tool,
3 Removal hole.
F Press-in force.

– replacing the shaft protective sleeve,
– pressing into the locating bore to a different depth,
– reworking the shaft and fitting a shaft protective sleeve.

Usage parameters

Overpressure

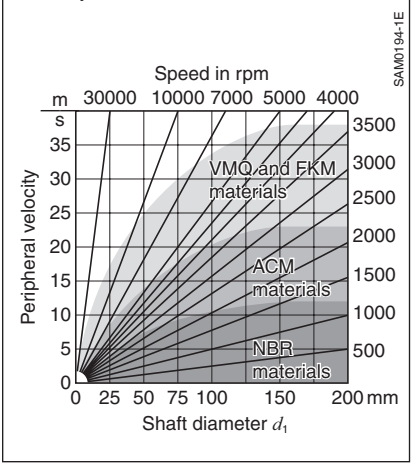


If the sealing cup is subjected to overpressure, it is pressed against the shaft, increasing the contact area of the sealing lip against the shaft. This increases friction and heat build-up. At overpressure, therefore, the guide values for the maximum permissible circumferential speed are not applicable, but instead these must be decreased in proportion to the intensity of the pressure. At high circumferential speeds, however, already overpressures of 0.01 to 0.02 MPa can cause problems. By using an additional back-up ring, it is possible to use the DIN types A, AS, C and CS pictured in Figure 2 above 0.05 MPa. The separate back-up ring is to be adapted to the back face of the sealing cup. It should not however rest on the sealing cup while there is no overpressure applied. The back-up ring must be adjusted to fit as accurately as possible.

In type TRU the strengthening ring is fashioned in such a way that it supports the sealing cup (Figure 9). Type TRP has a short and sturdy sealing lip which permits an overpressure without additional support. When a back-up ring is installed or when thrust rings are used, overpressures of 0.4 to 0.5 MPa can be permitted at moderate circumferential speeds.

At high overpressures seal types with rubber outer casings should be chosen (type TRA) so as to prevent leakage at the locating bore. At overpressure the seal is at risk of shifting in the axial direction in the housing bore (pressing out). This can be avoided by securing the seal with a shoulder, a spacer ring or a retaining ring.

Figure 9: Permissible pressure of the medium to be sealed for supported radial shaft seals and for pressure seals

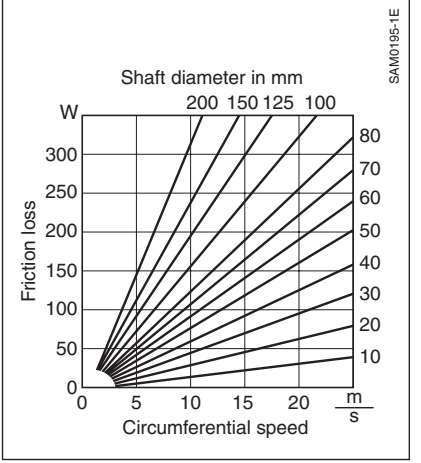


a) Diagram,
b) Type TRU,
c) Type TRP/6CC,
d) Type TRA/CB with back-up ring.

Circumferential speed and rotational speed

Different sealing-cup designs influence the level of friction and thus result in varying temperature increases. The upshot of this is that the different sealing-cup designs permit different circumferential speeds. Figure 10 features guide values for the maximum permissible circumferential speed for sealing elements without protective lip made of NBR, ACM, FKM

Figure 10: Permissible speeds in state at zero pressure acc. to DIN 3761



and VMQ in operation at zero pressure and where adequate lubrication or cooling of the sealing edge is guaranteed by the medium to be sealed. The permissible continuous temperatures in Table 2 must be taken into account and may not be exceeded. The bend demonstrates that larger shaft diameters permit higher circumferential speeds than smaller shaft diameters. This is because there is greater heat dissipation as the shaft cross-section increases.

Friction losses

Friction loss is often of a magnitude that must be taken into account. This applies particularly when lower power output is transmitted. Friction loss is influenced by the following factors: Seal design and seal material, spring force, rotational speed, temperature, medium, shaft design, and lubrication.

Figure 11 demonstrates which friction losses in watts are caused by a radial shaft seal without protective lip when it is installed according to the manufacturer's technical directions. In certain cases the friction loss can be reduced by special sealing-lip design. Decreasing the spring force or using a special rubber quality can also achieve the same result. In this connection it must be noted that the friction loss during the seal's "breaking-in period" is greater than that shown in Figure 11. The standard breaking-in period is a few hours.

Figure 11: Friction loss for a nitrile-rubber seal, type TRA

Pneumatic seals

Sealing against compressed air entails a variety of challenges, which are faced with pneumatic valves. Different factors from those relevant to hydraulic seals come to the fore.

As a rule, pneumatic applications are operated with an air pressure of 0.8 to 1.0 MPa, in exceptional cases up to 1.6 MPa, and for high-pressure valves sometimes even up to 5.0 MPa. Speeds are in the range of 0.2 to 1.0 m/s, and in special applications up to 5.0 m/s.

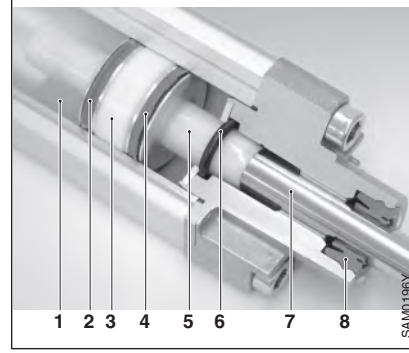
Leakage, friction and lubrication
The leakage of air plays a subordinate role. Friction has a much greater influence on the power output of a pneumatic application. Lubrication is therefore very important. Since the use of oiled air is declining, most pneumatic sealing systems are lubricated with grease on a one-off basis during installation. This lubrication must be maintained over the entire service life. One resulting requirement imposed on a pneumatic seal is hence that the lubricating grease is not wiped in the application. There are therefore differences, when compared with hydraulic seals, in the geometry of the sealing edge and the resulting pressure path.

Alternatively, seals with dry-running properties can be used. However, these are for the most part ruled out for economic reasons.

Sealing system
The most important components of a pneumatic sealing system are pictured in Figure 1.

Piston seals
Piston seals are as a rule “internal” seals and ensure that a pneumatic cylinder can move in that they prevent the medium (air or gas) from overrunning. Piston seals are seated on the moving component and are for the most part double-acting, i.e. the seal acts in both directions. It seals when the piston moves to the left and when it moves to the right. This is often manifested in a symmetrical profile.

Rod seal
Rod seals are as a rule “external” seals and ensure that no medium can escape to the atmosphere. Rod seals are seated in the housing and are for the most part single-acting. The seals acts only in one direction, with these frequently being manifested in an asymmetrical profile.



Dirt wipers
Dirt wipers protect the system against dirt, foreign particles, swarf, and moisture. This prevents premature failure of the components. Single- and double-acting wipers are used, depending on the application and sealing system.

Cushioning seal
Cushioning valves damp the impact of the piston and also assume the function of a non-return valve.

Guide band
Guide bands guide the piston and the rod. They accommodate radial forces, absorb vibrations, and prevent metal-to-metal contact.

Figure 1 shows a standard cylinder comprising the above-mentioned components.

Figure 1: Sealing system of a pneumatic cylinder with piston seal and rod seal
1 Cylinder barrel, 2 Piston seal,
3 Guide band, 4 Piston seal,
5 Piston extension, 6 O-ring, 7 Piston rod,
8 Rod seal.

Design types
Aside from classic profile seals such as the O-ring or the X-ring, there are also standard sealing elements for pneumatics. Figure 2 shows some of these seals.

Beyond simple sealing elements the trend is towards the assembly such that complete pistons are already used in many applications (Figure 3).

Materials
Different materials are used to suit the application: Elastomers, polyurethane and polytetrafluoroethylene (PTFE).

Elastomer seals
Elastomer materials (above all NBR and FKM) are, thanks to their cost effectiveness, the main material used in the production of pneumatic seals. Simply fitting is a positive side effect. Challenges for elastomer seals can be presented by high abrasion.

Figure 2: Pneumatic seal profiles for standard cylinders

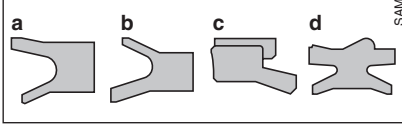
(cf. Figure 1, Profile of rod seal).



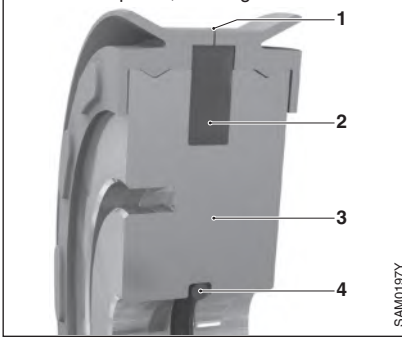


Figure 3: Pneumatic complete piston
1 Double-acting seal arrangement,
2 Magnet ring (for position sensing),
3 Aluminum piston, 4 O-ring.

Polyurethane seals
As belonging to the family of elastomers, polyurethane must be considered separately. As an abrasion-resistant and flexible material, it is often classified between elastomers such as NBR, FKM and PTFE.

PTFE seals
Compared with elastomers, PTFE is frequently not cost-effective because of the manufacturing process involved. It does however offer advantages in conditions of high pressure, wear and friction when there is no lubrication.

Applications
Pneumatic components are used in practically every branch of industry. They feature most strongly in automation engineering or process automation. Here, pneumatic units are used among others for gripping, turning, separating, suction or driving. These components ensure highly efficient, precise and economical production and assembly systems. Open and closed loop control is performed by pneumatic cylinders and valves.

Another area of application is commercial vehicles (trucks, buses, trains). Here they are used in the drive, chassis and suspension, and transmission, in among others non-return valves, pressure-control valves, and switching valves. Cylinders are used in these sectors for example for the precise control of throttle valves.

But pneumatic systems are being used with increasing regularity in other sectors such as biosciences, the food and drinks industries, the chemical process industry, and the electronics industry.

Two-component seals

Multi-component injection molding
Basically, the term multi-component injection molding covers all materials and their combinations which can be combined in the injection-molding process. The following material combinations are the most frequently encountered at present:
– thermoplastic with thermoplastic,
– thermoplastic with thermoplastic elastomer,
– thermoplastic with elastomer,
– multi-color injection molding.

Basic principles
There are various process technologies which can be used in the manufacture of multi-component molded parts. All production technologies are based on the same production process, which works with two or more injection units; however, an explicit distinction is made here between the single-stage process and the two-stage process.

Single-stage process
In the single-stage process the premolded part is transported by a handling unit from one side to the other station in the mold. The later multi-component molded part is now either ejected by means of a mold movement (e.g., ejector pin) or else removed by the handling unit and deposited on a cavity-specific basis. Only one closing unit (machine) is used here.

Two-stage process
In the two- or multi-stage process one of the components can even be made of metal with engineers currently endeavoring to replace metal parts as much as possible with technical plastics and hence to achieve a weight reduction. The two- or multi-stage process is performed by way of at least two closing units and hence on two autarkic machines or tools. Here too the insertion parts (metal) or premolded parts are inserted into the designated cavities of the respective mold and ejected by mold movement or deposited by a handling unit or a robot on a cavity-specific basis.

Process technologies
A distinction can basically be made in the process technologies between processes with separate contours, components or with contours that run into each other or components.

Composite injection molding
In the case of composite injection molding the combinations should exhibit good chemical adhesion to each other, such as for example a seal to technical components.

Assembly injection molding
Here material combinations that exhibit no chemical adhesion to each other are chosen, since otherwise the function of the component (e.g., a joint) is no longer assured.

Sandwich injection molding or co-injection technique
In this process different material properties are combined with each other, e.g., a rigid outer skin with a foamed core; therefore there does not necessarily have to be adhesion.

Multi-color injection molding
Here the same material is processed in different colors in one component (e.g., in multi-color car tail lights).

Fill simulation (mold flow analysis)
In all the processes mentioned and the design of molds, fill simulation is today one of the most important aids in the field of multi-component injection molding. It delivers detailed results and shows how problems can be avoided across the full injection-molding process. It provides useful information on pressure and temperature distribution and on possible positions of air pockets and joint lines in the component to be produced. In this way, potential flaws in molded parts and molds can in a fill simulation already be detected and eliminated in the development phase.

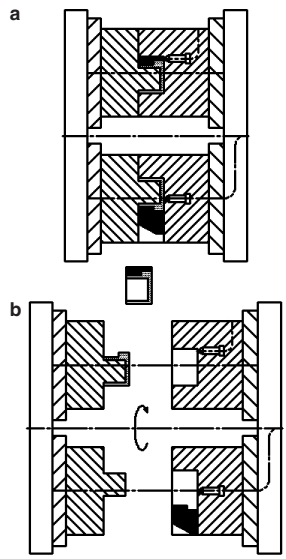
By detecting these potential flaw sources early, it is possible already at an early stage to eliminate the potential cost drivers in multi-component injection-molded parts.

Composite techniques
With the composite techniques there are a number of ways of combining the materials with each other. The correct composite technique depends here on a number of factors: Use of the component, choice of the materials used, mechanical load on the component, and quantities of the component required. According to these criteria the following composite techniques are currently predominant:
– mechanical bonding by undercuts,
– chemical bonding of the two materials,
– chemical bonding by previous priming (bonding agent),
– chemical bonding by surface treatment of the substrate.

Tool techniques
Rotary table
The rotary table is as a rule located between the closing-side mold half and the clamping plate. In this way it is possible to place components from a first cavity into a second cavity. First the material is injected into a first cavity (Figure 1). After intermediate opening and turning, the pre-molded part is now introduced into the second cavity. The cavity additionally opens a cavity for the second plastic. Following a successful injection process the mold is opened again and the finished two-component part is ejected. In parallel with this second operation the next pre-molded part is already produced in the first cavity.

Turning tool
With this turning technique the turning movement is effected not on the machine side, but by a mechanism in the mold (Figure 2). This can be performed for example by a plate in the mold.

Figure 1: Rotary-table process
a) Simultaneous filling of both cavities.
b) Finished part is ejected, turning of the rotary table on the machine plate including the pre-molded part.



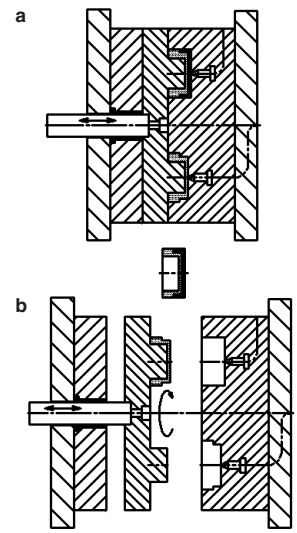


Figure 2: Turning tool
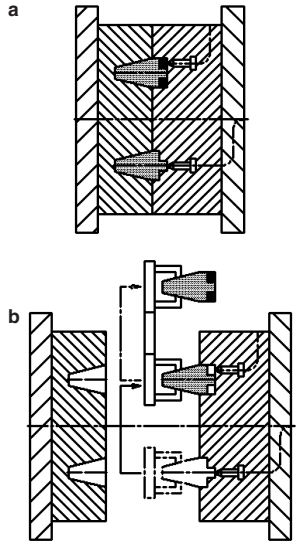
a) Simultaneous filling of both cavities.
b) Finished part is ejected, turning of the mold plate including the pre-molded part.

Turnstiles and turning cores
Instead of turning the complete closing-side mold half, in this solution only an intermediate plate in the mold (also called indexing plate) is turned with the pre-molded part.

Transfer technique or insertion technique
With the transfer or insertion technique the pre-molded part is transferred or inserted, via a gripper robot or by hand, from one cavity to the other (Figure 3). The second material is then injected here. Transfer technique also refers to the manufacture of the pre-molded part on a machine, removal and insertion in a second machine, and hence a two-stage process.

Core-back technique (slide technique)
The core-back technique (Figure 4) offers the opportunity of manufacturing two-component parts without having to open the mold. The first plastic is injected while the cavity for the second component is kept sealed by a sliding insert in the mold. Once this injection process has finished, the sealed cavity can be opened and the second component processed after the slide is actuated. On contact of the second material the contact-surface temperature can be monitored and adjusted much more effectively with this process than with rotating tool systems.

Figure 3: Transfer or insertion technique
a) Simultaneous filling of both cavities.
b) Finished part and pre-molded part are removed or inserted by the handling unit.



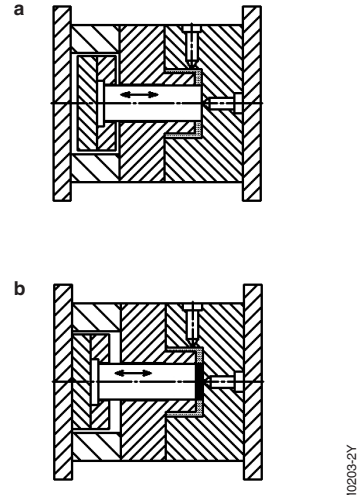


Figure 4: Core-back or slide technique
a) Cavity is filled with one component.
b) Core or slide is pulled and thus the sealed cavity is opened.

Rod and piston sealing systems

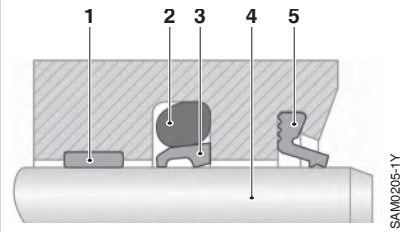
Hydraulic rod seals

Elements

A rod sealing system as a rule consists of five elements (Figure 1): Rod seal, rod guide, wiper, rod surface, and hydraulic fluid. The individual elements interact with each other. For example, a guide with a lot of play necessitates a seal which can elastically compensate this play. This must be observed particularly in a low-temperature application (–40 °C), since the flexibility of the elastomer decreases (see Elastomers). A further interaction can arise for example between the sealing element and the rod. If the rod surface is too rough, wear will occur on the sealing element, possibly on the wiper, and on the guide band. This wear results in leakage, even though the seal is not the cause of this.

Design

Rod seals are asymmetrical seals whose profile is optimized by a sealing edge in such a way that they can as effectively as possible wipe the medium to be sealed from the rod and hence provide a seal. The choice of sealing element is primarily dependent on pressure, required friction, temperature, media resistance, viscosity, lubricity, and price. The following general rule can be formulated: If the price and not the friction at medium pressures is the dominating factor and liquids of normal viscosity and lubricity are involved, elastomer grooved rings or polyurethane (PU) can be used. If, on the other hand, low friction or higher pressures are required, PTFE sealing-edge rings are to be recommended. The same applies in the case of high viscosity or poor lubricity.



PTFE seals are activated by an elastomer energizing element – usually an O-ring – since PTFE has no rubber-elastic properties. It does however have very low friction and high dimensional stability. PTFE sealing-edge rings do not wipe the hydraulic fluid out of the rod-surface topography as well as elastomer and PU seals. They should for this reason exhibit sufficiently good back-pumping behavior, i.e. they should have the capacity to delivery a lubricant layer of a few molecule layers drawn out during the advance stroke back against the primary pressure into the pressure chamber during the return stroke. Thanks to this behavior, PTFE seals have the advantage of always running on a few molecule layers, which increases their service life. In contrast, PU and elastomers wipe the fluid from the surface in order to be tight. They exhibit only limited back-pumping capacity. On account of the lubricated extension and retraction and the low friction coefficient, the seal is prevented from squeaking or humming much more effectively than PU or elastomer seals.

Such systems are used for example in sealing the piston rod of a single-tube shock absorber or in sealing the rack of a hydraulic rack-and-pinion steering system. In this way, even the translatory movements of a positioning cylinder can be sealed in transmissions or in clutches.

Wipers

The function of wipers is to wipe dirt, dust and water from the rod and thus keep them away from the sealing system. Sealing-edge rings are used together with double wipers (with a wiper lip and an inward-wiping sealing lip) or with double-edge wipers (with a lip on which a wiper lip and a sealing edge are positioned). Double-edge wipers have a lower friction than double wipers. Grooved rings manage with a one-lip wiper. They constitute a compromise between a sharp wiper edge with good wiping properties and a

Figure 1: Hydraulic rod seal
1 Guide band, 2 O-ring, 3 Seal, 4 Shaft, 5 Wiper.

minimally rounded edge which does not wipe fluids as consistently.

Elastomers or PU can be used as materials for wipers. In exceptional cases PTFE can be used if substances permanently adhered to the rod are to be wiped. Even for wipers which do not come into contact with the hydraulic fluid, it is important to ensure media resistance on account of the draw-out lubricant layer of the rod seal (this exists for wipers – even PU and elastomers).

Rod guides

Guide rings – actually bands – must be designed in accordance with the requirements with regard to transverse force, friction, media resistance, and temperature. Temperature, friction and media resistance do not pose a problem to the most widely used extended PTFE guides. They cover a temperature range of –40 to +200 °C and have the lowest friction values. The media compatibility of PTFE is assured in most cases; only the resistance of the extenders has to be checked. These types of rings and bands can support medium transverse forces. For higher transverse forces a number of rings can be used or a thermoplastic (e.g., PA) can be chosen. It must be noted that all thermoplastic rings significantly lose their load capacity at temperatures in excess of 80 °C. The duroplastic bands familiar from industry are for price reasons only used in exception cases in the automotive sector (see Guides and guide bands).

Hydraulic fluids

Hydraulic fluids are for the most part specified. They should not contain any solid particles. These can reach between seal, guide, wiper or rod surfaces and damage or mark both the elements mentioned and the rod surface; this will then cause leakage. Lubricity and viscosity must be taken into account in the choice of seal.

Rod surface

A hardened or chromium-plated or even otherwise hard-coated surface (consultation with the seal manufacturer here) can at least reduce the problem of striation by hard particles. Lesser damage to PTFE seals normally repairs itself. The required roughness of the rod is dependent on the seal material and the relative speed. PTFE seals require a smoother surface than PU and elastomer seals. The value $R_z < 2.3$ µm applies to PU and elastomer seals with a maximum speed of less than 0.5 m/s. For PTFE seals this values is between 0.5 µm and 1.3 µm. The low value applies to high speeds and high frequencies (from approximately 0.8 m/s or 5 Hz), the higher value to slower movements. At high pressures and high speeds the surface should have a hardness of HRC > 50 with a case hardness depth $CHD > 0.15$. Generally, closed (plateau-shaped) surface profiles are to be preferred to open (pointed) profiles. All surface values are measured in the seal's axial direction of movement.

Installation of rod seals

Rod seals must be compressed in diameter in the course of installation if no split groove is provided. The compression limit is 13 % of the sealing diameter. Compression can be performed with a mounting tool (e.g., cone) with a lead-in chamfer of approximately 10 to 15° which upsets the sealing element to such an extent that it can pass through the bore diameter and snap into the groove.

A PU hose or an axially slotted tube can be used to push the seal into the cone. Subsequent calibration by a rod with a large diameter if possible and a lead-in chamfer of less than 15° are required at least for PTFE seals. The outside diameter of the lead-in chamfer should smaller than the seal diameter to be calibrated. The calibration is for the most part carried out with the original piston rod, on which a calibrating tip is attached. It is important here that it has a burr-free transition from the tip to the rod which has not sharp edges and thus does not damage the seal. The surface of the calibrating tip or the calibrating tool should have the same surface quality as that of the rod.

Installation by compression (kidney-shaped installation) of PTFE seals, as is sometimes suggested in industrial applications, must be avoided in automotive applications in that permanent deformation of the seals cannot be ruled out. A split groove must be provided if installation by compression is not possible.

Hydraulic piston seals

Seal, guide, medium, surface

The same applies by extension to piston sealing systems as to rod sealing systems. Normally, piston sealing systems have no wipers. This function is at least assumed in part by piston guide rings or piston bands. Piston seals are as a rule not subject to the same high tightness requirements ("only" internal leakage) as rod sealing systems, which must keep oil safely away from the atmosphere. Pistons seals are to exhibit equally good tightness in both directions of movement. For this reason, they have a symmetrical cross-section for the most part. Alternatively two grooved rings – back to back – must be used.

One interesting solution is a PTFE piston seal, which activates a sealing edge in each case as a function of the applied pressure. The pressure allows the seal to tilt in such a way that an edge is formed depending on the pressure direction and thereby can operate like a rod seal.

Piston guidance

The same principles as for rod sealing systems and rod guides apply to the choice of the right piston guide rings or guide bands. It proved to be advantageous to place a guide ring or guide band on either side (right and left) of the seal. This enables the guides to work to a limited extent as wipers (see Guides and guide bands).

Hydraulic fluids

See here Hydraulic fluids for rod sealing systems.

Piston surfaces

The same surface-roughness and surface-hardness figures apply to piston seals as to rod sealing systems. A non-hardened, drawn or rolled surface can also be used in special applications. Surface compression produces textures which allow the surface to become harder.

Installation of piston seals

Piston seals can be stretched via a cone with a lead-in chamfer of approximately 10 to 15° onto the piston diameter if the elongation does not exceed 30 % of the inside diameter. The elongated seals then snaps into the groove. A PU hose or an axially slotted installation tool (e.g., tube) can be used to push the seal into the cone.

Subsequent calibration is required for PTFE seals. This can be done with a separate calibrating tool or with the cylinder itself. The calibration tool is a cylinder with a lead-in chamfer of less than 15 ° and a bore diameter as close as possible to the piston diameter. The outside diameter of the lead-in chamfer should be at least as large as the outside diameter of the seal to be calibrated. Both in relation to the calibration tool and the lead-in chamfer on the cylinder it is important to ensure that the surface is as good as on the cylinder barrel so as to avoid damage to the sealing element. The transition from the calibration tool to the cylinder should be burr-free and have no sharp edges.

A split groove must be provided if the elongation of the seal exceeds 30 %.

Guides and guide bands

Guide bands have two essential functions to perform in rod and piston sealing systems: Guiding the piston or rod precisely and – if necessary – accommodating transverse forces. Different materials can be used to perform these functions, e.g., bronze, composite materials, or extended PTFE materials. Bronze bushings must be additionally lubricated and are expensive. In the case of composite materials, different guides and guide bands are possible. There are fabric-reinforced duroplastic guide rings, which support a relatively high transverse force, but are not suitable for dry running and even when lubricated have a relatively high friction. The market also offers guides which have a slotted sheet-metal ring on which bronze particles are sprayed and a PTFE layer is rolled in. These bushings offer outstanding guidance quality and low friction, but are at the expensive end of the spectrum.

A further guidance option is provided by wire-mesh bushings which are wrapped in PTFE and likewise have low friction.

Guide bands made of extended PTFE provide a popular and economical solution in vehicle manufacturing. They exhibit good friction, damp vibrations, and can support transverse forces up to a certain degree.

In the case of guides it must generally be noted that they do not assume the function of a seal. For this reason, the two ends of the guide rings (bands) create a gap (Figure 2). In the case of bushings or guides with narrow play (without a gap), it is important to ensure that no drag streams occur which are superimposed on the system pressure. A bypass may be required in these cases.

The thickness of guide bands depends on the diameter to be guided. The smaller the diameter, the harder it is to bend a thick band for example around a piston and hold it in position. Guide bands with thicknesses ranging from 0.85 to 2.5 mm are used in the automotive sector. The thinner the bands, the smaller their deformations under load and accordingly the better guidance quality they have. Refer to the relevant catalogs for calculation of the permissible load. PTFE materials extended to varying extents are available depending on application and medium.

Typical fields of application for guide bands are, for example, guiding the piston in a single-tube shock absorber or guiding the rod or the piston in a positioning cylinder for translatory movements (transmissions, clutches).

Figure 2: Guide band

Elastomer materials

General limits of use

The areas of application of elastomer materials are very wide-ranging (see also Materials, Elastomers). Correspondingly different also are the specific requirements which are imposed on the materials in each case (e.g., abrasion resistance, damping performance, insulating effect, long-lasting sealing force, resistance to fatigue cracks, compressive strength, media resistance).

Heat resistance and swelling behavior in oil

The following charts provide a general overview of the different limits of use in accordance with the general classification ASTM D2000 [15], based on the oil and heat resistance of the materials. Figure 1 shows the maximum working temperature and the change in volume after a storage period of 70 hours in the reference oil IRM 903. Figure 2 shows the operating-temperature range. These temperature ranges apply to applications in which contact with media which act aggressively against the respective material is excluded.

Elastomers

Generally speaking, the different elastomers can be roughly characterized as follows. The sequences of capital letters used for the elastomer ID codes are standardized in DIN ISO 1629 (Rubbers) [16].

IIR (isobutene-isoprene rubber)

Isobutene-isoprene rubber (butyl rubber) is characterized in particular by its very low permeability to air, water vapor and other gases. In addition, aside from good ozone, weather and aging resistance, IIR also has good resistance to organic and inorganic chemicals. The possible operating temperature is in the range –40 to +110 °C (briefly up to +120 °C).

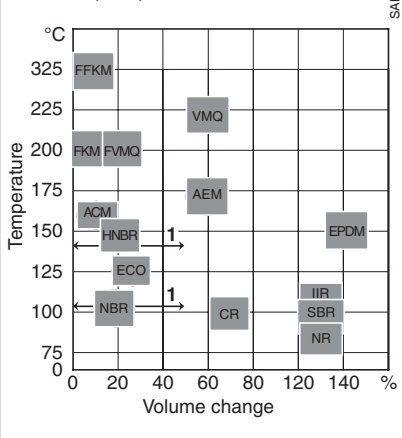
Due to the low gas and moisture permeability IIR is used predominantly in tires.

CR (chloroprene rubber)

In general vulcanized chloroprene rubber exhibits relatively good ozone, weather, chemical and aging resistance, in addition high flame retardance, good mechanical properties, good abrasion resistance, and good flexibility at low temperature. The operating-temperature range is –35

Figure 1: Oil and heat resistance of elastomers

1 Value dependent on the acrylonitrile content (ACN)



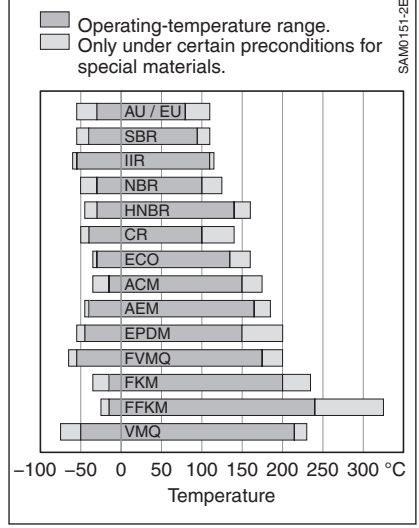


Figure 2: Operating-temperature ranges for elastomers

to +90 °C (briefly up to +120 °C). Special types can be used down to –55 °C.

CR materials are used among other things as seals against refrigerant, in outdoor areas, and in adhesive.

SBR (styrene butadiene rubber)
Of particular note in SBR materials are the outstanding mechanical properties, particularly the abrasion resistance. Accordingly, the material is mainly used in tires, but can also be found in V-belts.

In the field of seals SBR plays a lesser role, with resistance to typical media in an automobile such as oil or fuel not being given. The operating-temperature range is –40 to +110 °C (briefly up to +120 °C).

ECO (epichlorohydrin rubber)
The particularity of ECO materials is their good resistance to engine oils and fuels as used in automobiles. Moreover, the extremely low gas permeability, the weather and ozone resistance, and the low compression set must be mentioned.

The operating temperature is specified at –40 to +120 °C (briefly up to +140 °C), special types down to –60 °C.

Because of its outstanding dynamic properties, ECO is used in vehicles particularly for engine bearings and vibration dampers. But ECO is also frequently used in fuel lines.

NBR (nitrile butadiene rubber)
The properties of vulcanized NBR are mainly dependent on the ACN content (ACN: acrylonitrile), which can rang between 18 % and 50 %. This determines the oil resistance, which is however always contrary to the flexibility at low temperature.

Vulcanized NBR generally exhibits very good mechanical properties and good abrasion resistance at an operating temperature of –30 to +100 °C (briefly up to +120 °C). Special types can be used down to –50 °C.

NBR is used primarily for seals (also dynamic) or for hoses in contact with mineral oils and greases.

HNBR (hydrogenated nitrile butadiene rubber)
HNBR is produced by selective hydrogenation of the butadiene groups of NBR. In addition to the ACN content the properties are therefore also influenced by the degree of saturation set in the process.

The basic properties of HNBR are comparable with those of NBR. The operating temperature is however clearly improved by the saturation of the main chain and is in the range of –30 to +140 °C (briefly up to +160 °C). Special types can be used down to –40 °C.

They are used mainly in parts which come into contact with mineral oils and greases. However, the material also has good resistance to cooling water and to diesel fuel.

EPDM (ethylene propylene diene rubber)
EPDM has very good heat, ozone and aging resistance, also high elasticity and very good low-temperature performance. The operating temperature is with peroxidic cross-linking in the range –45 to +150 °C (briefly up to +175 °C). With sulfur cross-linking the heat resistance reduces to +130 °C (briefly up to +150 °C).

EPDM is frequently used in glycol-based brake fluids, in cooling water, in refrigerant, and, due to its outstanding weather resistance, for example in door seals.

ACM (polyacrylic rubber)
ACM exhibits very good ozone, weather and hot-air resistance, but only medium strength, low elasticity and relatively unfavorable low-temperature performance. Its operating-temperature range is –20 to +150 °C (briefly up to +175 °C). Special types can be used down to –35 °C.

ACM materials are used as seal materials primarily because of their particular resistance to lubricating oils with high additive levels (also sulfurous) in higher-temperature applications.

AEM (ethylene acrylate rubber)
Compared with ACM, AEM usually exhibits better mechanical properties, much better temperature resistance, and a very good compression set. Its operating-tem-

perature range is –40 to +160 °C (briefly up to +190 °C).

AEM materials are, like ACM, used as static seals in the underhood area (engine, transmission) primarily because of their particular resistance to lubricating oils with high additive levels in higher-temperature applications.

FKM (fluorine rubber)
Depending on their structure and fluorine content, fluorinated elastomers differ in their media resistance and flexibility at low temperature. Aside from their very good resistance to fuels, oils and other aggressive media, they are characterized by low gas permeability and very good ozone, weather and aging resistance. The operating-temperature range of fluorine rubbers is –20 to +200 °C (briefly up to +230 °C). Special types can be used down to below –40 °C.

FKM is used, because of its very good resistance to fuels, predominantly in applications such as fuel injectors, fuel lines, and the like.

It is important to mention the really high price of this elastomer group, which varies markedly depending on the polymer type used.

VMQ (silicone rubber)
The particularity of silicone rubbers is their high thermal resistance, the outstanding flexibility at low temperature, good dielectric properties, and above all good weather resistance. Silicone rubbers are hydrophobic and are used above all in the field of aqueous media. Special formulations are resistant to engine and transmission oils and water vapor. Depending on the version, the possible operating temperatures are in the range –50 to +200 °C (briefly in part also up to +230 °C).

Silicones are used in automobiles to seal electrical plug-in connections and sometimes also in radiators at high temperatures.

A subgroup, LSR (liquid silicone rubber), is very interesting because of its workability, above all for two-component parts with plastics.

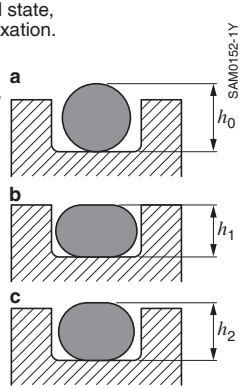
FVMQ (fluorosilicone rubber)
Fluorosilicone rubber has, in comparison with silicones, much better chemical resistance in hydrocarbons, aromatic mineral oils and fuels. The possible operating-temperature range is specified at –55 to +175 °C (briefly in party also up to +200 °C).

PUR (polyurethanes)
The group of polyurethanes is extremely multilayered. The most diverse ranges of application can thus be individually covered, a standardization of the properties is not possible, and the materials are therefore conceived around their corresponding ranges of application. Depending on the recipe, outstanding recovery performance, extreme flexibility at low temperature, and optimum hydrolysis resistance are achieved. Generally, this material group exhibits low gas permeability, good mineral-oil resistance, high strength and abrasion resistance, but also more unfavorable heat resistance. Depending on the type, temperature operation ranges of –50 to +110 °C, briefly even higher, are achievable.

Characteristic data and testing of elastomer materials

Different properties are brought to bear depending on the use to which elastomers are put. To be able to assess the suitability of a material for a certain application, the custom is to conduct tests in advance which are meant to simulate the conditions in the later application. These tests are also intended to define or specify the properties of a material. Some of the most common test methods are described in the following.

Density



Density must be considered as one of the most fundamental properties. This test is – at a constant test temperature – to a large extent not dependent on further parameters such as parts geometry or similar, which is why it tends to be used as a specific material constant as the first identification check in material tests. Usually the density is determined using the buoyancy method according to ISO 1183-1 [17] in which the density is calculated from the measured weight in air and in a test liquid.

Compression set

An important parameter for sealing performance is the compression set of the elastomer material under the influence of temperature. Elastomers demonstrate under load, as well as an elastic component, a permanent, plastic deformation (Figure 3). The greater the compression-set value, the worse the elastic behavior of a material.

Figure 3: Depiction of compression set

a) Cylindrical disk before deformation,
b) in the deformed state,
c) after stress relaxation.
h_0 Original height,
h_1 Height in the deformed state,
h_2 Height after stress relaxation.

Common test specimens

The compression set is determined according to DIN ISO 815 [18]. A common test specimen is a cylindrical disk with a diameter of 13 mm and a height of 6.3 mm. The test can basically also be carried out with a suitable cross-section on seals (e.g., on O-rings).

Common parameters

The deformation is 25 %. The test temperature is chosen on the basis of the elastomer type. The test duration must be defined and is usually 24 h, 72 h, 168 h, or a multiple thereof.

To be able to compare the results, it is absolutely essential to define all the parameters exactly.

Calculation

The compression set is calculated as follows:

$$\text{Compression set} = \frac{h_0 - h_2}{h_0 - h_1}.$$

h_0 Original height,
h_1 Height in the deformed state,
h_2 Height after stress relaxation.

Compressive-stress relaxation

This test, for example according to 3384 [19], is similar to the compression-set test, but here it is not the recovery performance after stress relaxation that is measured but the specifically created counterforce in the compressed state that is determined. It requires much more technical apparatus to be measured, but has a much better correlation with the sealing force for static seals in the installed state.

Common test specimens

– Cylindrical disk with a diameter of 13 mm and a height of 6.3 mm
– O-rings with a diameter of 14 mm and a cross-section of 2.65 mm
– Plain compression rings with a diameter of 15 mm and a square cross-section of 2 mm edge length.

The test can basically be carried out with a suitable cross-section on any seal.

Common parameters
The deformation is 25 %. The test temperature is chosen on the basis of the elastomer type. The test duration must be defined and is usually 24 h, 72 h, 168 h, or a multiple thereof.

Test methods
Two different methods may be used: In method A the deformation and all the counterforce measurements are made at test temperature. In method B the test specimens are stored at the test temperature, with the deformation and all the force measurements being made at room temperature.

The measurement can be conducted in air and in media.

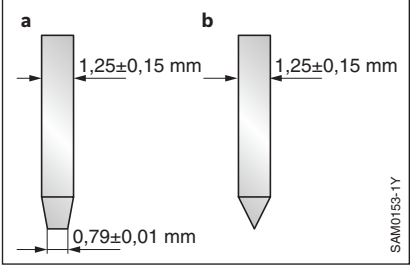
Calculation
The compressive-stress relaxation $R(t)$ is calculated as follows:

$$R(t) = \frac{F_0 - F_t}{F_0} \cdot 100$$

$R(t)$ Compressive-stress relaxation after a specified time t, expressed as % of the initial counterforce,
F_0 Initial counterforce after 30 min,
F_t Counterforce after the specified test duration t.

Hardness
The hardness is one of the most frequently mentioned properties of rubber materials. Nevertheless, the values can be very misleading. Hardness is the resistance of a body to the indentation of an indenting body of a specific shape under a defined compressive force.

Primarily two methods are used for hardness tests on standard test specimens and on finished parts made of elastomer materials:
– Shore hardness (indentation hardness according to the durometer method) according to ISO 7619-1 [20] for measurements on standard test specimens.
– IRHD hardness (International Rubber Hardness Degree) according to ISO 48 [21] for measurements on standard test specimens and finished parts.



The measured values are dependent on
– the modulus of elasticity of the elastomer,
– the visco-elastic properties of the elastomer,
– the thickness of the test specimen,
– the geometry of the indenting body,
– the exerted pressure,
– the speed of the pressure increase,
– the time after which the hardness is registered.

The following also replies here: To be able to compare the results, it is absolutely essential to define all the parameters exactly. Because of these influencing variables, it is moreover not possible to compare the results obtained with a durometer (Shore hardness) directly with IRHD values.

The tests are to be carried out at 23 ± 2 °C.

Hardness tests according to Shore A and Shore D
The Shore A hardness tester (truncated cone) can be sensibly used in the hardness range 10 to 90. Harder specimens should be measured with the tester according to Shore D (pointed cone) (Figure 4).

Figure 4: Test specimens (indenting bodies) for hardness testing
a) Shore A, truncated cone,
b) Shore B, pointed cone.

Standard test specimen
– Diameter at least 30 mm
– Thickness at least 6 mm
– Top side and underside smooth and level.

For a thinner material it is permitted to use layers if the minimum specimen thickness is achieved with a maximum of three layers. None of the layers may be less than 2 mm thick.

Hardness tests according to IRHD
Testing the ball indentation hardness according to IRHD (International Rubber Hardness Degree) is applied both to standard test specimens and to finished parts.

The thickness of the test plate must be adapted to the hardness range. According to ISO 48 the hardness is subdivided into two ranges (Figure 5).

Soft: 10 to 35 IRHD
– Specimen thickness above 10 mm bis 12 mm.

Normal: Above 35 IRHD
– Specimen thickness 6 to 10 mm,
– Specimen thickness 1.5 to 2.5 mm (micro-hardness).

Hardness values determined on finished part or specimens of other dimensions deviate as a rule from the values m,measured on standard specimens. This applies mainly in the case of curved surfaces. In order to avoid measuring errors, it is essential to position the measuring tip on curved surfaces at the highest point. In the event of very small cord thicknesses, positioning aids such as magnifying glasses, centering pins and automatic laser positioning can be used.

Testing of tensile stress-strain properties according to DIN 53504 [22] or ISO 37 [23]
This test serves to determine the typical mechanical characteristic values of an elastomer such as tensile strength, elongation at break and the stress values of test specimens of a particular shape when subjected to stress at constant speed up to break (Figure 6).

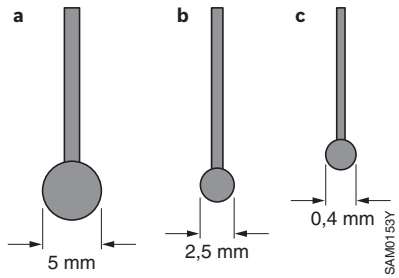
Tensile strength
The tensile strength R_m is calculated as the quotient from the measured maximum force F_{max} and the initial cross-section A_0 of the test specimen:

$$R_m = \frac{F_{max}}{A_0}.$$

Elongation at break
The elongation at break ε_R is obtained as the quotient from the change measured at the moment of break $L_R - L_0$ (measured length L_R) and the initial measured length L_0 of the test specimen:

$$\varepsilon_R = \frac{L_R - L_0}{L_0}.$$

Figure 5: Test specimens (indenting bodies) for hardness testing acc. to IRHD
a) Soft, ISO 48 "L"/"CL",
b) Normal, ISO 48 "N"/"CNL",
c) Normal, ISO 48 "M"/"CM".



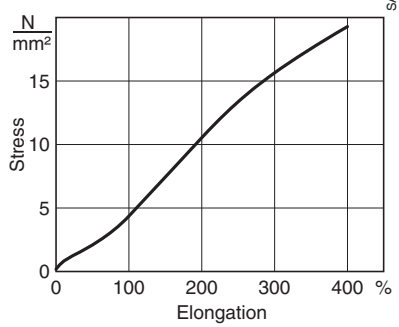


Figure 6: Force-deflection curve

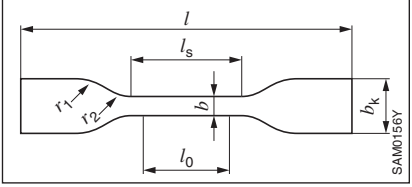
Stress value
The stress value σ is the quotient from tensile force F_i available when a certain elongation is achieved and the initial cross-section A_0. Usually the value is specified at 100 %.

$$\sigma = \frac{F_i}{A_0}$$

Common test specimens
Common test specimens are S2 tensile bars which are stamped out of a 2 mm test plate (Figure 7).



The test can basically also be carried out on O-rings and is described accordingly. However, the results determined here are not directly comparable with the values of standardized tensile bars.

Common parameters
The tests are generally carried out at the test temperature of 23 ± 2 °C. Often of interest are tests at increased or low temperature which are carried out in special tempering chambers.

Testing of tear-propagation strength according to DIN ISO 34-1 [24] or ASTM D624 [25]
This test measures the force that is required to tear a specified test specimen either by continuing an already existing cut or through the full width of the test specimen.

Common test specimens
Test specimens are tensile bars of different geometries which are stamped out of a 2 mm test plate. It must be noted that each test specimen leads to a completely different result, which is why only results of the absolutely identical method can be compared with each other.

Figure 7: Test specimen for testing the tensile stress-strain properties

Test temperature
The tests are carried out at the test temperature of 23 ± 2 °C.

Testing of media and temperature resistance
Elastomers, like all organic materials, have a limited service life. External factors such as media, temperature, ozone and oxygen influence the material properties. Elastomers can swell, shrink, harden or even crack if they are used under the wrong conditions.

In order to check the suitability of an elastomer under different conditions, it is necessary to conduct compatibility tests according to DIN ISO 1817 [26] in media or according to DIN 53508 [27] in air. Media compatibility can be tested with standardized test medium (e.g., ASTM oils, FAM test fuels) or in concrete operating media from the application.

The influence of a liquid on vulcanized elastomer can cause the following:
– absorption of the liquid by the elastomer,
– extraction of soluble constituents from the elastomer,
– chemical reaction with the elastomer.

The following changes are recorded in this test:
– change of mass, volume and dimensions,
– change of hardness and tensile stress-strain properties according to DIN 53504 [28] after exposure and if necessary after subsequent drying.

Common test specimens
S2 tensile bars according to DIN 53504 are used as test specimens. The test can basically also be carried out on seals (e.g., O-rings.

Common parameters
The test temperature is chosen on the basis of the elastomer type. The test duration must be defined and is usually 24 h, 72 h, 168 h, or a multiple thereof.

To be able to compare results, it is absolutely essential to define all the parameters exactly.

Testing of flexibility at low temperature
The properties of elastomers are very much influenced by temperature extremes. At high temperatures, the material may be subject to anything ranging from hardening to irreversible destruction. On the other hand, the material becomes rigid or hard and brittle at low temperature due to reduced chain mobility and loss of elasticity. This effect is reversible.

Different test methods are used to record this low-temperature effect:
– Calorimetric testing (DSC, Differential Scanning Calorimetry): This enables the T_g value (glass transition temperature) to be determined.
– Static measurement (TMA, Thermomechanical Analysis): This can be used to determine the TR10 value; it describes the recovery of an elongated specimen at low temperature by 10 %, according to ASTM D1329 [29] or ISO 2921 [30].
– Dynamic measurement (DMA, Dynamic-Mechanical Analysis): This can be used to determine the TR value (low-temperature characteristic for the sealing force at low temperature, see above) and further characteristic values.

Each test method leads to a slightly different measuring result, there is no direct correlation between the results.

As well as these analytical methods there is the possibility of determining the freezing-temperature range of a material by means of simple bending tests or a hardness test.

Testing of ozone resistance
Materials which in their polymer structure contain double bonds in the main chain (unsaturated polymers like NBR, HNBR and CR) are susceptible to ozone from the ambient air, above all in the elongated state. Testing of ozone resistance is conducted according to ISO 1431-1 [31] in special test chambers where the test specimens are subjected statically to tensile strain over the test duration. In this test it is assessed
– whether cracks are present in the test specimen after a defined test duration, or
– after what test duration cracks appear with a defined ozone concentration.

Common test specimens
The tests can be carried out on test bars or with a suitable cross-section also on seals.

To be able to compare results, it is essential to define clearly the following parameters: Temperature, ozone concentration, relative humidity, elongation, test duration, and test method.

Testing of rebound resilience
Elastomers are never 100 % elastic; instead, their property is always composed of a viscous component and an elastic component.

The damping property is of interest for certain applications. This can be determined for example by way of the rebound resilience according to DIN 53512 [32] or ISO 4662 [33], whereby a pendulum of defined mass (defined kinetic energy) strikes a test specimen and the height reached after the impact is measured.

Maximum damping corresponds to a value of 0 %. Minimum damping could be at a value of 100 %, but this cannot be achieved.

Common test specimens
The tests are carried out on 12 mm thick test specimens.

Detachable connections

Positive or form-closed joints

Operation

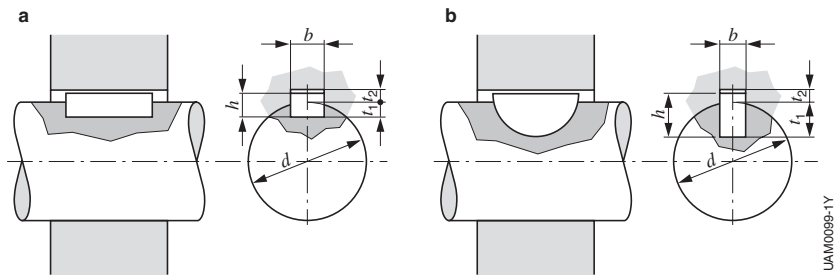
Positive or form-closed joints have the task of transferring forces, which themselves maintain contact via mating surfaces, by means of their geometrical shape. The forces are always transferred perpendicularly to the mating surfaces, resulting mainly in compressive and shear stress ([1], [2]).

Positive locking or form closure creates detachable connections, since as a rule a clearance or a transition fit exists (see Tolerances) between the touching surfaces (e.g. between a shaft and the bore of a hub, [3]). Depending on the choice of fit, relative axial movements may occur during operation. If necessary, they must be prevented by suitable locking devices. Among others, retaining rings according to DIN 471 [4] or slotted lock nuts according to DIN 981 [5] are used for this purpose.

Feather-key and Woodruff-key couplings

Feather-key couplings (Figure 1a) are used for the torsion-resistant connection of belt pulleys, gears, coupling hubs, etc. to shafts. Feather keys are sometimes used to secure frictional joints or to fix a specified position in the circumferential direction.

The cheaper Woodruff key (Figure 1b), the round side of which fits into the shaft, is mainly used for this purpose in automotive construction and to transfer smaller torques.



In the case of feather-key couplings, the groove faces lie against the feather-key faces. In contrast to keyed joints, there is clearance (backlash) between the rear of the feather key and the base of the groove. This means that the forces are transferred exclusively via the flanks of the feather key.

For feather-key width, the tolerance zone h 9 (key steel to DIN 6880 [6]) is provided. For groove widths b, the tolerance zones specified in Table 2 apply.

Table 1: Symbols and units

Quantity		Unit
D	Diameter	mm
F	Force	N
K_A	Application factor (service factor)	–
M_t	Torque	Nm

l_{tr}	Supporting feather-key length	mm
n	Number of drivers	–
p	Surface pressure	N/mm²
t_1	Groove depth (shaft)	mm
t_2	Groove depth (hub)	mm
σ_b	Bending stress	N/mm²
τ_s	Shear stress	N/mm²
φ	Contact-surface ratio	–

Figure 1: Positive or form-closed joints
a) Feather-key coupling, b) Woodruff-key coupling. Symbols, see Table 1.

A sliding fit must be used if a hub must move on the shaft in the longitudinal direction (e.g. gear in manual-shift transmission). Usually, the sliding spring is firmly bolted into the shaft groove. Round (Shape A) and angular (Shape B) feather keys (Figure 2) are manufactured. DIN 6885 [7] defines the standard in terms of their shape and dimensions, depending on the shaft diameter (Table 3).

In practice, feather keys are designed only for surface pressure. If $p \leq p_{perm}$, the required supporting feather-key length (see Table 1) is

$$l_{tr} = \frac{2\,K_A\,M_t}{d\,(h - t_1)\,n\,\varphi\,p_{perm}} \quad .$$

For round-faced feather keys (Shape A), the feather-key length is $l = l_{tr} + b$. For straight-faced ones (Shape B), it is $l = l_{tr}$. For the permissible surface pressures, the standard gives $p_{perm} = 0.9\,R_{e,min}$, where $R_{e,min}$ is the minimum yield point of the shaft, hub or feather-key material. With one feather key ($n = 1$), the contact-surface ratio is $\varphi = 1$, and with two feather keys, it is $\varphi = 0.75$.

Table 2: Tolerances for groove widths

Groove fit	Fixed fit	Easy fit	Sliding fit
in hub	*P* 9	*N* 9	*H* 8
in shaft	*P* 9	*J* 9	*D* 10

Profiled shaft-hub connections

Instead of inserting multiple feather keys into shaft grooves, the shaft cross-section can also be shaped directly in the form of a polygonal profile, and the mating hub cross-section has a corresponding shape. (Table 4). Profiled shafts are also used if the hub must be axially movable relative to the shaft (e.g. steering column for a height-adjustable steering wheel). The profiled shaft connection has the advantage

that it does not require any additional separator (feather key) to transfer torque. The hub can be centered on the shaft over the smallest shaft diameter. This is called internal centering and very smooth running can thus be achieved.

The hub can also be centered via the flanks of the drivers or the toothing. This flank centering ensures very low circumferential backlash between shaft and hub and is therefore very suitable for alternating and jerky torques. As with the feather key, a rough design is drawn up based on surface pressure.

Bolt and pin connections

Bolt and pin connections provide a simple and inexpensive means of connecting two or more components. These are among the oldest and most widely used types of connection.

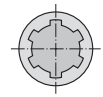
Bolt connections

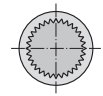
Bolt connections are mainly used for joining linkages (Table 5), shackles, chain links, and connecting rods, as well as axles for bearing impeller rings, rollers, levers, etc. Since relative movements occur in these connections, at least one part must be movable. The main prevailing stresses are surface pressure (Table 6) and shear. Bending stress is negligible in most cases. It only occurs to a significant extent in the case of bolt connections which are relatively long in relation to their diameter.

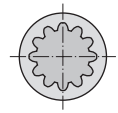
Pin connections

Pins are suitable for the permanent connection of hubs, levers, and set collars on shafts or axles (e.g. transverse-pin joint). They also secure the precise position of two machine parts, and are suitable as guide pins to fix springs, etc. (Table 5). Since they are forced into holes as press fits with tolerances, all parts are permanent. The pin can be knocked out with a punch without damaging the components.

Table 4: Profiled shaft-hub connections







Designation	Standard	Illustration	Driver	Centering	Contact-surface ratio
Spline shaft	ISO 14 [8] DIN 5464 [9]	 UAM0101-1Y	Prismatic driver	Inner	$\varphi = 0.75$

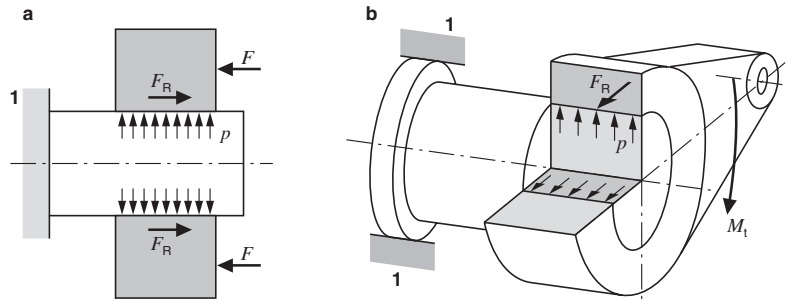
Frictional joints

Operation

For frictional joints, press fits are produced in the joints (the friction surfaces being the effective areas) in which the parts to be assembled are in direct contact (Figure 1). The surface pressure p can be generated by bolt forces, keys, elastic separators, or the elasticity of the components themselves. The resulting normal force $F_N = pA$ (with friction surface A) induces a frictional force F_R, which opposes a movement caused by external forces ([1], [2]).

Press fit

Application



For a press fit (cylindrical interference fit), the required surface pressure is produced by the elastic deformation of the shaft and hub, resulting from an interference fit. "Interference fit" is the pairing of cylindrical fitting parts which have an interference before assembly (Figure 2).

Because press fits are easy to produce and can transfer even jerky and variable torques and linear forces, they are suitable for the joints of cylindrical surfaces which do not have to be released afterwards (e.g. gear on shaft, wheel on axle, bushing in housing). Cylindrical press fits are classed as hard-to-detach connections, since with high interference during removal the surfaces of shaft and bores are detrimentally affected.

Elastic design of cylindrical interference fits
A press fit must be designed so that at least a minimum surface pressure p_{min} is present in order to ensure the transfer of the greatest occurring stress, and so that a maximum surface pressure p_{max} is not exceeded and the components are not overstressed.

Basically, two calculation objectives are possible: The required fit is defined for a given load (Table 2) or the permissible load is determined for a given fit (Table 3). In the following equations index I denotes the inner part (shaft) and index A the outer part (hub) of the press fit.

The diameter ratios (see Figure 2)

$$Q_A = \frac{D_F}{D_{Aa}} \text{ and}$$

$$Q_I = \frac{D_{Ii}}{D_F}$$

and the specific allowance [1]

$$\xi = D_F \left[\frac{1}{E_I} \left(\frac{1+Q_I^2}{1-Q_I^2} - \nu_I \right) + \frac{1}{E_A} \left(\frac{1+Q_A^2}{1-Q_A^2} + \nu_A \right) \right]$$

can be used to design press fits with reference to their function and the required component safety.

The nominal diameter is inserted into the calculation for the joining diameter D_F. When joining an interference, loss results from plastic leveling of the roughness

Table 2: Definition of fits for given stress [1]

Stress M_t or F_a given	$\sigma_{perm} = R_e / S_F$ or $\sigma_{perm} = R_m / S_B$ given
Required fit: $p_{min} = \frac{\sqrt{F_a^2 + \frac{4 M_{t,nom}^2}{D_F^2}}}{\mu \pi D_F b} K_A$	Permissible fit in hub: $p_{max} = \left(1 - Q_A^2\right) \sigma_{perm} / \sqrt{3}$ Permissible fit in hollow shaft: $p_{max} = \left(1 - Q_I^2\right) \sigma_{perm} / \sqrt{3}$
Required allowance: $Z_{min} = p_{min}\, \xi$	Permissible allowance: $Z_{max} = p_{max}\, \xi$
Required interference: $U_{min} = Z_{min} + 0.8\,(R_{zI} + R_{zA})$	Permissible interference: $U_{max} = Z_{max} + 0.8\,(R_{zI} + R_{zA})$
Select ISO fits with $U_k \geq U_{min}$ and $U_g \leq U_{max}$

Smallest pressure: $P_k = \frac{Z_k}{\xi}$	Greatest pressure: $P_g = \frac{Z_g}{\xi}$
Permissible stress: $M_t = 0.5 p_k \mu \pi D_F^2 b$ (only M_t) $F_a = p_k \mu \pi D_F b$ (only F_a) $M_t = \frac{D_F}{2}\sqrt{(p_k \mu \pi D_F b)^2 - F_a^2}$ (F_a given) $F_a = \sqrt{p_k \mu \pi D_F b - \frac{4M_t}{D_F^2}}$ (M_t given)	Hub safety factor: $S_F = \frac{1-Q_A^2}{\sqrt{3}\,p_g} R_e$ or $S_B = \frac{1-Q_A^2}{\sqrt{3}\,p_g} R_m$ Hollow-shaft safety factor: $S_F = \frac{1-Q_I^2}{\sqrt{3}\,p_g} R_e$ or $S_B = \frac{1-Q_I^2}{\sqrt{3}\,p_g} R_m$

peaks. According to DIN 7190 [13], the smoothing of the two surfaces with 40 % of the averaged peak-to-valley heights R_{zI} (shaft) and R_{zA} (bore) is taken into account in the calculation.

The maximum tensions occur according to the equations in Table 2 and Table 3 at the internal diameters of hollow shaft and hub. Solid shafts are noncritical, and do not usually have to be calculated.

Assembly

There are two types of press fit depending on the assembly method: linear and transverse. Linear press fits are produced by "cold" assembly at room temperature. The large press-fit forces required are usually applied by hydrostatic presses. The press-fit velocity should not exceed 2 mm/s. For the press-fit force:

$$F_e = \frac{(U_g - 0.8\,(R_{zI} + R_{za}))\,\mu \pi D_F b}{\xi}.$$

Before transverse press fits are made, either the outer part is expanded by heating, or the diameter of the inner part is reduced by supercooling, so that the parts can be assembled stress-free. If the outer part is heated, it shrinks onto the

Table 4: Poisson ratio, modulus of elasticity, and linear coefficient of thermal expansion for metallic materials

Material	Poisson ratio ν	Modulus of elasticity E [N/mm^2]	Coefficient of linear expansion α [10^{-6}/K]	
			Heating	Cooling
Gray cast iron	0.24	100,000	10	–8
Malleable cast iron	0.25	90,000 to 100,000		
Steel	0.3	200,000 to 235,000	11	–8.5
Bronze	0.35	110,000 to 125,000	16	–14
Red brass	0.35 to 0.36	110,000 to 125,000	17	–15
CuZn	0.36	80,000 to 125,000	18	–16
$MgAl_8Zn$ AlMgSi	0.3 0.34	65,000 to 75,000	23	–18

inner part as it cools (shrink fit). If the inner part is cooled so that it expands when it is heated to room temperature, this is an expansion fit. To make force-free assembly possible, a joint clearance of $ED = 0.001 \cdot D_F$ must be provided.

With the ambient temperature t_U, the maximum interference U_g and the coefficient of linear thermal expansion α (Table 4) the assembly temperature of the hub comes out for a shrink fit at

$$t_A = t_u + \frac{U_g + \Delta D}{\alpha_A D_F}$$

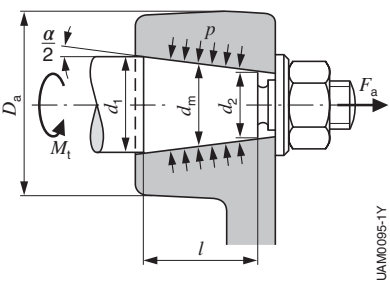
and for an expansion fit at

$$t_I = t_u - \frac{U_g + \Delta D}{|\alpha_I|\, D_F}.$$

Tapered connection

Application

A tapered connection (tapered interference fit) is suitable for transferring dynamic forces and torques. They are used predominantly to secure hubs to shaft ends, e.g. the V-belt pulley on the alternator or the drill head in the drill spindle. Taper and taper angle are standardized, among others also connecting elements like the terminals on starter batteries, in DIN 254 [14].



Tapered connections for the most part can be retightened and easily detached. As a shaft-hub connection they exhibit no shaft weakening and have very good centering (i.e. no imbalance).

However, the disadvantages are the high production costs and the lack of adjustability in the axial direction. The following applies (Figure 3) to the

taper ratio $C = \frac{(d_1 - d_2)}{l}$
and to the
taper angle $\tan\frac{\alpha}{2} = \frac{(d_1 - d_2)}{2l}$.

The following taper ratios are specified as guidelines (DIN 254 [14], DIN 406 [15]):
$C = 1:5$ connection is easily detachable,
$C = 1:10$ connection is detachable only with difficulty.

Figure 3: Tapered connection

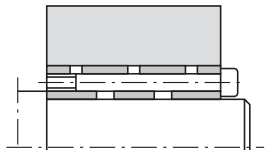
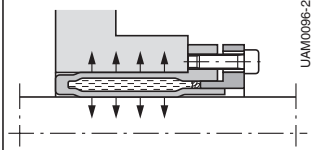
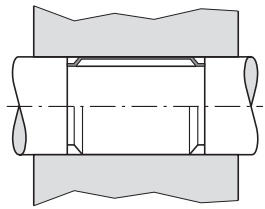
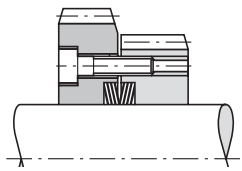
d_2 Small taper diameter,
d_m Middle taper diameter,
l Common length,
p Surface pressure,
α Taper angle,
M_t Torque,
F_a Assembling force (fastener force).

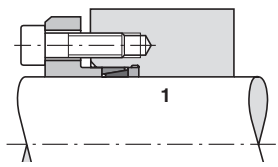
Operation

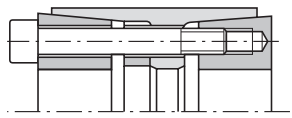












The effective area pair of a tapered connection takes the form of a truncated cone (frustum). The required surface pressure p is usually applied by an axial bolt force F_a. The relationship between the axial press-fit force F_a and the transferable torque M_t is expressed by the following equation [1]:

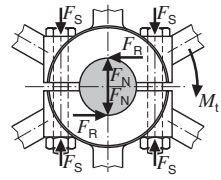
$$F_a \geq \frac{2K_A M_{t,nom}}{\mu_u d_m}\left(\sin\frac{\alpha}{2} + \mu_a \cos\frac{\alpha}{2}\right).$$

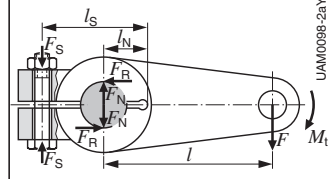
Load excesses (impacts) which can occur during operation are taken into consideration with the application factor K_A, which according to DIN 3990 [16] can range between 1 and 2.25. This equation also takes into account the possible difference between the coefficients of friction μ_u in the circumferential direction and μ_a in the axial direction. Self-locking exists if an expulsion force (F_a becomes negative) is required to detach the connection. This means that a torque can be transferred even if the bolt is removed after the parts are axially stressed. In contrast, with a non-self-locking tapered connection, there is no pressure between the effective areas after the axial application force is released. The condition for self-locking is:

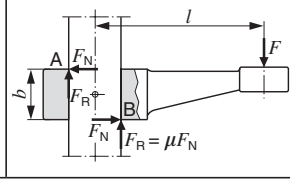
$$\frac{\alpha}{2} \leq \arctan\mu_a.$$

Table 5: Taper-lock joints.

Designation	Illustration	Features
Clamping sleeve (Spieth)	 UAM0096-1Y	Axial distortion is applied to enlarge the outside diameter of the clamping sleeve and reduce the inside diameter. The danger of loosening under dynamic loads is reduced by using long bolts.
Hydraulic hollow-jacket spring collet (Lenze)	 UAM0096-2Y	Axial distortion is applied to generate a pressure in a thin-walled hollow cylinder. The spring collet is self-centering because of even pressure distribution, and thus has true-running properties. At higher temperatures, the thermal expansion of the pressure fluid must be taken into account.
Tolerance ring (Dr Tretter)	 UAM0096-3Y	Tolerance rings are slotted and made from thin wave-shaped sheet metal. The required initial force is provided by forced deformation of the elastic connecting member. They can bridge relatively large machining tolerances, compensate for thermal expansion, and transfer torques.
Star washer (Ringspann)	 UAM0096-4Y	Star washers are thin-walled, very flat conical shells with radial slots. The axial initial force is translated by forced deformation into a fivefold to tenfold radial force. Star washers do not center.
Taper-lock ring (Ringfeder)	1 Precentering  UAM0096-5Y	Taper-lock rings consist of two coaxially arranged conical rings. Radial prestressing is achieved by axially distorting the rings. Taper-lock rings do not center. They are not self-locking and thus can easily be detached.
Taper-lock set (Bikon)	 UAM0096-6Y	Axial distortion is applied by means of the bolts belonging to the taper-lock set. Taper lock sets are very true-running and can transfer very large torques, particularly with multiple pairs of effective areas.







Component safety
The critical component is the hub. It is calculated as an open, thick-walled hollow cylinder. If $Q = d_m/D_a$, the following applies to the safety of the hub, with elastic design, depending on the modified shear-stress theory (DIN 7190):

$$S_F = \frac{1-Q^2}{\sqrt{3}} \cdot \frac{\left(\sin\frac{\alpha}{2}+\mu_A\cos\frac{\alpha}{2}\right)\pi d_m l}{F_{a,max}}.$$

Taper-lock joints
The required surface pressure in the effective areas can also be applied by elastic separators (Table 5). The great advantage of these taper-lock joints is that they can be used to fix hubs, gears, couplings, etc. securely to smooth, cylindrical shafts. Unlike cylindrical interference fits, they can be freely adjusted axially and tangentially, and are above all easily detachable. They are, therefore, particularly suitable for hubs (e.g. belt pulleys), which must be adjustable and replaceable. Their disadvantages include the space required and the high costs. They are usually designed as specified by the manufacturer (see manufacturer catalogs and Table 5).

Clamp joints
In the case of clamp joints, external forces apply the required surface pressure to the joint, mostly by means of bolts. The joints with a sectional or slotted hub are preferably used for low torques which have little fluctuation. Their advantage is that the hub position is easily adjustable in the axial and tangential directions. They provide a very easy means of fixing wheels or levers to smooth shafts. However, there are also self-locking clamp joints. Here, the tilting force F_K generates edge pressures in A and B (Table 6) to prevent axial movement.

Table 6: Clamp joints

Designation	Illustration	Features

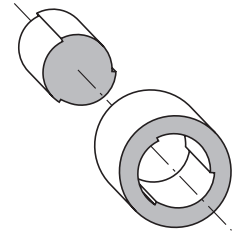
Keyed joints

Longitudinal keyed joints



A one-sided radial distortion is achieved by driving in a standardized key (key angle = 0.57°) between the shaft and hub. However, because of their imprecise assembly (hammer assembly) and the resulting eccentricities, keys are only of secondary importance.

Circular keyed joint

A new type of keyed joint is the 3-part circular-key sectional profile (Figure 4). Three circular keys are arranged circumferentially on the cylindrical surface of a shaft (inner part). The hub (outer part) contains an appropriate number of corresponding keys in a cylindrical hole. Twisting results in radial distortion and this can transfer large axial and tangential forces in any direction.

As opposed to press fits, circular keyed joints are detachable. They are used, for example, for shaft-hub connections, for camshafts and for hinges in vehicle construction.

Figure 4: 3-part circular-key sectional profile

Threaded fasteners

Basic principles

Operation

A threaded fastener is used to make secure joints that are detachable any number of times. The purpose of screws and bolts is to stress the mating parts so that the static or dynamic operating forces acting on the joint do not cause any relative movement between the parts ([1], [17], [18], [19], [20]).

When a fastener is tightened or loosened, a screwing motion takes place. In one full rotation of the fastener, an axial shift corresponding to the pitch P occurs. If a fastener line is uncoiled on a cylinder that has a flank diameter d_2, it will produce a straight line with a pitch angle $\varphi = \arctan(P/(\pi d_2))$.

In general, fasteners are right-threaded (the straight line rises to the right). Special applications may require left-threaded bolts.

For normal fixing bolts or screws, metric thread profiles (DIN 13 [21], ISO 965 [22]) are used. For pipes, fittings, threaded flanges, etc., pipe threads (DIN ISO 228-1 [23], DIN EN 10226-1 [24]) are used. Refer to Figures 7 through 9 and Tables 7 through 10 for the dimensions of these threads.

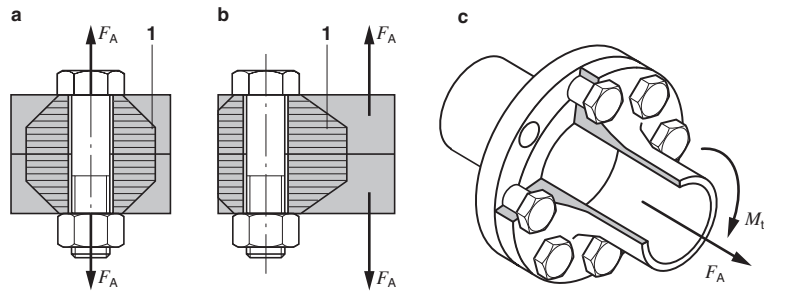
Calculations for threaded fasteners
The prevailing basis for calculating high-stress threaded fasteners is VDI Directive 2230 [25]. It can be used as a simple, sufficiently precise calculation of the forces and stresses in the thread and the required tightening and loosening torques for a cylindrical single-threaded fastener, which can be considered as a section of a highly rigid multiple-threaded fastener. This means that, in many cases, even complex multiple-threaded fasteners can be considered as single-threaded fasteners. The precondition for this is that the fastener axes are parallel to each other and perpendicular to the parting planes. The components must also be elastic. Another important factor here is that only centrally preloaded and centrally stressed fasteners are considered. For large, eccentric stresses, which may cause the parting line to gape open, please refer to VDI 2230 (Figure 1).

Property classes
According to DIN EN ISO 898-1 [26], the properties of a fastener are identified by two numbers separated by a decimal point. The first number equals 1/100th of the minimum tensile strength; the second is a number that is 10 times the ratio of the yield point in relation to the tensile strength. Multiplying the two numbers gives 1/10 of the minimum yield point (example: 8.8 $\rightarrow R_e = R_{p0.2}$ = 640 MPa).



The property class of a standard nut is identified by one number. This number corresponds to 1/100 of the minimum tensile strength of a bolt of the same property class. To optimize material exploitation, therefore, bolts and nuts of equal property classes should always be paired (e.g. bolt 10.9 with nut 10).

Tightening of threaded fasteners
Prestress
Threaded fasteners are preloaded joints in which the fastener is expanded by f_{SV} by being tightened, and the parts or plates to be tightened are pressed together by f_{PV}. The deformation depends on the dimensions (cross-section and length) and on the materials (moduli of elasticity). According to Hooke's Law, in the elastic range, these are proportional to the prevailing linear force. The ratio of force F to change in length f is the spring rate

$$R = \frac{F}{f} = \frac{E \cdot A}{l}.$$

If the rigidities of fasteners and stressed parts are known (they can be calculated according to VDI 2230), the preloaded threaded fastener can be represented by a load-extension diagram. After assembly, an equilibrium of forces arises so that the preload in the bolt and the stressed parts are of identical size (Figure 2a).

Figure 1: Stresses applied to threaded fasteners
a) Centrally stressed and centrally loaded fastener,
b) Eccentrically stressed and eccentrically loaded fastener,
c) Multiple-threaded fastener.
1 Area of pressure application.

Operating forces

In the case of transversely stressed threaded fasteners (operating force F_Q perpendicular to fastener axis), the forces are transferred in the parting plane by friction. Provided that the frictional forces, which are generated by the fastener preload, are greater than the operating forces to be transferred, the assembly load-extension diagram does not change. This means that the fastener "notices" nothing about the external stress.

At a coefficient of friction μ_T in the parting line, n_S number of fasteners, i number of friction surface pairs, and S_R factor of safety against sliding, the required minimum clamping force is calculated as follows:

$$F_{K,min} = F_V \geq \frac{S_R F_Q}{\mu_T n_S i} .$$

If an external operating force F_A acts in the direction of the fastener axis according to Figure 1, the bolt is extended by f_A. At the same time the compression of the stressed parts is reduced by the same amount. The bolt is thus subjected to an additional stress of F_{SA}, whereas the stressed parts are relieved by F_{PA}. The additional fastener force F_{SA} thus depends on the rigidity and yield of the fastener (Figure 2b).

The "softer" the fastener (tensile bolt: long and thin), the smaller the additional bolt stress F_{SA} caused by an external axial operating force F_A. This must be the objective, particularly with dynamic operating forces (e.g. for cylinder-head bolts).

Force application

The rigidities of the fastener and the stressed parts also depend on force application. If the external axial operating force F_A is applied directly to the fastener head, the force-application factor $n = 1$. For the application of force in the parting line $n = 0$. Real force applications range between these two extreme values (Figure 3). In this case, only part of the stressed parts is relieved. This hardens the spring rate R_P of the stressed parts, since grip is reduced. The stressed parts are hammered onto the fastener, which then becomes apparently longer and therefore softer. Small n values therefore result in small additional fastener forces. This has a good impact on the fastener safety factor. However, the clamping force is reduced at the same time, and this is not good for the joint function.

There is no simple method of calculating the force-application factor n, which defines the point of force application. Either n ($0 \leq n \leq 1$) is estimated, or an approximate calculation is made according to VDI 2230. The forces specified in the load-extension diagram can be calculated in accordance with Table 2.

Fastener forces and torques

Calculation model

The simplest way to represent force ratios in a threaded fastener is by concentrating the surface pressure distributed to all thread turns on a single nut element. During tightening and loosening, the nut

Table 2: Fastener forces (depending on force application)

Force	Force application at fastener head $n=1$	Force application any $0<n<1$	Force application in parting line $n=0$
Max. fastener force	$F_S=F_V+\Phi F_A$	$F_S=F_V+\Phi_n F_A$	$F_S=F_V$
Clamping force	$F_K=F_V-(1-\Phi)F_A$	$F_K=F_V-(1-\Phi_n)F_A$	$F_K=F_S-F_A$
Additional fastener force	$F_{SA}=\Phi F_A$	$F_{SA}=\Phi_n F_A$	$F_{SA}=0$
Additional plate force	$F_{PA}=(1-\Phi)F_A$	$F_{PA}=(1-\Phi_n)F_A$	$F_{PA}=F_A$

Where $\Phi=\frac{R_S}{(R_P+R_S)}$ and $\Phi_n=n\,\Phi$.

element moves along the bolt thread, which, if unwound, represents a slanting plane or a wedge (Figure 4).

Tightening a threaded fastener
When tightened, the nut element is pushed up the wedge by the peripheral force F_U. The resulting normal force F_N causes a frictional force F_R which acts in the opposite direction and includes the angle of friction ρ. But since all standardized thread profiles have sloping flanks, as shown in the section in Figure 4, the actual normal force F_N is perpendicular to the sloping thread surface. Therefore only the component $F'_N=F_N\cdot\cos\alpha/2$ appears in the plane force polygon. The following then applies to the frictional force:

$$F_R=F_N\cdot\mu_G=F'_N\cdot\mu'_G.$$

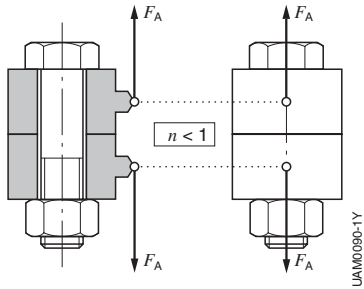
In order to calculate the force polygon in a plane parallel to the fastener axis, an apparent coefficient of friction is introduced:

$$\mu'_G=\frac{\mu_G}{\cos\alpha/2}=\tan\rho'.$$

When the peripheral force acts on the flank diameter d_2, the thread torque becomes

$$M_G=F_V\cdot\frac{d_2}{2}\cdot\tan(\varphi+\rho').$$

Figure 3: Force application between fastener head and parting line
n Force-application factor.



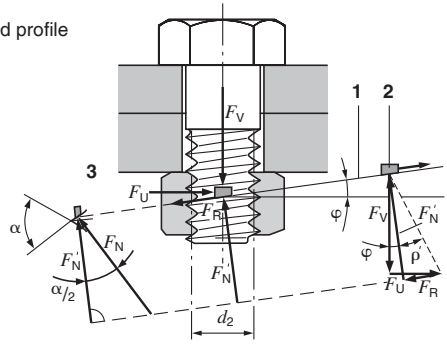


Figure 4: Forces for tightening a threaded fastener
1 Bolt thread,
2 Nut element,
3 Section through thread profile and nut element.

To tighten a bolt to preload F_V, a head friction torque M_{KR} is required to overcome the friction between the head and nut bearing surfaces, in addition to the thread torque M_G. At a coefficient of friction μ_K and a mean head friction diameter D_{Km}, the head friction torque is calculated as follows:

$$M_{KR} = F_V \cdot \mu_K \cdot \frac{D_{Km}}{2}.$$

The bolt tightening torque applied during assembly is then:

$$M_A = M_G + M_{KR} = F_V \left(\frac{d_2}{2} \tan(\varphi + \rho') + \mu_k \frac{D_{km}}{2} \right).$$

Loosening a threaded fastener
When a threaded fastener is loosened, the frictional force changes in the opposite direction to the tightening action. The bolt loosening torque (release torque) is calculated as follows:

$$M_L = F_V \left(\frac{d_2}{2} \tan(\varphi + \rho') - \mu_k \frac{D_{km}}{2} \right).$$

In the case of self-locking threads ($\varphi < \rho'$), the loosening torque becomes negative. This means that a torque must be applied in the opposite direction to the tightening action.

Design of threaded fasteners

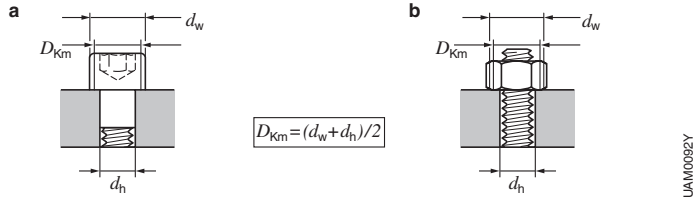
Overstressing
If the minimum thread reach $m = (1.0 \text{ to } 1.5) \cdot d$ is maintained, a threaded fastener fails if overstressed, not because the thread turns are stripped, but because the cylindrical screw bolt ruptures.

Assembly stress
When the fastener is tightened to preload F_V, it is stressed up to tensile stress. Due to the thread torque M_G, it is also stressed to torsion. As the friction in the thread prevents the bolt from turning back, the torsional stress also acts after tightening. According to the distortion-energy theory (see Mechanics, Basic principles) the equivalent stress in the bolts is

$$\sigma_{red,M} = \sqrt{\sigma_{z,M}^2 + 3\,\tau_t^2} \le v \cdot R_{p0.2}$$

with tensile stress

$$\sigma_{z,M} = \frac{F_{V,max}}{A_S} = \frac{\alpha_A \cdot F_V}{A_S}$$



and torsional stress

$$\tau_t = \frac{M_{G,max}}{W_t} = \frac{16 \cdot \alpha_A \cdot F_V \cdot d_2 \cdot \tan(\varphi + \rho')}{2 \cdot \pi \cdot d_3^3}.$$

The tightening factor α_A takes account of the imprecision which is unavoidable during assembly. For torque-controlled tightening (torque wrench) it is $\alpha_A = 1.4$ to 1.6, for pulse-controlled tightening (impact wrench) it is $\alpha_A = 2.5$ to 4.0.

To ensure high functional security, it is necessary to aim for the highest possible material exploitation. This is taken into account by efficiency v. Table 3 shows the permissible preload forces and tightening torques during assembly for different coefficients of friction at 90 % efficiency (v 0.9) of the standardized minimum yield point.

Figure 5: Effective diameter D_{Km} for head friction torque
a) For Allen screw (d_w = head diameter),
b) For hexagonal bolt/nut (d_w = width across flats).

Static stress
An axial operating force F_A increases tensile stress in the bolt. Since, in the operating state, the effect of torsional stress is less than in the fitted state, VDI 2230 applies to reduced stress:

$$\sigma_{red,B} = \sqrt{\sigma_z^2 + 3(0.5 \cdot \tau_t)^2} < R_{p0.2}$$

at tensile stress:

$$\sigma_z = \frac{F_{S,max}}{A_S} = \frac{\alpha_A \cdot F_V + F_{SA}}{A_S}.$$

Vibrational stress
At a dynamic operating force F_A, the variable stress component σ_a must not exceed the permissible variable stress σ_A. The following applies:

$$\sigma_a = \frac{F_{S,max} - F_{S,min}}{2 \cdot A_S} \leq \sigma_A.$$

The permissible variable stress σ_A does not depend on the property class, but on the nominal diameter only (Table 4).

Surface pressure between head and nut bearing surface
In the case of a large preload, the surface pressure on the head and the nut bearing surfaces must be checked. Excessive surface pressures can cause plastic deformation and loss of preload. This can result in threaded fasteners coming loose.

The surface pressure p resulting from the maximum fastener force must not exceed the permissible surface pressure limit p_G (guideline values for p_G, see Table 5):

$$p = \frac{4 F_{S,max}}{\pi\left(d_w^2 - d_h^2\right)} \leq p_G.$$

Threaded-fastener locking devices
The spontaneous loosening of a threaded fastener is caused by complete or partial loss of preload, which in turn is caused by settling events (loosening) or relative movements in the parting line (unscrewing).

Loosening
Contact stress f_z caused by plastic deformation results in loss of preload

$$F_z = \frac{R_p \cdot R_S}{R_p + R_S} \cdot f_z \,.$$

Contact stress f_z in µm depends on the surface properties and the number of parting lines (Table 6).

Total contact stress equals the sum of individual component parts. However, contact stress determined in this way is only valid if the surface pressure limits are not exceeded. Otherwise, significantly greater settling will arise. Locking devices are intended to reduce or compensate for settling.

The following measures provide reliable protection against loosening:
– High preload,
– Elastic threaded fasteners,
– Low surface pressures due to large bearing surfaces and sufficient thread reach,
– Low number of parting lines,
– No plastic or quasi-elastic elements (e.g. seals) with stress.

Unscrewing
Dynamic stresses, particularly perpendicular to the fastener axis, may cause threaded fasteners to come loose despite sufficient preload. If transverse movements can occur, locking devices to prevent unscrewing insure that the joint retains its function. Suitable measures include:
– Avoid transverse movements by positive locking in the parting line,
– Elastic threaded fasteners
– Large grip lengths,
– High preload,
– Suitable locking devices (locking or bonding elements, Figure 6).

Areas of application: For joining parallel internal threads to valves and fittings, threaded flanges, etc. with tapered external threads.

Snap-on connections on plastic components

Features

Snap-on connections are a cheap and efficient way of fitting plastic components. They are used to connect housing halves, on plug connectors, and to secure mounting parts in plastic housings. They exploit the high expansibility of the plastics with relatively low rigidity.

All snap-on connections are characterized by the brief excursion of a resilient element in the joining process before it snaps into place behind a locating lug. Depending on the configuration of the joining angles at the snap-on elements, it is possible to produce nondestructively detachable and nondetachable connections (Figure 1).

The basic shapes [27] of snap-on connections are (Table 1):

– Resilient snap-on hooks (bending springs fixed on one side),
– Torsion snap-on hooks,
– Resilient clips,
– Ring-shaped snap-on connections, also segmented (slotted lengthways),
– Spherical snap-on connections, also segmented.

Figure 1: Snap-on connection (principle)
a) Decisive variables,
b) Joining and release angles (detachable connection: $\alpha_2 < 90°$, nondetachable connection: $\alpha_2 \geq 90°$).

A Stop against overextension of the torsion axis.
B Button side for releasing the torsion snap-on hook must be more stiffly designed than the side with engagement hook.

Design guidelines and layout

The spring elements are designed to accommodate the permitted elongation of the plastic in the joining process. The least favorable material condition must be taken into account here (e.g. dry polyamide).

The elongation-dependent secant modulus

$$E_s = \frac{\sigma_1}{\varepsilon_1}$$

is used (determination depicted in Figure 2). The corresponding stress-strain diagrams can be taken for example from the CAMPUS database [29] or obtained from the material manufacturers.

In order to achieve a uniform distribution of strain and optimum material utilization in the bending range of the spring elements, the thickness from the root to the free end should decrease by half. As an alternative, the width to the end of the hook can be reduced to one quarter. Radii at the point of connection of the spring element to the component are recommended in that they help to eliminate concentrations of strain.

When joined, the spring element must be fully returned to its initial state in order to prevent creeping under load and thus permanent deformation. Tensile stress in the snap-on element as a result of operational forces is permitted.

The permitted excursion (spring travel f) in joining is dependent on the geometry of the snap-on hook and the permitted elongation ε of the plastic (Table 2). Formulas for different cross-sectional shapes can be taken from the relevant technical literature ([28], [30], [31]) or are provided by special calculation programs.

Included in the calculation of the excursion force Q are the rigidity of the plastic as the secant modulus E_s and the geometry as the bending moment/section modulus W.

The joining force F is calculated from the excursion force Q, the joining angle α_1 (usually 30°), and the coefficient of friction μ between the joining components according to the formula:

$$F = \frac{Q\,(\mu + \tan\alpha_1)}{(1 - \mu\,\tan\alpha_1)}\,.$$

Values for the section modulus W and the friction coefficient μ can also be taken from the technical literature ([28], [30], [31]).

The release force of a snap-on connection is calculated according to the same formula as the joining forced, where the release angle α_2 of the snap-on hook (usually 60°) is to be used. In the case of a nondetachable connection ($\alpha_2 \geq 90°$), the thrust capacity of the snap-on element limits the strength.

Figure 2: Determination of secant modulus E_s
$E_{S1} = \sigma_1/\varepsilon_1$,
E_0 Modulus of elasticity.

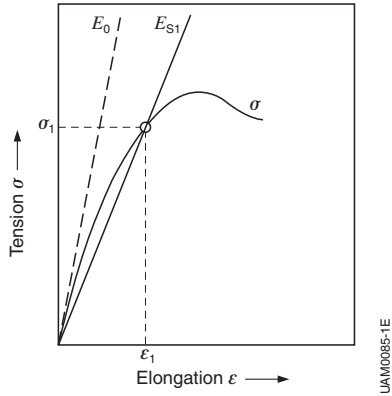

Table 2: Reference values for permitted elongation ε for snap-on connections. [28]
(For single, brief joining operation, in case of frequent joining operations reduction of the values by approx. 40 %).

Calculation programs
Different plastic manufacturers provide easy-to-use calculation programs as a customer service (e.g. "Snaps" from BASF [32], "FEMsnap tool" from Covestro [33], "FEMSnap" from Lanxess [34]). Most of the material data for manufacturers' product ranges are integrated into these programs. It is also possible and recommended to check the snap-on-hook design by means of FEM analysis within the framework of component development.

Permanent joints

Welding

Automotive components and subassemblies are joined using a wide and highly varied range of welding and bonding techniques [1], [2]. Resistance and fusion welding are among the most commonly applied welding methods. The overview in Figure 1 shows the most important resistance-welding procedures used in production technology (for procedure types and symbols, see DIN 1910, Part 100, [3]).

Resistance welding

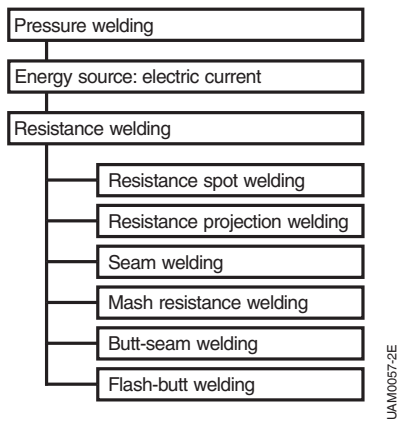
Resistance spot welding

In resistance spot welding, locally applied electrical current is used to melt the contact surfaces of the parts to be joined into a soft or fluid state. The parts are then joined together under pressure (Figure 2a and 2b). The spot-welding electrodes which conduct the welding current also convey the electrode force to the parts to be joined (joining parts). The amount of heat required to create the welding spot is determined in accordance with the equation

$Q = I^2 R t$ (Joule's Law).

The precise amount of heat required Q is a function of welding-current intensity I, resistance R, and welding time t. A good and adequate spot diameter can be achieved by the coordination of welding-current intensity I, electrode force F, and welding time t.

According to the manner in which the current is conducted, a distinction is drawn between bilateral direct resistance spot welding (Figure 2a) and unilateral indirect resistance spot welding (Figure 2b).



The electrode for a specific spot welding operation is selected with reference to shape, outside diameter and point diameter. Since the joining parts should be as free as possible of scaling, oxides, paints, grease, and oils, they receive where necessary appropriate surface pretreatment prior to welding.

Applications:
- Joining of sheet parts up to an approximate 3 mm single sheet thickness in the lap joint or as a welding flange.
- Multiple-sheet as well as two-sheet joints of different sheet thicknesses and sheet materials.
- Spot-weld bonding in combination with adhesive.

Resistance projection welding

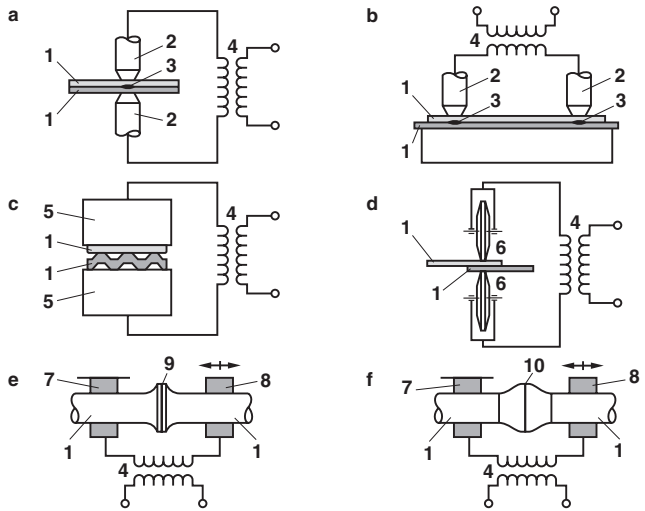
Projection welding (Figure 2c) is a process in which electrodes with a large surface area are employed to conduct the welding current and the electrode force to the workpiece. The projections, which are generally incorporated into the thicker of the joining parts, cause the current to concentrate at the contact points. The electrode force levels the projections partially or completely again during the welding process. A permanent, inseparable joint is produced at the welding seams, i.e. the contact points. One or more than one projection can be welded simultaneously, depending on the type of projection (round, longitudinal or annular) and the power available from the welding appa-

Figure 1: Classification of resistance-welding process in acc. with DIN 1910-100

ratus. Depending on the number of spots welded, a distinction is drawn between single-projection welding and multiple-projection welding.

Resistance projection welding requires high welding currents applied for short periods of time.

Applications:
– Welding parts of different thicknesses.
– Welding multiple projections in a single operation.



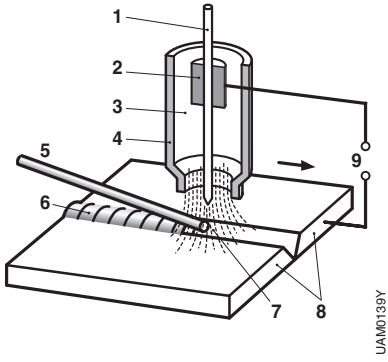
Seam welding
In this process, roller electrodes replace the spot-welding electrodes used in resistance spot welding (Figure 2d). Contact between the roller set and the workpiece is limited to an extremely small surface area. The roller electrodes conduct the welding current and apply the electrode force. Their rotation is coordinated with the movement of the part.

Applications:
– Production of sealed welds or seam spot welds (e.g. fuel tanks).

Flash-butt welding
In flash-butt welding, the butt ends of the workpieces are joined under light pressure (Figure 2e) while the flow of current at the contact surfaces produces localized heat and melting (high current density) (current supply via copper jaws). The metal's vapor pressure drives molten material from the contact patches (burn-off). The welded joint is then created by upsetting the workpieces with a high compressive force.

The butt ends should be parallel to each other and at right angles to the direction in which the force is applied (or virtually so). Smooth surfaces are not required. A certain amount of extra length must be factored in to compensate for the losses incurred in the flash-butt welding process.

Figure 2: Resistance-welding processes
a) Bilateral resistance spot welding, b) Unilateral resistance spot welding,
c) Resistance projection welding, d) Seam welding, e) Flash-butt welding, f) Butt-seam welding.
1 Part to be joined, 2 Spot-welding electrodes, 3 Welding spot, 4 Transformer,
5 Large-surface electrodes, 6 Roller electrodes, 7 Fixed copper jaws,
8 Longitudinally movable copper jaws, 9 Weld joint with seam, 10 Weld joint with bead.



The result is a weld with the characteristic projecting seam.

Applications:
– Joining in the butt joint, e.g. rims, link chains.
– Workshop procedures, e.g. for saw bands.

Butt-seam welding
This process (Figure 2f) employs copper jaws to conduct the welding current to the workpieces to be joined. When the welding temperature is reached, the current switches off. Constant pressure is maintained and the workpieces then weld together (requirement: properly machined butting faces). The process does not completely displace contamination that may be present at the butt ends. The result is a weld with the characteristic projecting bead.

Applications:
– Joining in the butt joint, e.g. shafts, axles.

Figure 3: Principle of tungsten inert-gas welding

2 Current contact tube,
3 Inert gas,
4 Inert-gas nozzle,
5 Welding filler,
6 Weld seam,
7 Arc,
8 Workpieces,
9 Energy source.

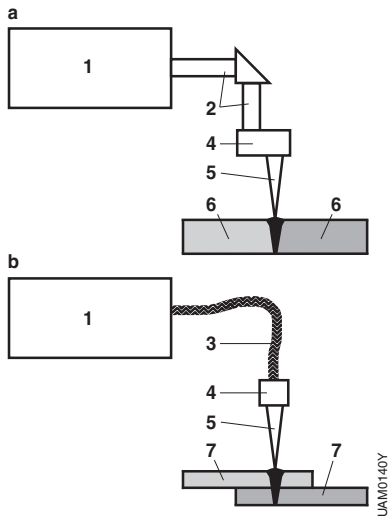
Fusion welding
The term "fusion welding" describes a process employing limited local application of heat to melt and join the parts. No pressure is applied. Shielded (inert gas) arc welding is a type of fusion welding. The electrical arc extending between the electrode and the workpiece serves as the heat source. Meanwhile, a layer of inert gas shields the arc and the melted area from the atmosphere. The type of electrode is the factor which distinguishes between various techniques:

Tungsten inert-gas welding
In this process, an arc is maintained between the workpiece and a stable, non-melting tungsten electrode. The shielding (inert) gas is argon or helium. The rod-shaped weld metal is supplied from the side (Figure 3).

Gas-shielded metal-arc welding
In gas-shielded metal-arc welding, an arc is maintained between the melting end of the wire electrode (material feed) and the workpiece. The welding current flows to the wire electrode via a current-contact nozzle in the welding torch. Metal inert-gas (MIG) welding uses inert gases (slowly reacting and noble gases such as argon, helium, or combinations of the two) as protective gas. MIG welding is used with materials which are particularly sensitive to oxidation, e.g., aluminum, magnesium, titanium, and nickel alloys.

Metal active-gas (MAG) welding, on the other hand, uses an active gas (e.g., CO2 or mixed gases containing CO2, argon and sometimes oxygen). MAG welding is used above all for unalloyed and low-alloy steels. Using inert gases with low active-gas admixtures for high-alloy, e.g., stainless steels is also referred to as MAG welding.

Laser-beam welding
Laser-beam welding (or laser welding for short) involves the use of light as the energy source to melt on the workpieces to be welded. The monochromatic laser radiation is generated in a laser source, where the wavelength is determined by the respective excitation medium. CO_2 lasers and NdYAG lasers (solid-state lasers) are used in industrial practice [5], [6]. Newer developments are diode lasers and fiber lasers.



Depending on the wavelength, tube guides with refraction mirrors (CO_2 lasers) or optical fibers (e.g. NdYAG lasers) are required to direct the beam from the beam generator to the weld (Figure 4). To utilize the energy of the laser beam for welding, it is necessary to implement focusing with mirror or lens systems. This allows particularly high energy flux densities to be achieved at the weld, resulting in the deep-welding effect, which provides for particularly deep, but at the same time, narrow seams. In the simplest case welding is performed without filler metal.

Feeding the workpiece relative to the focusing optics, the optics relative to the workpiece or a combination of the two is used to direct the beam along the seam. Systems with optical fibers are particularly well suited to moving the focusing optics, e.g. during robot-controlled welding of three-dimensional seam geometries.

In the case of remote welding the beam is directed over the workpiece from a relatively large distance (long focal length of the focusing optics) by moving the focusing mirror or the focusing lens inside the focusing optics.

It is possible to operate several machining stations with one beam generator by using beam switches.

Figure 4: Principle of laser-beam welding
a) Beam direction by mirror,
b) Beam direction by optical fiber.

2 Beam direction by refraction mirror,
3 Beam direction by optical fiber,
4 Focusing optics,
5 Focused laser beam,
6 Workpieces (butt joint) with weld seam,
7 Workpieces (lap joint) with weld seam.

Applications:
– Joining of steel sheets using a lap joint in body manufacturing,
– Joining of unalloyed and low-alloy steels as butt joint in chassis and assembly components,
– Joining of high-alloy steels in exhaust-gas systems,
– Joints in seat systems,
– Joining of aluminum alloys (with filler metal).

Other welding processes
The following welding processes are also used in the automotive industry [5], [6]:
– Electron-beam welding,
– Friction welding,
– Arc pressure welding (stud welding),
– Stored-energy welding (pulsed-current arc welding).

Soldering

In soldering, a supplementary material (solder) is melted onto two or more parts of similar or varying metallic composition in order to produce a permanent connection between them. Flux or protective gas is also used [7], [8], [9].

Fluxes (non-metallic substances) are applied to remove oxide layers from the surfaces of the soldering points after cleaning and to prevent new layers from forming: This makes it possible to apply a consistent coat of solder to the joint surfaces. Information on fluxes can be found in DIN EN ISO 9454-1 [10] and DIN EN 1045 [11].

The melting temperature of the solder is below that of the parts being joined. The solder is distributed along the join to produce the connection without the parts themselves being melted.

The strength of a soldered joint can be equal to that of the base material itself. To achieve the required strength, it is necessary to have narrow soldering gaps in which the adjacent, higher-strength base material prevents the solder from deforming.

Information on the temperature range, the heat source and the geometry of the joint shape (structure) is used to describe the soldered joints. In terms of the working temperature, a distinction is made between soft soldering and hard soldering. The working temperature is defined as the lowest surface temperature at the connection between the workpieces to be joined at which the solder can be melted and distributed to form a bond. Information on solders can be found in the DIN sheets DIN EN ISO 9453 [12], DIN EN ISO 12224-1 [13], DIN EN ISO 17672 [14].

In terms of the joint shapes, a distinction is basically made between close-joint soldering (soldering gap up to 0.5 mm) and V-Joint brazing (soldering gap larger than 0.5 mm).

Distinction by working temperature

Soft soldering

Soft soldering is employed to form permanent solder joints at melting temperatures below 450 °C (as with soldering tin). Soft solders which melt at temperatures of 200 °C and below are also known as quick solders.

Soft-soldering applications:

– Used in electrical engineering for contacts (e.g., flow soldering of printed-board assemblies).

Hard soldering

Hard soldering (brazing) is used to form permanent joins at melting temperatures above 450 °C (as with copper, copper/zinc and silver alloys, e.g. silver brazing filler).

Brazing applications:

– V-joint brazing: steel sheets in body manufacturing, also of different qualities and in the case of large wall-thickness differences.
– Close-joint soldering: radiators, pipes in the assembly area.

Manufacturing methods

The method used for heating provides yet another criterion for describing soldered joints. The most important types are furnace, induction, open-flame, and iron soldering.

Sweating

Heating is performed in through-type or vacuum furnaces with defined temperature and time characteristics. Before entering the furnace, the components are secured and the solder is inserted or applied as a paste. Additional fluxes are not required. The furnace atmosphere and the vacuum assume the flux function without leaving residues on the components.

Induction soldering

Heating is locally limited by inductive means.

Induction soldering is mainly used for round components, e.g., pipes for cooling water or oil.

Flame soldering
Heating is performed by individual torches or in a gas-heated system. Depending on the specific soldering operation, oxyacetylene burners (familiar from gas welding), propane torches or soldering lamps are employed. The solder is usually supplied from the side in the shape of a rod. The flux is applied separately or integrated in the solder.

Flame soldering is used for very small production batches and prototypes or to rework and repair, for example, pipes.

Iron soldering
A hand-held or mechanically guided soldering iron provides the heat. Irons can also be used to solder pretinned surfaces.

Iron soldering only used in soft soldering.

Further processes
– Salt-bath soldering,
– Dip soldering,
– Resistance soldering, as well as,
– MIG soldering,
– Plasma soldering, and
– Laser soldering.

Close-joint soldering and V-joint brazing
Furthermore, with regard to the geometry of the solder and the soldering flux, a distinction is made between close-joint soldering and V-joint brazing.

Close-joint soldering
The soldering gap is filled by the capillary effect of the liquid solder. The strength of the soldered joint is determined entirely by the strength of the base materials. Typical manufacturing processes are sweating, flame soldering and induction soldering.

V-joint brazing
The soldering gap is filled by the force of gravity. The strength of the soldered joint is determined above all by the strength of the solder filler. Typical manufacturing processes are arc and laser soldering.

Adhesive technologies

Adhesives
An adhesive is a non-metallic material which can join workpieces (parts to be joined) by means of adhesion and its internal strength (cohesion) without the structure of the part to be joined being significantly altered. An adhesive enables the creation of permanent material joints between homogeneous or heterogeneous material pairings.

Organic and inorganic adhesives as they harden build up firstly adhesion with the material surfaces by way of chemico-physical interactions (adhesion or adhesive forces) and secondly the necessary structural strength (cohesion). Depending on their chemistry, these adhesives harden for example at room temperature, at increased temperatures or under UV radiation with different mechanisms.

Hardening (cross-linking) and adhesion occur, in accordance with the chemical basic structure and formulation, over a certain period of time, depending on for example temperature or air humidity. The reaction types are called polymerization, polyaddition and polycondensation. Spatially interlinked macromolecules are the result. Adhesives can, depending on the required hardening temperature, be subdivided into the category of those that harden at room temperature or at higher temperatures (100 to 200 °C).

Two different types of adhesive are used, based on their recipe and form of presentation: single-component and two-component adhesives.

Two-component adhesives
These are adhesives which are made up of two components which must be mixed together to harden. The stoichiometric mixture ratio of the two components must be maintained exactly. Component A contains the basic resin. The second component (component B) contains a hardener which initiates the cross-linking reaction and links the resin molecules from component A to each other. An accelerator may be added to the hardener. Hardening usually occurs at room tem-

perature, but can by accelerated by the additional influence of slightly increased temperatures (80 to 120 °C) and thus completed more quickly.

Single-component adhesives
Single-component adhesives contain all the constituents necessary to form a bond in one phase. These systems contain inhibitors which prevent a premature chemical reaction (hardening) between the reacting agents present in the one phase (monomers, resin and hardener; premixed two-component adhesive). Single-component adhesives do not require the additional process step of mixing the components as a two-component adhesive requires.

Hardening must, depending on the chemical formulation, be initiated by higher temperatures (in an oven, by induction or infrared radiation), ultraviolet radiation or air humidity, and completed. In this process the inhibitors are neutralized and the accelerators also contained in the adhesive are released to speed up the hardening process.

Most single-component adhesives must be stored under cooled conditions (electrical conductive adhesives down to −20 °C in an upright deep-freezer, structural adhesives and sealants at 4 to 10 °C in a cold warehouse) or in a dark environment (UV adhesives) until they are ready for use.

Structural designs of adhesive connections
Adhesive connections should be designed so that predominantly shear loads occur. Overlapping joints are particularly suitable. Butt joints subjected to tensile or sliding forces should be avoided.

Combinations of adhesive bonding with other joining methods, e.g. welding, screwing or riveting, can have beneficial effects. The joining spots secure the components during the adhesive hardening time. Stress concentrations for example at the edges of weld spots or at rivet spots can also be minimized. Constructions of this nature provide enhanced structural integrity, rigidity, and damping when subjected to dynamic loads.

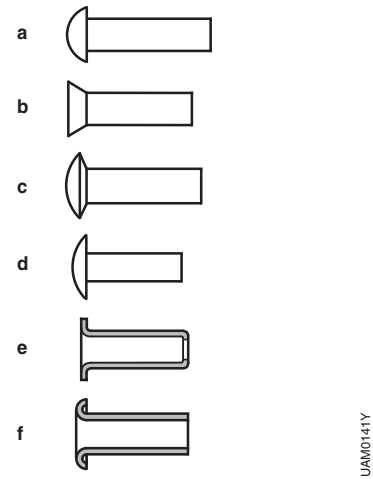
Examples of adhesives with technical application potential
The most important adhesives are epoxy resins, silicones, polyurethanes, and acrylates.

Silicone and polyurethane adhesives
Silicone and polyurethane adhesives are important particularly in bonds with dynamic loads, but also where tightness against liquid media (e.g. water) is called for. Depending on the medium (polar, nonpolar), there is however a risk of flexible adhesives swelling (e.g. in fuel). This process can be reversed provided the system can be re-dried during operation and the adhesive has not suffered any damage (e.g. material embrittlement by extraction). Thanks to their flexibility (elastic properties), these adhesives can compensate the different coefficients of thermal expansion of the parts to be joined in the temperature-application range by means of their deformability (low modulus of elasticity above a crystallization temperature of −60 °C to −40 °C) such that only low mechanical stresses can be built up in the bond. Compared with polyurethanes, silicones are also highly suitable for use at high application temperatures up to approximately 220 °C.

Epoxy adhesives
Epoxy adhesives, on the other hand, are predominantly very brittle and hard adhesives which can, depending on their formulation, be used up to approximately 200 °C. Compared with flexible adhesives, they are much less susceptible to swelling in liquid media. High-strength epoxy resins lack the ability of silicones to compensate by means of deformability (elongation) mechanical stresses in the adhesive bond which are caused by different coefficients of thermal expansion of the parts to be joined in the temperature-application range. Exceptions are adhesives which, thanks tor their special formulation (e.g. impact-resistant modification), are used specifically for bonds in body manufacturing in order specifically to reduce the mechanical forces and energies that occur in a crash situation and to maintain the structural integrity of the passenger cell. Epoxy adhesives facilitate bonds with

very high adhesive strengths (high modulus of elasticity up to the glass-transition temperature; this is in the range of 80 to 200 °C, depending on the chemical recipe of the adhesive components).

Acrylate adhesives
Acrylates are capable of fast hardening reactions and therefore highly attractive for use in production processes. These adhesives can harden, depending on their chemical architecture, in response to ultraviolet radiation, mixing of components, at increased temperatures or also in response to air humidity ("superglue") within a few minutes down to a matter of seconds. On the other hand, acrylates do not demonstrate as pronounced thermomechanical performance as silicone and epoxy adhesives above approximately 120 °C or in aggressive media.



Automotive applications
Adhesive joining has become a standard technique in automotive engineering. The individual areas of application can be classified as follows:
– Electronic components: sealing/bonding of housings for sensors, ECUs and video systems; electrically and thermally conductive bonding of electronic component in power modules and electronic circuits.
– Electric motors: magnetic bonds in rotors and stators.
– Body shell: raised-seam and brace bonding for attached components.
– Assembly line: attachment of insulating material, appliqués, moldings, mirror-support bracket to windshield.
– Component production: bonding of brake pads, laminated safety glass (LSG), rubber-metal connections to absorb vibration.

Riveting

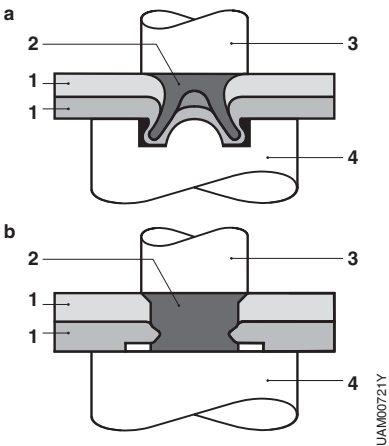
Classic riveting
Process
Riveting is used to produce a permanent fixed connection between two or more components made of identical or dissimilar materials. Here the components to be joined are pierced together by means of drilling or punching. The rivet is then inserted into the hole as the joining element. Depending on the method and application, riveted joints are divided into the following categories:
– Permanent rigid connections (interference fits, for example in mechanical and plant engineering),
– Permanent, sealed connections (for example in boilers and pressure vessels),
– Extremely tight seals (for example in pipes, vacuum equipment).

A distinction is drawn between cold and hot riveting, depending on the temperature used. Cold riveting is employed for rivet joints up to 10 mm in diameter in steel, copper, copper alloys, aluminum,

Figure 5: Rivet shapes
a) Mushroom-head rivet,
b) Countersunk-head rivet,
c) Oval countersunk-head rivet,
d) Flat round-head rivet,
e) Hollow rivet,
f) Tubular rivet.

etc. Rivets with diameters in excess of 10 mm are installed hot.

The most common rivet shapes are (Figure 5, [15]...[20]) the mushroom-head rivet (DIN 660), the countersunk-head rivet (DIN 661), the oval countersunk-head rivet (DIN 662), the flat round-head rivet (DIN 674), the hollow rivet (DIN 7339), and the tubular rivet (DIN 7340).



There are also standardized rivets for specialized applications, e.g. explosive rivets or blind rivets. Blind rivets are hollow and are expanded by a drift or punch.

Furthermore, rivets are frequently designed for use as function elements. Examples are rivet nuts and clinch bolts, which serve as bolting points.

The strength properties and the chemical composition of rivet materials are laid down in numerous national and international standards. In the interests of avoiding electrochemical corrosion, it is advisable wherever possible to use materials of the same kind for rivets and component.

In mechanical engineering in general and in tank manufacture riveting has largely been displaced by welding.

Figure 6: Joint with punch rivet
a) Semi-hollow rivet,
b) Solid rivet.
1 Workpieces,
2 Punch rivet,
3 Riveting die,
4 Die plate.

Advantages and disadvantages compared with other joining techniques
- Unlike welding, riveting exerts no influence such as hardening or structural transformation on the material.
- No distortion of the components.
- Suitable for joining dissimilar materials.
- Riveting weakens the components.
- Butt joints cannot be riveted, and
- Riveting is generally more expensive than welding when performed outside the factory.

Automotive applications
- Riveting pivot/joint pins (power-window units, hinges, windshield-wiper linkages).
- Riveting reinforcement plates (in the course of repairs).

Punch riveting

Process

The punch-riveting technique joins solid materials employing stamping and riveting elements (solid or semi-hollow rivets) without piercing in a combined cutting and joining operation. The parts to be joined do not have to be pierced or predrilled, as is the case with other riveting techniques.

Punch riveting with semi-hollow rivets

The first stage in punch riveting with a semi-hollow rivet (Figure 6a) is to position the joining point of the components to be joined on the (bottom) die plate. The riveting die descends and presses the semi-hollow rivet through the upper sheet into the lower sheet in a single stamping operation. The rivet deforms and the bottom spreads to form a securing element, usually without fully penetrating the lower sheet.

Punch riveting with solid rivets

The first stage in punch riveting with a solid rivet (Figure 6b) is to position the joining point of the components to be joined on the (bottom) die plate. The top section of the rivet unit, including the blank holder, descends and the riveting die presses the rivet through the parts to be joined in a single stamping operation.

Equipment
Hydraulic joining equipment is used to produce the joints; in equipment of this type the riveting die and the die plate are arranged in a very rigid, C-shaped frame. The rivets can be supplied to the riveting tool loose or via magazined carrier strips.

Materials
The rivets must be harder than the materials to be joined. The most common materials are steel, stainless steel, copper and aluminum with various coatings.

Features
– Possible to join similar and dissimilar materials (e.g. steel, plastic or aluminum), parts of various thicknesses and strengths, and painted sheets.
– No preliminary piercing or drilling, no heat or vacuum extraction required.
– The total material thickness that can be riveted is 6.5 mm for steel and 11 mm for aluminum.
– The joining process generates minimal heat and noise.
– Tools have a long service life (approx. 300,000 rivet applications) and deliver consistent joint quality over a long period of time.
– High process reliability through monitoring of the process parameters.
– High forces have to be applied.
– Larger tong projections of the riveting tools are only possible under limited conditions owing to the rigidity requirements.

Applications
– Punch riveting with solid rivets: joining metal sheets in automotive engineering, e.g. power-window drives in passenger cars.
– Punch riveting with semi-hollow rivets: joining materials in passenger-car body manufacturing, white goods (household appliances), joining metals to composites (heat shields).

Penetration-clinching processes

Processes
Penetration clinching ("clinching") comprises mechanical joining processes which combine penetration, cold upsetting and sometimes also cutting in a single continuous joining operation without the application of additional heat. Based on this principle, it can be assigned to the process of joining by forming (see DIN 8593-5, [21]).

Distinctions are made between processes with and without cutting and those where the joining point is round or rectangular in shape.

"Tox clinching"
Some process variations are still referred to in technical parlance by the original manufacturer's designations, e.g. "Tox clinching" for penetration clinching with a round die without cutting (Figure 7b). The tools employed for "Tox clinching" are relatively small. The diameter can be varied to suit specific applications. A force-travel curve typical of "Tox clinching" can be broken down into five characteristic phases (A-E) (Figure 8).

Penetration clinching
Penetration clinching (Figure 7a) currently allows blanks up to 3 mm thick to be joined, whereby the total thickness of the two blanks should not exceed 5 mm. The blanks being joined can be of the same material (e.g. steel to steel) or dissimilar materials (e.g. steel to nonferrous metal). Penetration clinching can be used to join coated sheets and painted parts, as well as components to which adhesives have been applied. Multiple penetration clinching can be used to produce numerous elements to be joined (up to 50) in a single process (one stroke of the press, for example).

Advantages and disadvantages of penetration-clinching processes
- No need for an acoustic enclosure.
- Tox clinching to a large extent does not impair corrosion protection.
- When combined with cutting, there is a partial loss of corrosion protection.
- No distortion due to thermal stress.
- Painted, protected (oil, wax) and glued sheets can be clinched.
- Different materials can be joined (e.g. steel to plastic).
- Energy savings, since no power supply for welding and no cooling-water system are required.
- One side of the workpiece has a projection similar to that produced by a rivet head, while the other side has a corresponding depression.

Automotive applications
- Steel and aluminum bodies,
- Windshield-wiper brackets,
- Fastening interior door panels,
- Hinges, locks,
- Seat systems.

Vehicle motion

Coordinate system

Vehicle motion is described by three translational and three rotational degrees of freedom (Figure 1). Generally, the system of coordinates (rectangular right-handed system) has its origin at the vehicle's center of gravity S. The x-axis (longitudinal axis) points forwards, i.e., in the direction of travel. It is situated in the plane that is perpendicular to the road surface. This plane is called the vehicle center plane. Situated perpendicular to the vehicle center plane is the y-axis (transverse axis), which points, when viewed in the direction of travel, to the left. The z-axis (vertical axis) points upwards (according to DIN ISO 8855 [1]).

Table 1: Quantities and units

Quantity		Unit
β	Float angle	degree
ψ	Yaw angle	degree
φ	Roll angle	degree
θ	Pitch angle	degree
a_x	Longitudinal acceleration	m/s²
a_y	Lateral acceleration	m/s²
a_z	Vertical acceleration	m/s²
a_t	Tangential acceleration	m/s²
a_c	Centripetal acceleration	m/s²
M_x	Rolling moment	N m
M_y	Pitching moment	N m
M_z	Yawing moment	N m
v_x	Longitudinal velocity	m/s
v_y	Lateral velocity	m/s
v_z	Vertical velocity	m/s

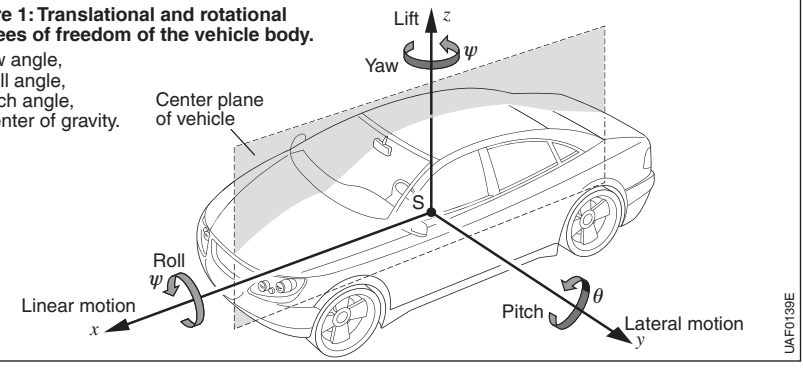
Degrees of freedom of vehicle motion

Translational motions

Definitions of motion variables

The translational motions are designated as follows:
– In x-direction: linear motion.
– In y-direction: lateral motion.
– In z-direction: lift.

Linear motion is caused by motive force, braking force, and frictional force. Lateral motion is a consequence of centrifugal force, crosswind force, and cornering force. Vertical motion is caused by wheel load and forces brought about by road-surface irregularities.



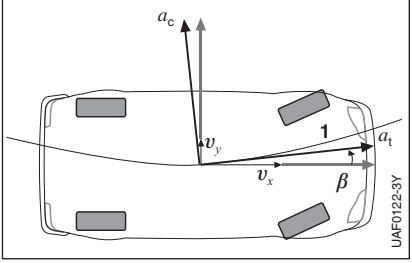
Translational velocities and accelerations

Single time derivation of the translational motion variables determines the linear, lateral, and vertical velocities (v_x, v_y, v_z) (quantities and units, see Table 1). Renewed derivation produces the linear acceleration a_x, lateral acceleration a_y, and vertical acceleration a_z.

Float angle

In the dynamics of lateral motion the center of gravity of the vehicle body does not always move along the x-axis. The angle that forms between the vehicle center plane and the instantaneous vehicle linear velocity (trajectory) is called the float angle β (Figure 2). It is counted from the

Figure 1: Translational and rotational degrees of freedom of the vehicle body.
ψ Yaw angle,
φ Roll angle,
θ Pitch angle,
S Center of gravity.



vehicle center plane to the trajectory. The float angle is calculated from the linear velocity v_x and the lateral velocity v_y in the following form:

$$\beta = \arctan \frac{v_y}{v_x}.$$

Because linear velocity during forward driving is by definition positive, the sign preceding the lateral velocity in this case also determines the sign preceding the float angle.

Centripetal acceleration and tangential acceleration
Acceleration is proportioned in the horizontal plane along the instantaneous vehicle trajectory into centripetal acceleration a_c and tangential acceleration a_t (Figure 2). The centripetal acceleration is that part which is perpendicular to the trajectory, while the tangential acceleration is that part in the tangential direction of the trajectory.

Figure 2: Float angle, centripetal and tangential acceleration
1 Trajectory.
β Float angle,
a_t Tangential acceleration,
a_c Centripetal acceleration,
v_x Longitudinal velocity,
v_y Lateral velocity.

Rotational motions
Definitions of motion variables
The following terms have been established to cover rotational motion.
– Yaw: Pure rotation about the z-axis with yaw angle ψ.
– Pitch: Pure rotation about the y-axis with pitch angle θ.
– Roll: Pure rotation about the x-axis with roll angle φ.

The signs preceding these rotations correspond to those of a rectangular right-handed system. The counting directions are shown in Figure 1. In many driving maneuvers the body simultaneously moves about more than one axis. Because, when viewed mathematically, the three rotations are not commutative, the following order for the rotations has been defined in DIN ISO 8855:
1. Yaw,
2. Pitch,
3. Roll.

Rotational velocities and accelerations
Single time derivation of the rotational motion variables produces the yaw, pitch and roll velocities. Renewed time derivation produces the yaw, pitch and roll accelerations.

Moments
Definitions
External forces acting on the vehicle can generate a moment about the center of gravity. This moment is broken down into three components.
– Portion of moment about the z-axis: Yaw moment M_z.
– Portion of moment about the y-axis: Pitching moment M_y.
– Portion of moment about the x-axis: Rolling moment M_x.

Running resistances

Total running resistance

The running resistance F_W at constant driving speed v is the sum total of rolling resistance F_{Ro}, aerodynamic drag F_L, and climbing resistance F_{St} (Figure 1):

$$F_W = F_{Ro} + F_L + F_{St}.$$

In the case of an acceleration the acceleration resistance must additionally be overcome (see Dynamics of linear motion). This resistance is not taken into consideration in the following examination.

The power which must be transmitted through the drive wheels to overcome running resistance (running-resistance power) is:

$P_W = F_W\, v$ (quantity equation) or

$$P_W = \frac{F_W\, v}{3600}$$ (numerical-value equation).

The numerical-value equation is calculated with P_W in kW, F_W in N, v in km/h (quantities and units, see Table 1).

Individual running resistances

Rolling resistance

The rolling resistance F_{Ro} is the product of deformation processes which occur at the contact path between tire and road surface. A measure of the rolling resistance is the coefficient of rolling resistance f_R. The following equation applies to the rolling resistance:

$$F_{Ro} = f_R\, G \cos \alpha = f_R\, m\, g \cos \alpha .$$

The rolling resistance is determined by the coefficient of rolling resistance f_R and by the normal force, the force N acting vertically on the road surface ($G \cos \alpha$, see Figure 1).

On made-up roads the proportion of the rolling resistance caused by deformation is negligible. On roads with a soft or yielding surface, however, the deformation work makes up a significant proportion of the rolling resistance (Table 2).

The deformation work on the tire is created by flexion of the tire. These losses are influenced by the flexing amplitude, which increases with increasing wheel load and decreasing tire inflation pressure, and by the flexing frequency, which increases with the driving speed. The flexing frequency is also higher on tires with a small radius.

Table 1: Quantities and units

Quantity		Unit
E	Greatest cross-sectional area of vehicle (frontal area)	m^2
c_W	Drag coefficient	–
F	Motive force	N
f_K	Cornering resistance	N
F_L	Aerodynamic drag	N
F_{Ro}	Rolling resistance	N
F_{St}	Climbing resistance	N
F_W	Running resistance	N
f_K	Coefficient of cornering resistance	–
f_R	Coefficient of rolling resistance	–
G	Force due to weight, $G = m\, g$	N
G	Gravitational acceleration ≈ 9.81 m/s^2	m/s^2

Quantity		Unit
h	Height of projected distance l	m
l	Distance	m
m	Vehicle mass	kg
N	Normal force	N
P_L	Aerodynamic drag in kW	W
P_{St}	Hill-climbing power requirement	W
P_W	Running-resistance power	W
p	Gradient (tan α)	%
t	Time	s
v	Driving speed	m/s
v_0	Headwind speed	m/s
α	Incline angle, Gradient angle	°
ρ	Air density	kg/m^3

An approximate calculation of the rolling resistance can be made using the coefficients provided in Table 2 and Figure 2.

In turns, the rolling resistance is augmented by the cornering resistance.

$F_K = f_K \; G$.

The coefficient of cornering resistance f_K is a function of driving speed, curve radius, suspension geometry, tires, tire inflation pressure, and the vehicle's response under lateral acceleration.

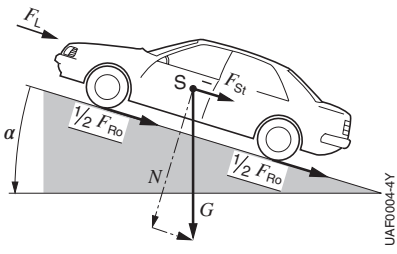

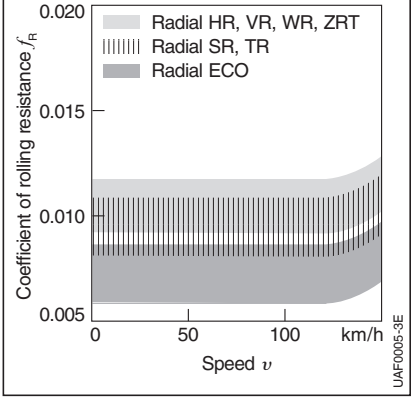

Figure 2: Coefficient of rolling resistance for radial car tires on smooth, level road surfaces under normal load and at correct tire inflation pressure

Aerodynamic drag

Aerodynamic drag is generated by air flowing round and through a vehicle as it is driving. It is calculated as a function of the air density ρ (ρ = 1.204 kg/m³ at sea level, normal pressure 1013 mbar, 20 °C), the cross-sectional area A of the vehicle, the drag coefficient c_w, and the square of the airflow velocity (sum total of driving speed v and headwind speed v_0) as:

$F_L = 0.5 \rho c_w A (v + v_0)^2$ or

$F_L = 0.0386 \rho c_w A (v + v_0)^2$

with v in km/h, F_L in N, ρ in kg/m³, A in m².

Typical value ranges for drag coefficient c_w and cross-sectional area A (frontal area) are listed for different passenger-car body configurations in Table 3. For commercial vehicles values for the drag coefficient of c_w = 0.4…0.9 and for the cross-sectional area of A = 4…9 m² are obtained.

The aerodynamic-drag power is

$P_L = F_L v = 0{,}5 \rho c_w A v (v + v_0)^2$ or

$P_L = 12.9 \cdot 10^{-6} c_w A v (v + v_0)^2$

with P_L in kW, F_L in N, v and v_0 in km/h, A in m², ρ = 1.204 kg/m³.

Table 2: Coefficients of rolling resistance

UAF0006-2E

Table information:
The mid-size class market segment features the lowest c_W values, followed by the luxury class, compact class, sports cars, closed convertibles, station wagons, vans, small cars up to the highest values for open-top convertibles and off-road vehicles.

However, the frontal area of a vehicle also has a significant influence on the power requirement for overcoming the drag. This changes the order with regard to the c_W value. Mid-size vehicles also require the lowest power here, followed by the compact class, sports cars and closed-top convertibles, which are nearly the same. This is followed by small vehicles and station wagons. Due to the size, luxury vehicles have fallen behind significantly and then open-top convertibles due to their high c_W value. Vans and off-road vehicles are found at the end.

This also shows that the aerodynamic drag at 40 km/h hardly differs between the classes. At 120 km/h, however, there are substantial differences because the power requirement increases with the speed cubed.

The largest cross-section of an automobile is:

$A \approx 0.9 \times$ lane width $\times$ height.

Table 3 shows values for the aerodynamic-crag power for different passenger-car body configurations at two different driving speeds. On account of the quadratic influence of the airflow velocity on the aerodynamic drag, the aerodynamic drag decisively determines the total running resistance at high speeds.

Empirical determination of coefficients for aerodynamic drag and rolling resistance

The vehicle is allowed to coast down in neutral under windless conditions on a level road surface. The time that elapses while the vehicle coasts down by a specific increment of speed is measured from two initial velocities, v_1 (high speed) and v_2 (low speed). This information is used to calculate the mean deceleration rates a_1 and a_2. The formulae and example from Table 4 are based on a vehicle weighing m = 1450 kg with a cross-section A = 2.2 m².

The method is suitable for application at driving speeds of less than 100 km/h.

Climbing resistance and downgrade force

Climbing resistance (F_{St} with positive sign) and downgrade force (F_{St} with negative sign) are calculated as:

$$F_{St} = G \sin\alpha = m\, g \sin\alpha$$

or, for a working approximation:

$$F_{St} \approx \frac{m\, g\, p}{100\ \%}.$$

This equation is valid for $p < 20$ % ($\alpha < 11$ °) gradient because at small angles:

$\sin\alpha \approx \tan\alpha$ (deviation below 2 % for $\alpha < 11$ °).

Refer to Table 5 for the climbing resistance, normalized to 1000 kg vehicle mass, as a function of the gradient p and the gradient angle α. "in" in the gradient scale in Table 5 means "divided by" and is customary in English-speaking countries.

Climbing power is calculated as:

$P_{St} = F_{St}\, v$ (quantity equation) or

$$P_{St} = \frac{F_{St}\, v}{3600} = \frac{m\, g\, v \sin\alpha}{3600}$$ (numerical-value equation)

with P_{St} in kW, F_{St} in N, and v in km/h. For a working approximation:

$$P_{St} = \frac{m\ g\ p\ v}{360{,}000}.$$

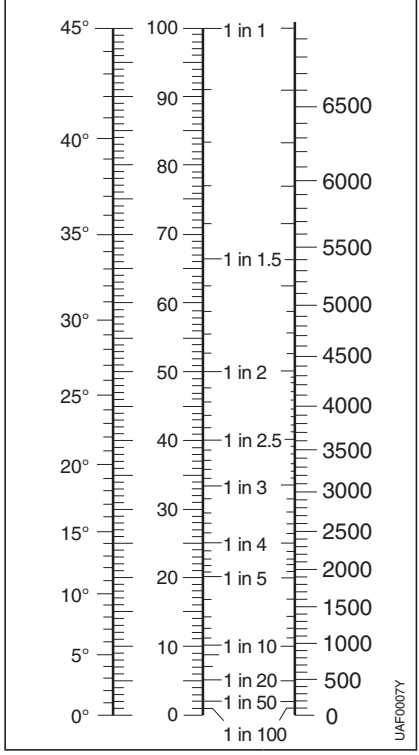

Table 4: Empirical determination of coefficients for aerodynamic drag and rolling resistance

	1st trial (high speed)	2nd trial (low speed)
Initial velocity Terminal velocity Interval between v_a and v_b	v_{a1} = 60 km/h v_{b1} = 55 km/h t_1 = 7.8 s	v_{a2} = 15 km/h v_{b2} = 10 km/h t_2 = 12.2 s
Mean velocity	$v_1 = \frac{v_{a1} + v_{b1}}{2}$ = 57.5 km/h	$v_2 = \frac{v_{a2} + v_{b2}}{2}$ = 12.5 km/h
Mean deceleration	$a_1 = \frac{v_{a1} - v_{b1}}{t_1}$ = 0.64 $\frac{\text{km/h}}{\text{s}}$	$a_2 = \frac{v_{a2} - v_{b2}}{t_2}$ = 0.41 $\frac{\text{km/h}}{\text{s}}$
Drag coefficient (all quantities as numerical values)	$c_W = \frac{6m(a_1 - a_2)}{A(v_1^2 - v_2^2)}$ = 0,29 (mit m = 1450 kg, A = 2.2 m²)	
Coefficient of rolling resistance (all quantities as numerical values)	$f_R = \frac{28.2(a_2 v_1^2 - a_1 v_2^2)}{10^3 \cdot (v_1^2 - v_2^2)}$ = 0.011	

Refer to Table 6 for the necessary climbing power, normalized to 1000 kg vehicle mass, as a function of the speed v and the climbing resistance F_{St} (values are limited to a vehicle power-to-weight ratio of 72 kW/t).

Table 5: Gradient angle and climbing resistance

Gradient angle α	Gradient p in %	Gradient	Climbing resistance F_{St} For m = 1000 kg in N

The gradient is:

$p = (h/l) \cdot 100\ \%$ or
$p = (\tan \alpha) \cdot 100\ \%$,

with h as the height of the projected distance l.

Example of calculating motive force and climbing power
To climb a hill with a gradient of p = 21%, a vehicle weighing 1,500 kg will require approximately 1.5 · 2 000 N = 3000 N of motive force at the wheels (value from Table 5) and at v = 40 km/h roughly 1.5 · 22 kW = 33 kW of climbing power (value from Table 6).

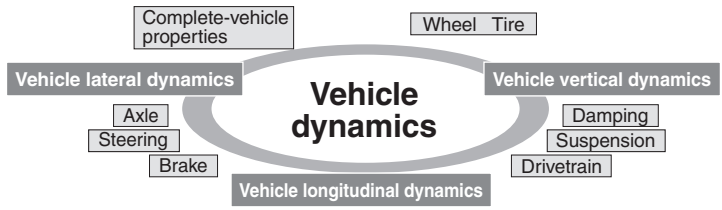
Motor-vehicle dynamics

Characteristics of vehicle dynamics

The dynamics of vehicles can be divided into three subareas (Figure 1):
– dynamics of linear motion,
– dynamics of lateral motion, and
– dynamics of vertical motion.



These three subareas can be roughly paraphrased as driving dynamics, agility, and low-frequency comfort without acoustics. Above all vehicle handling, which results from operation of the steering wheel, is considered in the dynamics of lateral motion. The dynamics of linear motion focuses on the acceleration behavior of the vehicle, i.e., all those situations in which the driver decelerates or accelerates. The dynamics of vertical motion concerns primarily the interaction with uneven roads and the effect of imbalance with rotating components, such as the wheel/tire system for example [1, 2, 3].

These three subareas should not be sharply distinguished from each other. There is for example the "Braking in a turn/curve" maneuver (see Driving-dynamics test procedures). This maneuver combines the dynamics of lateral motion with the dynamics of linear motion. Because this maneuver involves primarily the stability of the vehicle in the lateral direction and not deceleration values, it is assigned to the dynamics of lateral motion subarea. Another example the "tramp of a vehicle". This vehicle behavior combines the dynamics of lateral motion with the dynamics of vertical motion. Here an unwanted jerking motion is caused in the lateral direction which can arise when a wheel runs in a turn/curve over an uneven area and at the same time the damping is insufficient to maintain contact between tire and road.

Table 1: Quantities and units

Figure 1: Subareas of vehicle dynamics and the most important assemblies

Dynamics of linear motion

Features

The dynamics of linear motion (longitudinal dynamics) comprises the running resistances, the acceleration and deceleration, the forces and power outputs for drive and deceleration operations, and the energy expenditure required for these purposes, which is referred to as consumption (see Fuel consumption). The purpose of the motive and braking forces is to check the vehicle's dynamics of linear motion.

The change in a vehicle's motion caused by steering, acceleration and braking is brought about by forces which are transmitted to the road on account of friction between tire and road surface. The extent of the maximum transmissible force depends among other things on the force at the wheels acting on the road, the wheel load. The forces acting on the road are also influenced by speed-dependent aerodynamic lifting forces and downforces.

Motive force and engine speed

Vehicle with manual transmission

Motive force

The higher the engine torque M and overall transmission ratio i between the engine and drive wheels, and the lower the power-transmission losses, the higher the motive force F available at the driven wheels:

$$F = \frac{M\ i}{r} \cdot \eta \quad \text{oder} \quad F = \frac{P\ \eta}{v}.$$

η indicates the drivetrain efficiency. For a longitudinal engine $\eta \approx 0.88$ - 0.92, for a transverse engine $\eta \approx 0.91$ - 0.95.

The overall transmission ratio i for today's passenger cars is in the range of 1.5 to 20 and for off-road vehicles with additional reduction gears also much higher than this.

The motive force F is partially consumed in overcoming the running resistance F_W. Numerically higher transmission ratios are applied to deal with the substantially increased running resistance encountered on gradients (variable-speed transmission).

Vehicle and engine speeds

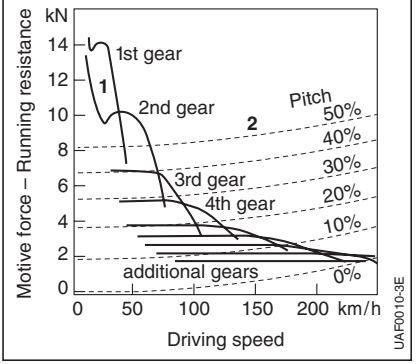
The following applies to the engine speed n in min^{-1} (rpm) with the dynamic rolling radius r of the tire in m and the driving speed v in m/s:

$$n = \frac{60\,v\,i}{2\,\pi\,r},$$

or with v in km/h:

$$n = \frac{1\,000\,v\,i}{2\,\pi\,60\,r}.$$

The driving speed v in m/s or in km/h can also be calculated from the engine speed according to the following formula:



$$v\left[\frac{\text{m}}{\text{s}}\right] = \frac{n\,\pi\,r}{30\,i} \quad \text{oder} \quad v\left[\frac{\text{km}}{\text{h}}\right] = \frac{0{,}12\,n\,\pi\,r}{i}.$$

Vehicle with automatic transmission

When the formula for motive force is applied to automatic transmissions with hydrodynamic torque converters, the engine torque M is replaced by the torque at the converter turbine, while the rotational speed of the converter turbine is used in the formula for engine speed. The relationship between $M_{\text{Turb}} = f(n_{\text{Turb}})$ and the engine characteristic $M_{\text{Mot}} = f(n_{\text{Mot}})$ is determined using the characteristics of

Figure 2: Tractive-force running diagram for a car with automatic transmissions and hydrodynamic torque converter at full load

1 Motive-force lines (tractive-force lines) for different gears,
2 Running-resistance lines for different gradient (sum total of aerodynamic drag, rolling resistance and climbing resistance).

the hydrodynamic converter (see Hydrodynamic torque converter).

Tractive-force running diagram
The tractive force (motive force) at the wheels for the individual gears as a function of the driving speed can be read from the tractive-force running diagram (Figure 2). The kink typical of a hydrodynamic converter resulting from the end of torque multiplication can be seen in the first two gears. The converter is locked up by a clutch in higher gears. The top speed in each case as a function of gear and gradient can be determined from the points of intersection of the tractive-force lines with the running-resistance lines (sum total of rolling resistance, aerodynamic drag, and climbing resistance). To the left of the point of intersection the motive force is greater than the running resistance and the vehicle is consequently accelerated. At the point of intersection the motive force is utilized entirely to overcome the running resistance and the vehicle speed thus remains constant.

Acceleration
The surplus force $F - F_W$ accelerates the vehicle. Or decelerates it when F_W exceeds F:

$$a = \frac{F - F_W}{k_m m} \text{ oder } a = \frac{P\eta - P_W}{v k_m m}.$$

During a translational acceleration of the vehicle the rotating parts of the drivetrain (wheels, flywheel, crankshaft etc.) are also rotationally accelerated. The additional rotational resistance force required for this purpose is taken into account in the form of the rotational inertia coefficient k_m as the apparent increase in vehicle mass due to the rotating masses. The rotational inertia coefficient is dependent on the ratio of the vehicle mass m to the mass moment of inertia of the drivetrain reduced to the powered axle. The latter is quadratically influenced by the overall transmission ratio i between the engine and the drive wheels. The moment of inertia of the engine, which is approximately linear to the displacement V_H, also has a significant influence (Figure 3).

Adhesion to road surface
Coefficient of static friction
The coefficient of static friction μ_r (between the tires and the road surface) is determined by the driving speed, the condition of the tires, and the state of the road surface (Table 2). The figures cited apply to concrete and asphalt road surfaces in good condition. As a rule, they are in the region of $\mu < 1$. The coefficients of sliding friction (with wheel locked) are usually lower than the coefficients of static friction.

Tires for street-legal sports cars attain μ_r values of up to 1.3. Their rubber compounds are softer than in conventional tires and their treads are less pronounced. Tires which are used in motor sport and in which special soft rubber compounds are

Table 2: Coefficients of static friction for pneumatic tires on various road surfaces

Driving speed in km/h	Tire condition	State of road surface				
		Dry	Wet, water level approx. 0.2 mm	Heavy rainfall, water level approx. 1 mm	Puddles, water level approx. 2 mm	Iced (black ice)
		Coefficient of static friction μ_r				
50	new	0.85	0.65	0.55	0.5	0.1 and less
	worn[1]	1	0.5	0.4	0.25

	worn[1]	0.95	0.2	0.1	0.05	–
130	new	0.75	0.55	0.2	0	–
	worn[1]	0.9	0.2	0.1	0	

[1] Worn to 1.6 mm tread depth (legal minimum in Germany as per § 36 StVZO (German Road Traffic Licensing Regulations)).

used can provide friction coefficients of up to $\mu_r = 1.8$. These are for the most part smooth-tread slicks where the microgearing effects between rubber and road surface can be particularly pronounced by maximizing the tire contact patch.

Aquaplaning
Aquaplaning has a particularly dramatic influence on the contact between tire and road surface. It describes the state in which a layer of water separates the tire and the (wet) road surface (Figure 4). The phenomenon occurs when a wedge of water forces its way underneath the tire's contact patch and lifts it from the road. The tendency to aquaplane is dependent upon such factors as the depth of the water on the road surface, the vehicle's speed, the tread pattern, the tread wear, and the load pressing the tire against the road surface. Wide tires are particularly susceptible to aquaplaning. An aquaplaning vehicle cannot transmit control and braking forces to the road surface, and may as result go into a skid.

Accelerating and braking

The vehicle is regarded as accelerating or braking (decelerating) at a constant rate when acceleration a is constant. The equations set out in Table 3 apply to acceleration from a standstill and braking (deceleration) to a standstill ($v = 0$).

Maxima for acceleration and braking (deceleration)
When the motive or braking forces exerted at the vehicle's wheels reach such a magnitude that the tires are just still within their limit of adhesion (i.e., maximum adhesion is still present), the relationships shown in Tables 4 and 5 exist between the gradient angle α, coefficient of static friction μ_r, and maximum acceleration or deceleration. In this connection, k indicates the ratio between the load on driven or braked wheels and the total weight. If all wheels are driven or braked, $k = 1$. At 50 % load distribution $k = 0.5$. In practice, the figures that can be achieved are always somewhat lower, as all the vehicle's tires do not simultaneously exploit their maximum possible adhesion during each acceleration or deceleration. Electronic traction control and braking systems (TCS, ABS, ESC) maintain the traction level in the vicinity of the greatest possible coefficient of static friction μ_r.

It follows from the formula in Table 4 that on a level road surface with tires that exhibit $\mu_r < 1$ for all-wheel-driven vehicles (where $k = 1$) the maximum acceleration is $g(\mu_r - f_R)$ (f_R coefficient of rolling resistance).

$a_{max} \approx 10 \cdot (0.5 \cdot 0.6 \pm 0.15)$ m/s²,
upgrade braking (+): $a_{max} = 4.5$ m/s²,
downgrade braking (–): $a_{max} = 1.5$ m/s².

Work and power
The power required to maintain a consistent rate of acceleration (deceleration) varies according to driving speed (Table 6). The power available for acceleration is:

Table 3: Accelerating and braking

	Equations for v in m/s	Equations for v in km/h
Acceleration or braking (deceleration) in m/s²	$a = \frac{v^2}{2s} = \frac{v}{t} = \frac{2s}{t^2}$	$a = \frac{v^2}{25.92s} = \frac{v}{3.6t} = \frac{2s}{t^2}$
Acceleration or braking time in s	$t = \frac{v}{a} = \frac{2s}{v} = \sqrt{\frac{2s}{a}}$	$t = \frac{v}{3.6a} = \frac{7.2s}{v} = \sqrt{\frac{2s}{a}}$
Accelerating or braking distance in m	$s = \frac{v^2}{2a} = \frac{vt}{2} = \frac{at^2}{2}$	$s = \frac{v^2}{25.92a} = \frac{vt}{7.2} = \frac{at^2}{2}$

Reaction, braking and stopping
(in accordance with ÖNORM V 5050 [4] and [5])

Hazard recognition time
The hazard recognition time, also known as the danger reaction time, is the period of time that elapses between perceiving a visible obstacle or its movement and the time required to recognize it as a hazard (Figure 5; quantities, see Table 7). It is necessary for the driver to turn his eyes towards the hazardous situation, the hazard recognition and danger reaction time will extend by roughly 0.4 s. It is further increased by poor concentration or tiredness.

Figure 5: Actions: Reaction, braking and stopping
a) Deceleration while braking,
b) Distance covered while braking.

Prebraking time
The prebraking time (t_{VZ}) is the period of time that elapses between the moment the hazard is recognized and the start of braking, defined by way of calculation. Based on the following formula, the prebraking time is in the range from approx. 0.8 to 1.0 s:

$$t_{VZ} = t_R + t_U + t_A + \frac{t_S}{2}\,.$$

The reaction time (t_R) is the period of time that elapses between the moment a defined incitement to action occurs and the start of the first specifically targeted action. Instinctive hazard recognition triggers an inherent, automatic reaction (spontaneous reaction, involuntary reflex), enabling the vehicle driver to determine both the point of the reaction as well as the position of the reason for the reaction, delayed by the distance covered during the prebraking time. Human beings require about 0.2 s for the spontaneous reaction; however, the reaction time will be at least 0.3 s if the driver needs to make a decision to perform a preventive or evasive action in response to conscious hazard recognition (choice reaction, voluntary action).

The transfer time (t_U) is the period of time the driver requires to transfer the foot from the accelerator pedal to the brake pedal. The transfer time is in the range of about 0.2 s.

The response time (t_A) is the period of time it takes to transmit the pressure applied at the brake pedal via the brake system through to the point when the braking action becomes effective (complete build-up of the application force and incipient increase in vehicle deceleration).

Table 7: Quantities and units

Quantity		Unit
t_{VZ}	Prebraking time	s
t_R	Reaction time	s
t_U	Transfer time	s
t_A	Response time	s
t_S	Pressure build-up time	s
t_B	Braking time	s
t_V	Full braking time	s
t_{AH}	Stopping time	s
s_{AH}	Stopping distance	m

The pressure build-up time (t_S) is the period of time that elapses between the braking action taking effect and reaching fully effective braking deceleration. Alternatively, half the pressure build-up time ($t_S/2$) may be assumed as the start of braking, determined by way of calculation.

In accordance with the EU Council of Ministers Directive EEC 71/320 Addendum 3/2.4 [6], the sum of the response time and pressure build-up time may not exceed 0.6 s. A poorly maintained braking system will lengthen the response and pressure build-up time.

Braking time
The braking time (t_B) is the period of time that elapses between the mathematically calculated start of braking and the moment the vehicle comes to a complete stop. This period of time comprises half the pressure build-up time ($t_S/2$) (calculation assumption: only half the pressure build-up time but complete braking deceleration), as well as the full braking time (t_V), during which maximum braking deceleration is actually effective.

$$t_B = \frac{t_S}{2} + t_V .$$

Stopping time and stopping distance
The stopping time (t_{AH}) is the sum of the prebraking time (t_{VZ}) and braking time (t_B).

$$t_{AH} = t_{VZ} + t_B .$$

The stopping distance (s_{AH}) can be calculated by way of integration (Tables 8 and 9).

Safety margin
The minimum safety margin must be equal to the distance covered during the prebraking time t_{VZ}. The figure for a prebraking time of t_{VZ} = 1.08 s for speeds in km/h would be $0.3v$ meters; however, a minimum of $0{,}5v$ meters is advisable outside of built-up areas.

Passing (overtaking)
The complete passing maneuver involves pulling out of the lane, overtaking the other vehicle, and returning to the original lane (Figure 6). Passing can take place under a wide variety of very different circumstances and conditions, so precise calculations are difficult. For this reason, the following calculations, graphs, and illustrations will confine themselves to an

examination of two extreme conditions: passing at a constant velocity and passing at a constant rate of acceleration. We can simplify graphic representation by treating the passing distance s_u as the sum of two (straight-ahead) components, while disregarding the extra travel involved by pulling out of the lane and back in again.

Passing distance
This passing distance is

$s_U = s_H + s_L$ (variables in Table 10).

The distance s_H which the more rapid vehicle must cover compared to the slower vehicle (considered as being stationary) is the sum of the vehicle lengths l_1 and l_2 and the safety margins s_1 and s_2.

$$s_H = s_1 + s_2 + l_1 + l_2 .$$

During the passing time t_u the slower vehicle covers the distance s_L which the faster vehicle has to travel in addition to s_H so that the safety margin is maintained (s_L in m, t_u in s):

$$s_L = \frac{t_U v_L}{3{,}6} \quad \text{(for } v \text{ in km/h).}$$

Passing at constant speed
On highways with more than two lanes, the overtaking vehicle will frequently be traveling at a speed adequate for passing before the actual process begins. The passing time (from initial lane change until return to the original lane has been completed) is then:

$$t_U = \frac{3{,}6\, s_H}{v_H - v_L}$$

with t in s, s in m and v in km/h, and the passing distance is

$$s_U = \frac{t_U v_H}{3{,}6} \approx \frac{s_H v_H}{v_H - v_L} .$$

Passing with constant acceleration
On narrow roads, the vehicle will usually have to slow down to the speed of the preceding car or truck before accelerating to pass. The attainable acceleration figures depend upon engine output, vehicle mass, speed, and running resistance. These generally lie within the range of 0.4 to 0.8 m/s², with up to 1.4 m/s² available in lower gears for further reductions in passing time. The distance required to complete the passing maneuver should never exceed half the visible stretch of road.

Operating on the assumption that a constant rate of acceleration a can be maintained for the duration of the passing maneuver, the passing time will be

$$t_U = \sqrt{\frac{2 s_H}{a}} .$$

The distance which the slower vehicle covers within this period is defined as $s_L = t_U v_L/3.6$; hence, the passing distance is:

$$s_U = s_H + \frac{t_U v_L}{3{,}6} ,$$

with t in s, s in m and v in km/h.

The left side of Figure 7 shows the relative distances s_H for speed differentials $v_H - v_L$ and acceleration rates a, while the right side shows the distances s_L covered by the vehicle being passed at various

Figure 6: Passing distance
Quantities, see Table 14.
(For clarity reasons s_L is depicted small here, in practical cases $s_L > s_H$.)
1 Passed vehicle,
2 Passing vehicle.

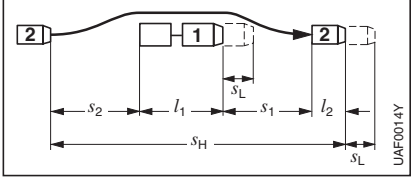

Table 10: Quantities and units

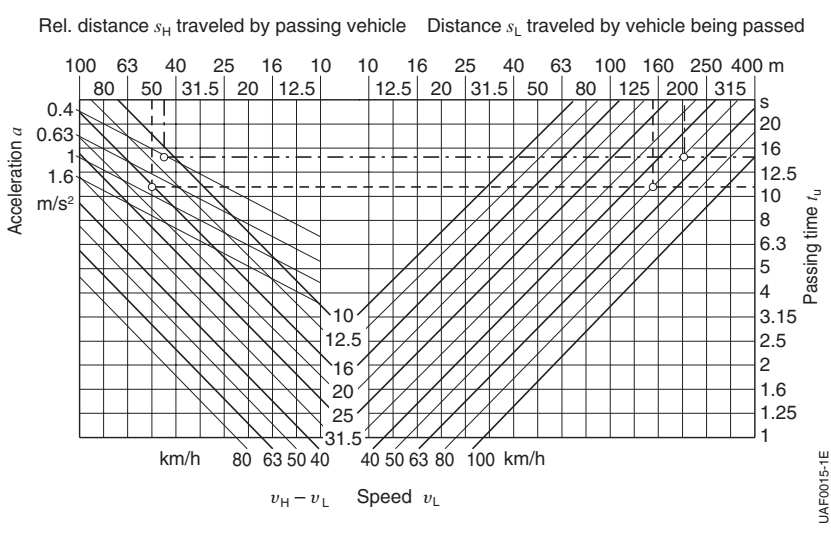
Quantity		Unit
a	Acceleration	m/s²
l_1, l_2	Vehicle length	m
s_1, s_2	Safety margin	m
s_H	Relative distance traveled by passing vehicle	m
s_L	Distance traveled by vehicle	m
s_U	Being passed	m
t_U	Passing distance	s
v_L	Passing time Speed of slower vehicle	km/h
v_H	Speed of faster vehicle	km/h

speeds v_L. The passing distance s_U is the sum of s_H and s_L.

First, determine the distance s_H to be traveled by the passing vehicle. Enter this distance on the left side of the graph between the Y axis and the applicable ($v_H - v_L$) line or acceleration line. Then extrapolate the line to the right, over to the speed line v_L.

Example 1 (constant acceleration):
$v_L = v_H = 50$ km/h (v at start of overtaking),
$a = 0.4$ m/s²,
$l_1 = 10$ m, $l_2 = 5$ m,
$s_1 = s_2 = 0.3\ |v_L| = 0.3\ |v_H| = 15$ m,
$\rightarrow s_H = 45$ m.

Solution
Enter intersection of $a = 0.4$ m/s² and
$s_H = 45$ m
in the left side of the graph.



Indication: $t_U = 15$ s, $s_L = 210$ m.
The following applies: $s_U = s_H + s_L = 255$ m.

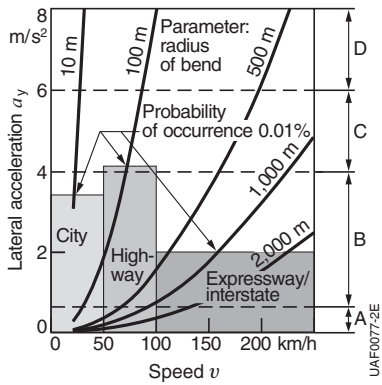
Example 2 (constant speed):
$v_L - v_H = 16$ km/h,
$v_H = 66$ km/h,
$v_L = 50$ km/h,
$s_1 = 0.3\ |v_L| = 15$ m,
$s_2 = 0.3\ |v_H| = 20$ m,
$\rightarrow s_H = 50$ m.

Solution
Intersection of $v_L - v_H = 16$ km/h with
$s_H = 50$ m
in the left side of the graph.
Indication: $t_U = 11$ s, $s_L = 150$ m.
The following applies: $s_U = s_H + s_L = 200$ m.

Visual range
For safe passing on narrow roads, the visibility must be at least the sum of the passing distance plus the distance which would be traveled by an oncoming vehicle while the passing maneuver is in progress. This distance is approximately 400 m if the vehicles approaching each other are traveling at speeds of 90 km/h, and the vehicle being overtaken at 60 km/h.

Figure 7: Graph for determining passing distance

Dynamics of lateral motion



Features

The dynamics of lateral motion deal with all the vehicle states in which a dynamic response occurs in the transverse direction to the vehicle longitudinal axis. These maneuvers are caused above all by the steering of the vehicle, but also by external influences such as crosswind.

When it comes to the dynamics of lateral motion, the primary focus is on firstly a vehicle response deemed to be appropriate by the driver on account of a steering input and secondly the stability of the vehicle. This behavior is determined by three properties of the vehicle:

- Properties of the complete vehicle: total mass, center of gravity, aerodynamics.
- Properties of the axles: kinematics and elastokinematics of the axle, behavior of the tires and brakes, and spring and shock-absorber setting.
- Properties of the controllers: electric steering assistance and driving-dynamics control.

Figure 8: Lateral-acceleration ranges
A Small-signal range,
B Linear range (relevant to normal car drivers),
C Transition range,
D Limit range (emphasis on stability, relevant to press and experts).

Ranges of lateral acceleration

Passenger cars can reach lateral accelerations of up to 10 m/s^2. This range is below sports racing cars, which can reach up to 40 to 50 m/s^2, but significantly above commercial vehicles, which depending on size and load can only achieve 4 to 5 m/s^2. Lateral acceleration is subdivided into the following ranges (Figure 8):

Small-signal range

The range from 0 to 0.5 m/s^2 is known as the small-signal range. The phenomenon to be considered in this range is the straight-running behavior, caused by crosswind and irregularities in the road, such as ruts. Crosswind excitation is induced by blustery, gusty wind and by driving into and out of wind shadow areas.

Table 11: Quantities and units

Quantity		Unit
δ	Axle steering angle (steering angle)	rad
δ_H	Steering-wheel angle	rad
α_v	Slip angle of front axle	rad

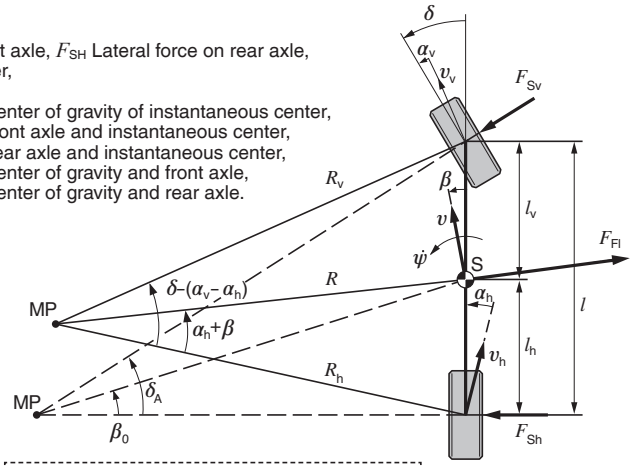
F_{SV}	Lateral force on the front axle	N
F_{SH}	Lateral force on the rear axle	N
F_{FL}	Centrifugal force	N
F_S	Crosswind force	N
M_Z	Crosswind yaw moment	Nm

Linear range
The range from 0.5 to 4 m/s^2 is known as the linear range, as the vehicle behavior that occurs in this range can be described with the aid of the linear single-track model. Typical maneuvers involving dynamics of lateral motion include sudden steering input, changing driving lanes as well as combinations of maneuvers involving dynamics of both lateral and longitudinal motion, such as load-change reactions when cornering.



Transition range.
In the lateral acceleration range from 4 to 6 m/s^2, depending on their design features, passenger vehicles are categorized as either still linear or already nonlinear. This range is therefore considered to be a transition range. In this range, vehicles with maximum lateral acceleration of 6 to 7 m/s^2 (e.g., true offroad vehicles) already feature nonlinear characteristics, while vehicles that achieve higher levels of lateral acceleration (e.g., sports cars) still behave in line with linear characteristics.

Limit range
The lateral acceleration range above 6 m/s^2 is reached only in extreme situations and is therefore referred to as the limit range. In this range, the vehicle characteristics are predominantly nonlinear, with the main emphasis shifted to vehicle stability. This range is reached on racing circuits or in situations leading up to accidents in normal road traffic.

The average driver generally drives in the range up to 4 m/s^2. This means both the small signal range as well as the linear range are relevant to the car driver when subjectively assessing the situation (Figure 8). For the average car driver, the probability of lateral acceleration occurring decreases exponentially with lateral acceleration.

Fast skidpad:
The wheels rolls with lateral slip → this results in slip angles and therefore also in lateral forces.

Slow skidpad:
The wheels roll without lateral slip → no slip angles and therefore also no lateral forces.

UAF0078-4Y

Linear single-track model

Features

Important deductions relating to the dynamic characteristics of lateral motion can be gained from the linear single-track model. The single-track model combines the lateral dynamic properties of one axle and its wheels to form one effective wheel [3]. In the simplest version, as illustrated here, the characteristics under consideration are positioned in the linear range. This means, for example, the lateral tire force is proportional to the slip angle, or the lateral aerodynamic force is proportional to the angle of impact. This model version is therefore called the linear single-track model. The nonlinear behavior of the complete vehicle in the lateral-acceleration range of 0.5 to 4 m/s^2 can already be described very well with these linear properties. The most important model assumptions are:

– Kinematics and elastokinematics of the axle are only modeled linearly,
– The lateral force buildup of the tire is linear and the aligning torque is ignored,
– The center of gravity is assumed to be at road level. The only rotational degree of freedom of the vehicle is therefore the yaw motion. Rolling, pitching and bounce are not taken into consideration.

With the assumptions of the linear single-track model the vehicle handling is reduced to two translational and one rotational degree of freedom of the vehicle body.

Self-steering effect

Figure 9 represents the single-track model in connection with the fast and slow skidpad. The planar motion of this rigid body can be interpreted as a rotation about the instantaneous center MP. The results in the following for the speed at the center of gravity S:

$$v = \dot{\psi} R .$$

This representation results in the following interrelationships describing the kinematics of slip angles [1, 2, 3]:

$$\alpha_v = \delta - \beta - \frac{\dot{\psi}\, l_v}{v} ; \quad \alpha_h = -\beta - \frac{\dot{\psi}\, l_h}{v} .$$

Together with the torque balance, it is possible to calculate the change in the steering-wheel angle in connection with increasing lateral acceleration a_y for the skidpad maneuver at a constant radius. This results in the definition of the self-steering gradient (quantities, see Table 11):

$$EG = \frac{d\delta}{da_y} = \frac{m}{l} \left(\frac{l_h}{C_v} - \frac{l_v}{C_h} \right) .$$

All passenger vehicles are designed so that they understeer in the linear lateral acceleration range. The EG value for passenger vehicles is in the range of about 0.25 degrees $\cdot$ s^2/m.

In terms of the dynamics of lateral motion, the self-steering gradient characterizes the stability and damping of the vehicle. In addition, the significance of the self-steering gradient for the average car driver becomes apparent in that the steering angle requirement increases the faster the cornering speed. This draws the driver's attention to the increasing lateral acceleration.

The float-angle gradient (SG) can be calculated from Figure 9. The float angle gradient should be as low as possible in order to increase the stability of the vehicle [1, 2, 3].

$$SG = \frac{d\beta}{da_y} = \frac{m}{C_h} \frac{l_v}{l} .$$

The SG value range for passenger cars is below 0.35 degrees $\cdot$ s^2/m. Greater float-angle gradients are perfectly manageable for experts, but already for stationary maneuvers give rise to a bad safety feeling for regular drivers and are therefore avoided.

Yaw gain

The yaw gain defines the degree of yaw response that a vehicle executes in response to a steering angle in the quasi-steady-state range. The yaw gain factor can be determined by conducting the follow test procedure: When driving at a constant speed, the steering wheel is turned with sinusoidal motion at a frequency of less than 0.2 Hz. The steering-angle amplitude is selected in order to achieve a maximum lateral acceleration of about 3 m/s^2.

Starting at a speed of 20 km/h, the maneuver is repeated at a speed that is increased by 10 km/h each time. Provided no aerodynamic influences occur at high speeds (lift or upthrust forces at the front and rear axles), the test will produce yaw gain curves that essentially agree with the following equation, derived from the linear single-track model [1, 2, 3]:

$$\left(\frac{\dot{\psi}}{\delta}\right)_{\text{stat}} = \frac{v}{l + EG\ v^2}$$

Figure 10 shows the yaw gain for a vehicle that tends to oversteer (EG < 0), that has neutral steering (EG = 0), and that understeers (EG > 0). Only the vehicle that understeers is acceptable at high speeds and therefore has the right vehicle dynamics even when driving in a straight line. The speed at which a vehicle that tends to understeer has the greatest yaw response is known as the characteristic speed v_{char}. In the linear single-track model, this speed is expressed as:

$$v_{\text{char}} = \sqrt{\frac{l}{EG}}$$

Damping factor

The following equilibrium of forces in the lateral direction is derived for the linear single-track model:

$$m\ a_{\text{y}} = F_{\text{SV}} \cos\delta + F_{\text{SH}}\ .$$

For the torque balance:

$$\theta\ \ddot{\psi} = F_{\text{SV}}\ l_{\text{v}} \cos\delta + F_{\text{SH}}\ l_{\text{h}}\ .$$

The damping factor D for excitation in terms of the dynamics of linear motion can be derived from the two equations:

$$D = \frac{1}{\omega_{\text{e}}} \left(\frac{C_{\text{v}} + C_{\text{h}}}{m\ v} + \frac{C_{\text{v}}\ l_{\text{v}}^2 + C_{\text{h}}\ l_{\text{h}}^2}{\theta\ v} \right)\ .$$

The following equation expresses the undamped natural frequency:

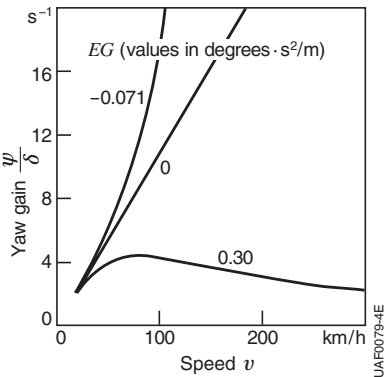
$$\omega_{\text{e}} = \sqrt{\left(\frac{C_{\text{h}}\ l_{\text{h}} - C_{\text{v}}\ l_{\text{v}}}{\theta} + \frac{C_{\text{v}}\ C_{\text{h}}\ l^2}{\theta\ m\ v^2} \right)}\ .$$

The damping factor of a vehicle can be identified, for example, from the yaw response of sudden steering or step input. The vehicle is designed to ensure that damping is as high as possible.

Figure 11 shows the damping factor and yaw gain for various self-steering gradients. This results in the following conflict of objectives:

– A high self-steering gradient is required if the vehicle is to have good straight-running characteristics,
– The self-steering gradient must be as low as possible to facilitate a high damping factor, particularly at high speeds.

Figure 10: Speed-dependent yaw gain



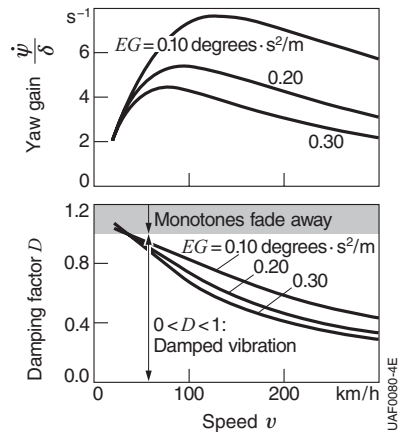


Figure 11: Damping factor and yaw gain

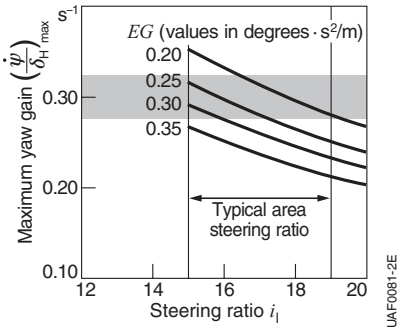
Lateral-agility diagram
A further important variable governing vehicle balance is the total steering ratio i_l. The steering-wheel angle, together with the total steering ratio i_l, is calculated from the axle steering angle:

$$\delta_H = i_l \ \delta .$$

This results in the following equation for maximum yaw gain [1]:

$$\left(\frac{\dot{\psi}}{\delta_H}\right)_{max} = \frac{1}{2\, i_l \sqrt{l\ EG}} .$$

This maximum is plotted in the lateral-agility diagram (Figure 12) as a function of the steering ratio. The diagram additionally shows the EG isolines. The self-steering gradient is constant along these curves. The desired target ranges for the yaw gain and steering ratio can be plotted in this diagram for the purpose of defining the necessary self-steering gradients.



If only the steering ratio is changed in a vehicle, the maximum yaw gain can be determined in the lateral-agility diagram by shifting the baseline along the EG isolines. The shift will be along the vertical axis if the axis characteristics are varied.

General single-track and two-track model
The linear single-track model can be used to specify analytically the self-steering gradient, the float-angle gradient, and the yaw gain with associated damping factor; this makes the relationships clear. If the desire is to describe real vehicle behavior more accurately, more and more nonlinearities must be taken into account. This can be realized for example by taking into account the nonlinear behavior of the lateral force from the slip angle. With such nonlinearities it is possible to develop single-track models which also describe the roll of the vehicles and the handling up to a steering frequency of 3 Hz and are also valid in the driving-dynamic limit range [7].

Almost exclusively so-called two-track models are used in the automotive industry to predict the dynamics of lateral motion. The big advantage of these two-track models lies in the component-oriented modeling of the complete vehicle and thus better integration in the development sequence.

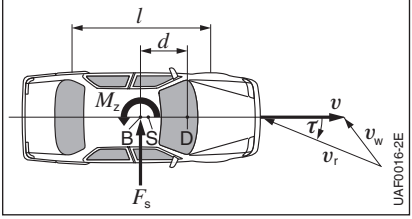
The use of two-track models is also sensible for the following aspects “Dynamics of lateral motion caused by crosswind” and “Roll behavior when cornering”.

Figure 12: Lateral-agility diagram
EG Self-steering gradient.

Dynamics of lateral motion caused by crosswind
Wind can induce lateral dynamics in motor vehicles. The vehicle responds to this external influence by drifting off course, lateral acceleration, and a change in yaw angle and roll angle. The driver then attempts to take corrective action to counteract this discrepancy. Consequently, the response capabilities of the driver as well as the correctability of the vehicle are taken into consideration in a second stage. According to current findings, the direct response of the vehicle to crosswind is the principal variable for subjectively assessing overall vehicle stability in crosswinds. This offers the advantage that the interaction between crosswind and vehicle response can be effectively observed by analysis.

Characteristically, the average car driver perceives two states induced by wind excitation:
– Natural crosswind, which can vary in terms of direction and wind velocity while driving,
– Driving into and out of wind shadow areas where forces of greatly varying strength can act on the vehicle.

The automotive industry strives to minimize the effects of excitations triggered by wind forces by taking the following vehicle factors into consideration:
– "Cornering stiffness" of the tires, i.e., to what extent the lateral force changes as the slip angle increases. The wheel load of the tire remains constant in this consideration,
– Total mass (weight) of the vehicle,
– Center of gravity,
– Axle characteristics,
– Equilateral and reciprocal suspension,
– Damping,
– Kinematics and elastokinematics of the axles,
– Aerodynamic shape and frontal area of the vehicle.



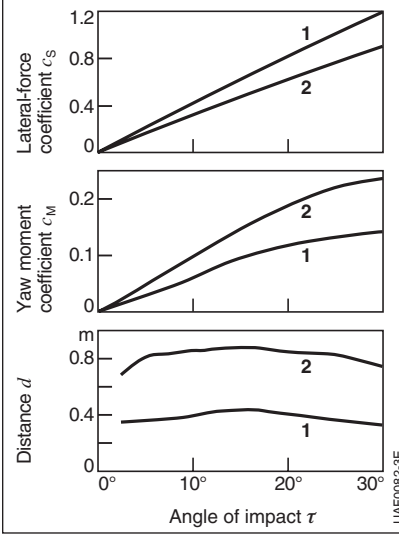
Aerodynamic forces and moments

When a vehicle moves at velocity v in a wind at a speed v_w, the vehicle will be subject to wind impact applied at the resulting velocity v_r. In connection with natural crosswind, the angle of impact τ generally differs from 0 degrees and therefore generates a lateral force F_S and a yawing moment M_Z that acts on the vehicle.

In aerodynamics [8] it is standard practice to specify dimensionless coefficients instead of forces and moments. Therefore:

$$F_S = c_S \frac{\rho}{2} v_r^2 A \; ; \; M_Z = c_M \frac{\rho}{2} v_r^2 A l .$$

Figure 13: Vehicle exposed to crosswind
D Center of pressure point, S Center of gravity, B Aerodynamic reference point.
v Driving speed,
v_w Wind velocity,
v_r Resulting velocity,
τ Angle of impact, F_S Crosswind force,
l Wheelbase, d Distance between B and D,
M_z Yawing moment.



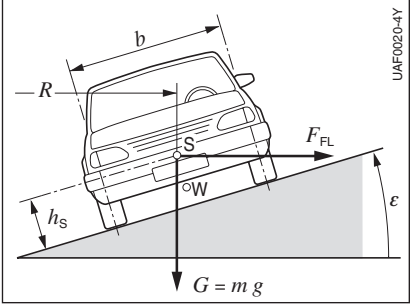
The moment M_Z and the lateral force F_S, which is defined at the mid-point of the wheelbase, can be represented by a single lateral force F_S when the point of impact is located at the center of the pressure point D (Figure 13). The distance d between the aerodynamic reference point B and the center of the pressure point D is calculated as follows:

$$d = \frac{M_z}{F_s} = \frac{c_M \; l}{c_S} \; .$$

To keep aerodynamic influences as low as possible, appropriate steps should be taken to ensure that the center of the pressure point D is as close to the vehicle's center of gravity S as possible. This consequently reduces the effective impact of the moment.

Figure 14 represents the aerodynamic coefficients of the two most typical structural shapes of vehicles, i.e., the station wagon and sedan, as a function of the angle of impact τ. The resulting distance d is considerably lower for stations wagons than for sedans (Figure 13). For vehicles

Figure 14: Lateral-force coefficient and pressure point
1 Station wagon, 2 Sedan.
d Distance between aerodynamic reference point B and center of pressure point D.



with the center of gravity located at the mid-point of the wheelbase, the station wagon structure is therefore less sensitive to crosswind than the sedan structure.

Roll behavior when cornering

When corning the vehicle body rolls about its roll axis. This rolling motion is caused by the centrifugal force F_{FL} (see Figures 9 and 15), which is applied at the vehicle's center of gravity. The magnitude of this rolling motion depends upon the rates of the springs and their response to alternating compression, and upon the lever arm of the centrifugal force (distance between the roll axis and the center of gravity). Like all rigid bodies, the vehicle body consistently executes a screwing or rotating motion; this motion is supplemented by a lateral displacement along the instantaneous axis.

Figure 15: Roll behavior when cornering
b Track width, h_S Height of center of gravity, R Curve radius, ε Curve banking, G Vehicle weight, F_{FL} Centrifugal force. S Center of gravity, W Roll center.

The higher the roll axis, i.e., the closer it is to a parallel axis through the center of gravity, the lower the vehicle inclination due to cornering with an alternating and parallel spring rate. But because the roll centers of the axes must stray upwards for this purpose, the track change increases. Excessive track changes may give rise to disrupted directional stability when driving on an uneven road and hence poor handling that compromises the feeling of safety. There is also the risk of the body lifting at higher lateral accelerations if the roll centers are too high. Therefore the roll centers are typically under 120 mm.

A frequently applied means for finding the approximate roll axis is based on determining the centers of rotation of an equivalent body motion. This body motion takes place in those two planes through the front and rear axles which are vertical relative to the road. The centers of rotation are those (hypothetical) points in the body which remain stationary during the rotation. The roll axis, in turn, is the line which connects these roll centers (instantaneous centers).

The complexity of the operations required for a more precise definition of the spatial relationships involved in wheel motion make it advisable to employ general, three-dimensional simulation models [1, 2, 3].

The greater the driving speed with the same curve radius, the more closely the driving-dynamic limit range is approached and there is the danger of skidding or overturning (see Table 12).

Table 12: Critical speeds in curves (numerical-value equations)

	Flat curve	Banked curve
Speed at which the vehicle exceeds the limit of adhesion (skid)	$v \le 11.28\sqrt{\mu_r\, r_k}$ km/h	$v \le 11.28\sqrt{\frac{(\mu_r + \tan\varepsilon)\, r_k}{1 - \mu_r \tan\varepsilon}}$ km/h
Speed at which the vehicle overturns	$v \ge 11.28\sqrt{\frac{b}{2}\frac{r_k}{h_s}}$ km/h	$v \ge 11.28\sqrt{\frac{\left(\frac{b}{2\,h_s} + \tan\varepsilon\right) r_k}{1 - \frac{b}{2\,h_s}\tan\varepsilon}}$ km/h

h_S Height of center of gravity (in m), μ_r Max. coefficient of friction, b Track width (in m), r_K Curve radius (in m), ε Curve banking.

Dynamics of vertical motion

Features

The dynamics of vertical motion of a vehicle are determined primarily by its behavior in the vertical direction when driving over road excitations. There are also excitations in the transverse and longitudinal directions and excitations of rotating bodies with imbalance, for example generated by imbalance in the wheel/tire combination, but the vertical excitations of the road are the primary concern here. The frequency range under consideration extends up to approximately 30 Hz. The purpose of the vehicle is to transfer the excitations of the road with the lowest possible accelerations to the vehicle occupants.

The most important parameters for setting up a vehicle are:

- spring and shock-absorber setting, if necessary also active systems such as active control damping,
- kinematics and elastokinematics of the axles,
- tire properties, here above all the spring stiffness in the vertical direction,
- tuning the engine and transmission mounts in both vehicles with internal-combustion engines and electrically powered vehicles.

The dynamics of vertical motion of a vehicle are also referred to as ride comfort; this relates to the haptically perceptible comfort, but not the acoustics.

Road excitation

Before a simplified model of the transfer behavior of a vehicle is presented, the issue of quantifying road excitation will be addressed.

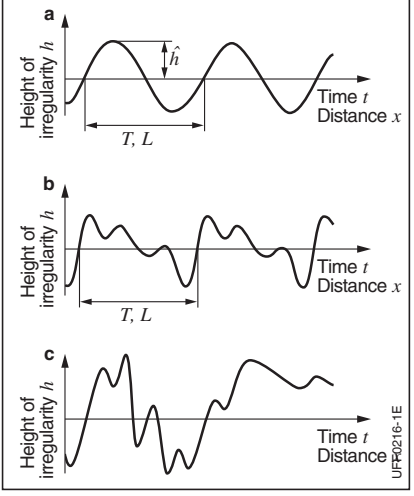
Road excitations are for the purpose of the dynamics of vertical motion divided into two groups:

- irregularity excitations of almost any length,
- individual events, e.g., driving over drain covers.

When describing courses of irregularity in a road of almost any length depending on the path or time, a distinction is made between harmonic (sinusoidal), periodical, and stochastic courses of irregularity (Figure 16).

Harmonic course of irregularity

In this case (Figure 16a), the irregularity height h following distance driven x or point in time t results in:



$$h(x) = \hat{h} \sin(\Omega x + \varepsilon), \qquad \text{(Equation 1)}$$

$$h(t) = \hat{h} \sin(\omega t + \varepsilon), \qquad \text{(Equation 2)}$$

where:

$\hat{h}$ Amplitude of irregularity height,
L Period length,
v Speed,
ε Phase displacement,
$\Omega = 2\pi/L$ Breakdown angular frequency,
$\omega = v\,\Omega = 2\pi\, v/L$ Time angular frequency.

Figure 16: Types of courses of irregularity
a) Sinusoidal course of irregularity,
b) Periodical course of irregularity,
c) Stochastic course of irregularity.
T Period duration,
L Period length,
$\hat{h}$ Amplitude of irregularity height.

Periodical course of irregularity
In the next step, it is no longer only purely sinusoidal but also periodical courses of irregularity (Figure 16b) that are assumed, which means that expressing the relationship as a Fourier series (periodical functions can be described as an infinite series of sinusoidal oscillations) results in:

$$h(x) = h_0 + \sum_{k=1}^{\infty} \hat{h}_k \sin(\Omega x + \varepsilon_k), \quad \text{(Equation 3)}$$

$$h(t) = h_0 + \sum_{k=1}^{\infty} \hat{h}_k \sin(\omega t + \varepsilon_k), \quad \text{(Equation 4)}$$

where:
h_0 Base amplitude,
$\hat{h}_k$ Amplitude,
ε_k Phase displacement,
$\Omega = 2\pi/L$ Breakdown angular frequency,
L Period length.

Stochastic course of irregularity
For real road surfaces, i.e., not only for periodical but also for random (stochastic) courses of irregularity (Figure 16c), in the transition into the complex syntax of the summation formula the integral is arrived at, thus moving from the discrete to the continuous spectrum [3]:

$$h(x) = \int_{-\infty}^{\infty} \underline{\hat{h}}(\Omega)\, e^{j\Omega x} d\Omega \quad \text{(Equation 5)}$$

with the continuous amplitude spectrum

$$\underline{\hat{h}}(\Omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} h(x)\, e^{-j\Omega x} dx\,. \quad \text{(Equation 6)}$$

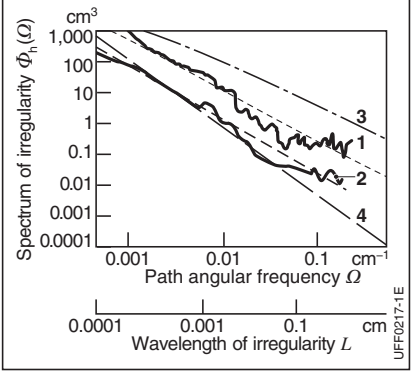
In the time range:

$$h(t) = \int_{-\infty}^{\infty} \underline{\hat{h}}(\omega)\, e^{j\omega t} d\omega \quad \text{(Equation 7)}$$

where

$$\underline{\hat{h}}(\omega) = \frac{1}{v}\, \underline{\hat{h}}(\Omega)\,. \quad \text{(Equation 8)}$$

From the description of the height profile $h(t)$ or $h(x)$ it is possible to obtain power spectral densities $\Phi_h(\Omega)$ (PSD) depending on the breakdown angular frequency. A mathematical definition and detailed discussion of these variables are not provided here. Refer to [1, 3]. For the following examination, the descriptive significance of the power spectral density that exists in the "energy in an infinitesimal frequency band" (with regard to path or time frequency) or the "power output in the natural frequency band" is sufficient.



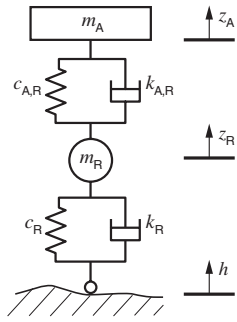
The power spectral densities specify the distribution of the power output of the excitation spectrum within the entire irregularity spectrum. This is usually represented in the double-logarithmic scale (Figure 17). An approximation of the courses of power spectral density on real road surfaces is possible here with straight lines, as described by the following equation:

$$\Phi_h(\Omega) = \Phi_h(\Omega_0) \left(\frac{\Omega}{\Omega_0} \right)^{-w} \quad \text{(Equation 10)}$$

where:
– $\Phi_h(\Omega_0)$ Power spectral density with a reference angular frequency Ω_0 (as a rule $\Omega_0 = 1\ \text{m}^{-1}$, which corresponds to a reference wavelength of $L_0 = 2\pi/\Omega_0 = 6.28$ m),
– w Surface undulation of the road surface (from 1.7 to 3.3; for standard roads $w = 2$).

If the degree of irregularity and the surface undulation of a road surface are known, all the parameters are set in the above linear equation and it can then be used to characterize different types of road surface. The degree of irregularity is defined as the power spectral density at a reference angular frequency, i.e., $\Phi_h(\Omega_0)$.

Figure 17: Irregularity spectrum depending on the breakdown angular frequency.
1 Ordinary road, 2 Expressway/freeway,
3 Upper range limit for poor roads,
4 Lower range limit for good roads.



The biggest advantage of power spectral density is that with the ISO standard ISO 8608:2016-11 [9] it sets out a standard so that all stochastic courses of irregularity can be classified from “very good” to “very bad”.

The disadvantage of power spectral density is that individual obstacles, such as for example drain covers, expansion joints on bridges, and so-called sleeping policemen, cannot be correctly resolved even though these are clearly discerned by the driver when driven over in the vehicle. These individual obstacles are therefore considered separately.

Figure 18: Dual-mass oscillator as quarter-vehicle model

m_R Wheel mass, including components that also vibrate (brake, proportional axle mass, etc.),
m_A The body mass supported by a wheel,
c_R Stiffness of the tire springs,
$c_{A,R}$ Wheel-related stiffness of the body springs,
k_R Dampening rate of the tire (usually negligible as $k_R << k_{A,R}$),
$k_{A,R}$ Wheel-related dampening rate of the body damper,
h Vertical excitation,
z_A Body coordinates in vertical direction,
z_R Wheel coordinates in vertical direction.

Quarter-vehicle model

The road excitations take effect on the vehicle body via the tires, wheel suspension, and the suspension/shock-absorber system. For theoretical analyses, vibration models of different complexity can be applied. With rising model complexity, there is an increase in the degrees of freedom. To improve clarity, the fundamental relationships within vibrating vehicle systems will be explained on the basis of the quarter-vehicle model (Figure 18). The name of the model indicates that only one quarter of the entire vehicle is considered. There is therefore only the important degree of freedom in the vertical direction. More detailed information can be found in [1], [3], and [10].

On specification of the masses, the rigidities, and damping factors, all of the parameters have been set in the quarter-vehicle model for technical analyses of the vibrations and two differential equations can be set up with the variables designated in Figure 18:

$$m_A\ddot{z}_A + k_{A,R}(\dot{z}_A - \dot{z}_R) + c_{A,R}(z_A - z_R) = 0\,, \qquad \text{(Equation 11a)}$$

$$m_R\ddot{z}_R - k_{A,R}(\dot{z}_A - \dot{z}_R) - c_{A,R}(z_A - z_R) + c_R z_R + k_R\dot{z}_R = c_R h + k_R\dot{h}. \qquad \text{(Equation 11b)}$$

The division of Equation 11a and Equation 11b by the mass in each case leads to the normal form of a differential equation of the 2nd order and delivers the damped natural frequency ω_g and the undamped natural angular frequency ω_u as well as the damping factors for the wheel D_R and the body D_A.

The following applies to the uncoupled and undamped natural angular frequency at the wheel:

$$\omega_R = \sqrt{\frac{c_R + c_{A,R}}{m_R}} \approx \sqrt{\frac{c_R}{m_R}} \quad \text{(since } c_R \approx 10\ c_A\text{).} \qquad \text{(Equation 12)}$$

The following applies accordingly to the body:

$$\omega_A = \sqrt{\frac{c_{A,R}}{m_A}}\,. \qquad \text{(Equation 13)}$$

In general, the damped natural angular frequency ω_g is calculated according to:

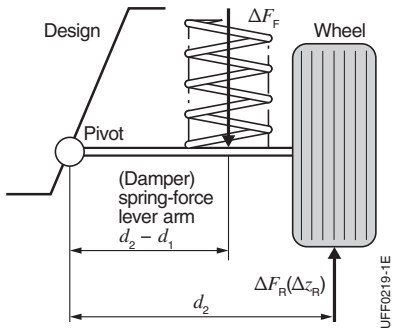
$$\omega_g = \omega_u \sqrt{1 - D^2}\,, \qquad \text{(Equation 14)}$$

whereby the following is also assumed as an approximation:

$$\omega_g \approx 0.9\ \omega_u\,.$$

The following applies to the damping factor D_R at the wheel:

$$D_R = \frac{k_{A,R}}{2m_R\omega_R} = \frac{k_{A,R}}{2\sqrt{(c_R + c_{A,R})\,m_R}} = \frac{m_A\omega_A}{m_R\omega_R}\,D_A\,, \qquad \text{(Equation 15)}$$



whereby experience has shown that $D_R \approx 0.4$ is to be aimed for. The same applies to the body:

$$D_A = \frac{k_{A,R}}{2m_A\omega_A} = \frac{k_{A,R}}{2\sqrt{(c_{A,R}m_R)}}\,. \qquad \text{(Equation 16)}$$

In this case, $D_A \approx 0.3$ has proven to be effective. The dynamic wheel-load fluctuations ΔG result in:

$$\Delta G = m_R\ddot{z}_R + m_A\ddot{z}_A = c_R(h - z_R) + k_R\,(\dot{h} - \dot{z}_R)\,. \qquad \text{(Equation 17)}$$

Figure 19: Spring ratio

$d_2 - d_1$ Spring-force lever arm.

First design of damping and spring stiffness

A rough design of the suspension/shock-absorber system of a motor vehicle can be made with the results of the quarter-vehicle model.

If a body natural frequency (usually $f_A \approx 1$ to 1.5 Hz) is specified and the body mass (or the proportion of the body mass on a wheel) is known, the wheel-related body spring rigidity can be determined:

$$c_{A,R} = \omega_A^2\ m_A\,. \qquad \text{(Equation 18)}$$

The conversion to the actual rigidity of the body springs takes place taking account of the ratio i between the wheel and spring movement in accordance with Figure 19. First of all, the actual spring force

$$\Delta F_F = c_A \Delta z_F \qquad \text{(Equation 19)}$$

and the wheel force ΔF_R are formulated with a spring compression Δz_R. The following applies to ΔF_R:

$$\Delta F_R = c_{A,R}\,\Delta z_R\,. \qquad \text{(Equation 20)}$$

The torque equilibrium around the pivot in Figure 19 leads to:

$$c_{A.R}\,\Delta z_R\,d_2 = c_A\,\Delta z_F\,(d_2 - d_1)\,. \qquad \text{(Equation 21)}$$

This can be used to convert the actual spring rigidity c_A in accordance with the geometric relationships to the wheel-related rigidity $c_{A,R}$:

$$c_{A,R} = c_A\,i^2 \qquad \text{(Equation 22)}$$

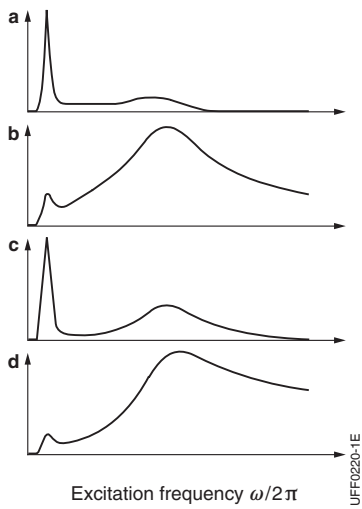
with the spring ratio i

$$i = \frac{(d_2 - d_1)}{d_2} = \frac{\Delta z_F}{\Delta z_R}\,. \qquad \text{(Equation 23)}$$

The same holds true for the vibration damper. For calculation of the body dampening rate (its effect on the wheel), the following applies in relation to the wheel in accordance with Equation 16:

$$k_{A,R} = 2\,D_A\,\sqrt{c_{A,R}\,m_R}\,. \qquad \text{(Equation 24)}$$

With $D_A = 0.3$ (see above) and m_A as a known variable of the vehicle under examination, the body dampening rate can be determined taking account of Equation 23.

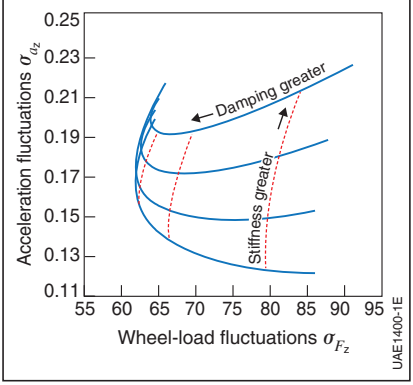


Conflict of aims in the first design of body spring stiffness and body damping

Equation 11a and Equation 11b can be used to calculate the transfer functions (enlargement functions). The amount of the transfer function is the quotient from the stationary proportion of the amplitude of the output variables (body acceleration or wheel-load fluctuation) and the amplitude of the input variable (vertical excitation, see Figure 18). The principle of the progression is shown in Figures 20c and 20d.

These transfer functions are now linked to the road irregularities. The results are the power spectral densities for the body acceleration (Figure 20a) and for the wheel-load fluctuation (Figure 20b) [3].

Figure 20: Transfer function and power spectral density for body acceleration and wheel-load fluctuations



(According to [3])
a) Power spectral density, body acceleration,
b) Power spectral density, wheel-load fluctuation,
c) Amount of transfer function, body acceleration,
d) Amount of transfer function, wheel-load fluctuation.

The higher excitation amplitudes of the road surface at low frequencies raise the vibration amplitudes in the natural frequency range of the body (1 to 2 Hz). In the natural frequency range of the wheel (10 to 14 Hz), however, the low irregularity amplitudes lead to drops in the power spectral densities compared to the transfer functions, which means the body movements become more dominant than the axle movements.

From the power spectral densities of the body accelerations and the wheel loads it is possible to calculate in each case the fluctuation of the body acceleration and the wheel load as a standard deviation [3]. When these two quantities for different body-stiffness values and body-damping values are plotted (Figure 21), it can be seen that it is possible for example with slight damping to reduce the fluctuations of the body acceleration and thereby improve ride comfort. At the same time, however, the wheel-load fluctuations increase and the situation may arise where the tire is no longer in contract with the ground, potentially resulting in wheel hopping. In a wheel-hopping situation there is the possibility of the tire generating lateral forces and consequently the vehicle potentially tramping, i.e., vehicle safety is diminished.

Figure 21: Relationship between wheel-load fluctuations and body-acceleration fluctuations as a function of body stiffness and body damping

Realistic vehicle models for the dynamics of vertical motion

Complete-vehicle models based on general multiple-body simulation programs are used to predict the dynamics of vertical motion. In this way, the component properties are directly parameterized and do not have to be converted. In addition, all the degrees of freedom of the body are then naturally excited, i.e., aside from the vertical direction, as in the quarter-vehicle model, lateral and longitudinal motion.

The torsion bars on the front and rear axles can also be evaluated with a complete-vehicle model. In this way, the vibrational behavior of the wheel and the engine/transmission combination can also be analyzed in order to come up with a favorable design of the engine and transmission mounts with the body damping and body stiffness.

For further refine the dynamics of vertical motion the body damping and body stiffness not only are defined by constant values as in the quarter vehicle but have nonlinear identifiers.

In the case of real vehicle axles the so-called secondary spring rate must be taken into account as well as the friction. The secondary spring rate can, depending on the axle type, be up to 20 % of the spring rate of the body spring. The reason for this is that the rubber mounts installed in the axle also possess a stiffness which becomes noticeable when the axle is deflected. Thus, the expressions found for the stiffness of the body spring and damping of the body damper are initial guide values.

Objectification of subjective perception

Only a short time after the introduction of the automobile, the first approaches to objectifying ride comfort were developed at the start of the 20th century. The influence of comfort – particularly in the case of professional drivers – on fitness (i.e., ensuring good physical and mental condition) as well as on the health of the driver and thus on overall road safety was recognized very quickly. Accordingly, attempts were made to shape meaningful variables to describe comfort and to compare these in the form of objective comfort factors for different variants of vehicles and roads. Since then, a number of different assessment methods have been defined, based almost exclusively on acceleration signals at and around the driver's seat. Here, the frequency-dependent sensitivity of people to vibrations and oscillations initiated at different positions as well as different types and directions (translatory or rotatory; x, y, z direction) is taken into account with the help of the corresponding frequency weighting filters.

Two widely used approaches are the VDI guideline 2057 [11] and the standard ISO 2631 [12]. Despite the relatively low overhead involved in these analyses compared to other methods, these have good informative value. At the same time, these form the basis for many approaches to comfort assessment that were developed in the 1990s and later (see [11], [13], [14], [15], [16]). In the methods used to date, it is normally the case that the accelerations caused by the excitation at different measuring points (initiation positions) are used to determine an overall comfort factor (possibly from a number of partial comfort factors at different measuring points) that is to represent a measure of the load on the occupants. The accelerations are first of all frequency-weighted (i.e., amplitudes of different frequencies are linked to frequency-dependent factors) and subsequently, for example with the RMS method (Root Mean Square, see [11]) in accordance with:

$$\overline{a}_{\mathrm{RMS}} = \sqrt{\frac{1}{T}\int_0^T a_{\mathrm{w}}^2(t)\,dt} \qquad \text{(Equation 26)}$$

or with the RMQ method (Root Mean Quad, see [14]) in accordance with:

$$\overline{a}_{\mathrm{RMQ}} = \sqrt[4]{\frac{1}{T}\int_0^T a_{\mathrm{w}}^4(t)\,dt} \qquad \text{(Equation 27)}$$

reduced to a value. Depending on the number of evaluated measuring points, an overall factor has to be formed in a subsequent operation. For the VDI guideline 2057, only the evaluation of the measuring point with the highest load is relevant. All translatory accelerations of this initiation position (hand, seat or foot) are taken into account equally in the calculation of the factor. However, no uniform specifications for weighting individual initiation positions have yet been developed.

Only in the recent past have the results of Weber, Fechner, and Stevens from the field of psychophysics [17] been taken into account in the objectification of subjective perception. Thus, the following effects must be taken into account in the evaluation of objective measurement data:

- lower perceptibility threshold,
- difference perceptibility threshold between two signals,
- order in which the signals are evaluated (order effect),
- masking effect.

Evaluation methods which take the Weber-Fechner law into account are much more accurate than simple absolute evaluations [18]. Nevertheless, these evaluation methods must be supported by a real road test or by trials with test subjects on suitable simulators.

Special operating dynamics for commercial vehicles

Essentially, commercial vehicles are governed with regard to driving dynamics by the same laws as for passenger cars. Supplementary aspects are described in the following. Typical differences between passenger cars and commercial vehicles are:

– The typical unladen curb weight and the gross weight rating for commercial vehicles is higher than for passenger cars. In Europe a typical heavy truck with two axles has a gross weight rating of 18 t; a typical semitrailer unit with a total of five axles has a gross weight rating of 40 t.
– Heavy trucks and buses often have more than two axles so as to be able to achieve greater vehicle weights. The difference between the vehicle weight in the laden and unladen states is much greater in trucks and light utility vans than in passenger cars.
– Trucks are very often operated with trailers.

Dynamics of linear motion of commercial vehicles

As in passenger cars the rolling resistance of a commercial vehicle comprises rolling resistance, aerodynamic drag, and if necessary climbing resistance. Because of the high weight, for heavy trucks on gradients greater than approx. 1 % climbing resistance is the dominant contributor to rolling resistance [19].

The permitted top speed of max. 80 km/h or 90 km/h for heavy commercial vehicles in the majority of European countries means that aerodynamic drag – unlike for passenger cars – never becomes the dominant factor.

Because commercial vehicles are limited in length in the EU (and many other countries), the front of the vehicle is essentially a vertical surface. The achievable c_w value is accordingly much higher than the value for passenger cars. An aerodynamically sound, modern truck used in long-distance haulage has a c_w value of around 0.5. For special superstructures much higher values can be expected (e.g., concrete mixers, timber trucks). The frontal area of a long-distance truck, on account of the legal requirements for width and height, amounts to around 10 m^2 (4 m high by 2.5 m wide).

Dynamics of lateral motion of commercial vehicles

Chassis system configuration

The aim is to achieve non-problematic, understeering handling. Stationary vehicle handling is defined as for passenger cars by the self-steering effect. It is influenced by

– the axle configuration,
– the geometry of the complete vehicle (wheelbase, track width),
– the axle-load distribution,
– the tires,
– the mechanical and hydraulic parameters of the steering gear,
– the stiffness and geometry of the steering linkage,
– the elastokinematics of the front and rear axles,
– the frame stiffness, and
– the roll stabilization at the front and/or rear axles.

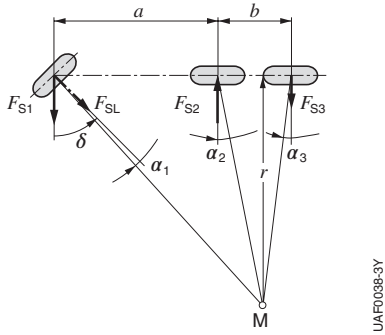
The self-steering effect of leaf-spring axles (“steel suspension”) is essentially determined by the inclination of the leaf springs in the longitudinal direction of the vehicle. Because the inclination of the leaf-spring branches changes with the load, the self-steering effect of leaf-spring axles is dependent on the vehicle load. This effect is referred to as “roll steer” of the axle in that it depends on the roll angle of the vehicle when cornering as well as on the compression/jounce.

Steering movements that result from the elasticity of axle bearings are a further component of self-steering. These are dependent on the cornering force on the wheel and are therefore referred to as “lateral-force steer”.

Heavy-duty trucks with air suspension are normally equipped with solid or rigid axles controlled with suspension arms and links. Self-steering can be influenced by a specific design of the flexibility of the link bearings. Because these axles are normally also fitted with ride-height control, the kinematic position of the links

and thus the "roll steer", in contrast to leaf-spring axles, are not dependent on the vehicle load.

External interference factors such as road-surface irregularities or crosswind, for example, must not give rise to any great disruptions of vehicle motion. The elastokinematic design of the chassis serves to minimize these interference factors. On the front axles the aim is to minimize steering movements as a result of parallel and alternating compression and rebound and as a result of braking. The kinematic points of the steering, for example, act as the setting levers in the configuration of the elastokinematics.



In the case of leaf-spring axles the connecting points of the leaf springs and the leaf-thickness progressions are important setting levers.

Geometrically nonlinear finite-element programs are used in the calculation to configure the elastokinematics. The configuration is monitored on elastokinematic test benches and in the complete-vehicle road test.

To date, axle control concepts involving independent wheel control have only been implemented on light utility vans and buses.

Figure 22: Cornering forces F_S and slip angle α on a three-axle vehicle with non-steered tandem axle

a Distance, front axle to first rear axle,
b Distance, first rear axle to second rear axle,
F_{Si} Cornering forces, i = 1, 2, 3, L,
α_i Slip angle, i = 1, 2, 3,
δ Steering angle,
r Radius,
M Instantaneous center.

In vehicles with multiple non-steered rear axles, such as 6×4 or 6×2 (six wheels, four or two of which are driven), a constraining torque is generated around the vehicle's vertical axis on account of the different slip angle at the first and second rear axles. The resulting lateral force on the axles is relevant for the maneuvering system and can be determined for small angles α ($\tan\alpha \approx \alpha$ in the radian measure; error < 1 % for α < 10 ° or p < 17 %) as follows (Figure 22; quantities, see key to Figure 22):

$F_{S1} = F_{S2} - F_{S3}$ and
$F_{S1}\,a = F_{S3}\,b$ (moment equilibrium),
where
$F_{S2} = c_{p2}\,n_2\,\alpha_2$,
$F_{S3} = c_{p3}\,n_3\,\alpha_3$.

Slip angle:

$$\alpha_2 = \frac{1}{r} \cdot \frac{c_{p3}\,n_3\,b\,(a+b)}{c_{p3}\,n_3(a+b) + c_{p2}\,n_2\,a},$$

$$\alpha_3 = \frac{b}{r} - \alpha_2.$$

– α_i is obtained in the radian measure,
– c_{p2} and c_{p3} are the slip stiffnesses from the tire maps,
– n_2 and n_3 is the number of tires per axle.

Tipping resistance

As the vehicle's total height increases, the vehicle will also have an increasing tendency to tip to the side in a turn before it starts to slide. In the same way as the overall dynamic behavior, the tipping limits of vehicles are determined by means of multibody-system simulations (multibody system, Figure 23). The simulations investigate various stationary and non-stationary maneuvers, e.g., steady-state circular-course driving ([20]) and double lane change [21]. The achievable lateral acceleration b at the tipping limit during steady-state circular-course driving is b = 6…8 m/s² for light utility vans and b = 4…6 m/s2 for trucks and buses.

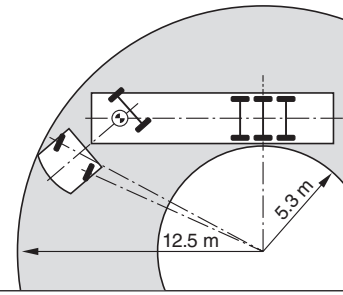
The driving-dynamics control systems prescribed by law (Electronic Stability Program) predominantly used in today's commercial vehicles have functions which reduce the risk of tipping. The interven-

tion threshold of these systems can be adapted within limits to the load and load distribution of the vehicle whereby these variables are estimated by an algorithm from the vehicle's instantaneous handling.

Width requirement
The width requirement of motor vehicles and truck-trailer combinations is greater during cornering than when the vehicle moves in a straight line. With respect to selected driving maneuvers, it is necessary to determine the radius described by the vehicle's outer extremities during cornering, both in order to ascertain its suitability for certain applications (e.g., narrow transit routes through constricted areas) and to confirm compliance with legal requirements [22] (turning-circle regulation, Figure 24). This is determined using multibody-system simulations or by means of real tests.

Handling characteristics
Objective analyses of vehicle handling are based on various driving maneuvers (see Driving-dynamics test procedures). For example, the vehicle's steady-state self-steering properties and roll behavior are assessed with the "Steady-state circular-course driving" test procedure. Moderately understeering self-steering properties that are easily manageable by the driver in this test procedure also provide

Figure 24: Turning-circle regulation [22] on example of a semitrailer unit
Representation of the permissible steady-state cornering radii.



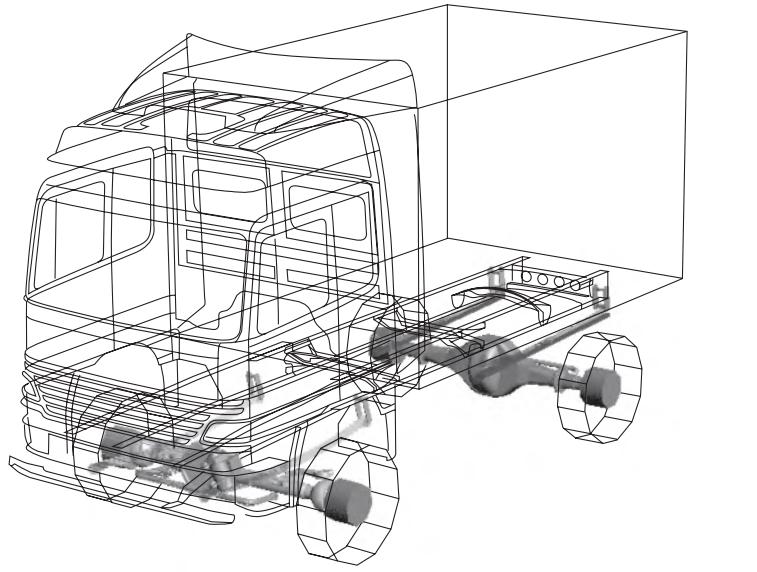


Figure 23: Multibody-system model of an all-wheel drive vehicle
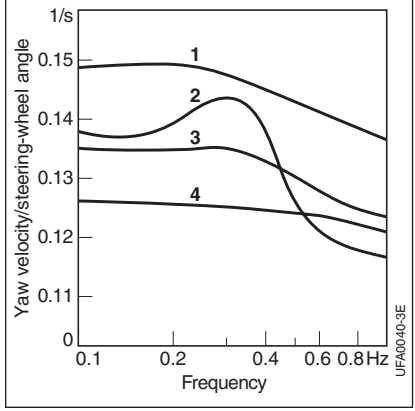
for determining self-steering effects and simulating operating dynamics.



a significant basis for a good subjective driving impression in dynamic steering maneuvers and in braking maneuvers. Dynamic handling can be evaluated for example with the “sinusoidal steering input” maneuver. Test procedures are additional used to evaluate driving stability in braking operations (e.g., braking in a turn/curve) and to evaluate the steering “feel” (“weave test”).

The dynamic lateral response of truck-trailer combinations (e.g., semitrailer, truck-trailer) generally differs from that of rigid vehicles. Particularly significant are the distribution of loads between truck and trailer or semitrailer, and the design and geometry of the mechanical coupling device within a given combination.

The vehicle's straight-running stability can be impaired by a variety of factors. These include gusts of crosswind, uneven road surfaces, obstacles on one side, ruts in the road surface, and crossfall cambers. The yaw oscillations caused by these impairments must decay rapidly if vehicle stability is to be maintained. These yaw oscillations can be assessed on the basis of the yaw-velocity frequency response (Figure 25). The yaw-velocity frequency responses of different truck-trailer combinations demonstrate excessive increase in resonance in the least favorable case (tractor-trailer unladen, center-axle trailer laden, curve 2 in Figure 25). This type of combination demands a high degree of driver skill and a defensive driving style.

Figure 25: Yaw-velocity frequency responses
1 Semitrailer unit (laden),
2 Truck-trailer unit (unladen with laden center-axle trailer),
3 Truck-trailer unit (laden), 4 Truck (laden).

With semitrailer units, braking maneuvers undertaken under extreme conditions can induce jackknifing. This process is initiated when, on a slippery road surface (μ-low), loss of lateral force is induced by excess braking force applied to the tractor’s rear axle or due to excess yaw moment under μ-split conditions. Installation of an driving-dynamics control system (Electronic Stability Program) represents the most effective means of preventing jackknifing.

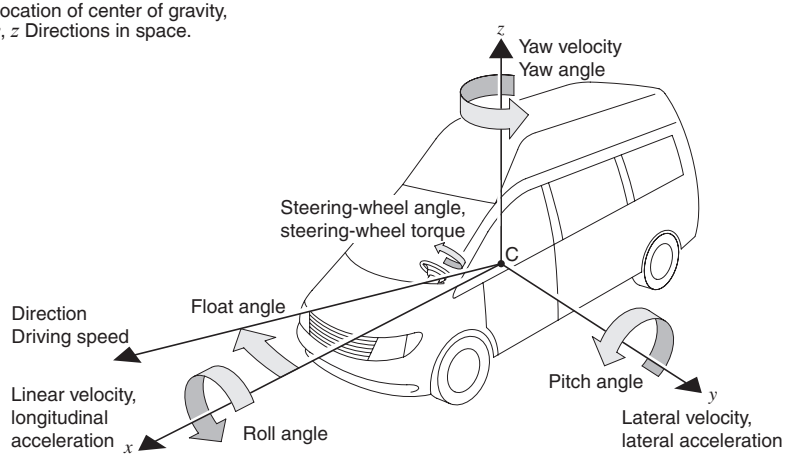
Driving-dynamics test procedures

Assessment of vehicle handling

Overall system

The science devoted to studying the dynamics of vehicle handling generally defines its subject as the overall behavior of the entire system represented by "driver – vehicle – environment" (Figure 2). The driver assesses the vehicle's handling qualities based on the sum total of his/her subjective impressions. Internationally standardized test procedures have been developed since the end of the 1970s. On the one hand, these test procedures are intended to describe vehicle handling as objectively and consistently as possible. On the other hand, they serve to determine characteristic variables which correlate well with the subjective driving impressions.



Most of the internationally standardized procedures are carried out in an open loop, i.e., with a defined steering input without controlling intervention by the driver. In this way, the result is not influenced by different steering strategies of individual drivers. Only a few procedures are carried out in a closed loop with the input of a specific course which can be taken by the driver in an individual way.

There are currently a total of roughly 20 ISO standards for driving-dynamics procedures, of which the following maneuvers used most frequently in vehicle development will be described here:
- Steady-state circular-course driving [1], [2].
- Test procedures for transient response [3], [4].
- Weave test and transition test [5], [6].
- Braking in a turn/curve [7], [8].
- Closing curve [9].

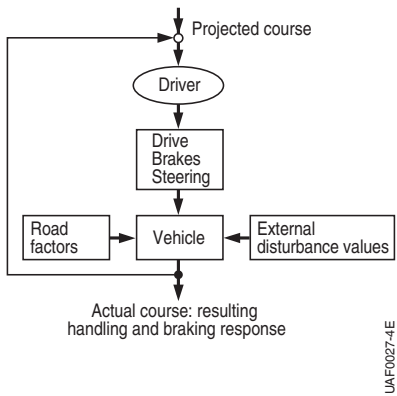
Further test procedures not explicitly described here are, for example:
- Double lane change (closed loop, [10]).
- Lateral stability of vehicle combinations [11], [12].
- Crosswind stability [13].
- Load changes when cornering [14].

These test procedures were originally created for automobiles ([15], [16]). Test methods based on these standards were later developed for heavy-duty commercial vehicles in order to cater for the unique handling characteristics of heavy-

Figure 1: Assessment quantities for driving dynamics
S Location of center of gravity,
x, y, z Directions in space.

duty commercial vehicles with their large mass and inertia figures.

General boundary conditions which must be equally observed for all driving-dynamics test procedures, for example, the condition of the road surface, environmental conditions and tires, are defined in a separate ISO standard (ISO 15037, [17]), which additionally defines what is required of the measuring techniques for driving-dynamics measurements.



Assessment quantities

The following measurable quantities are primarily used to assess vehicle handling (Figure 1):

- Steering-wheel angle and steering-wheel torque.
- Lateral acceleration.
- Yaw velocity.
- Roll angle.
- Float angle.

Depending on the test procedure defined, characteristic values are determined from these and other quantities for the purpose of describing and assessing vehicle handling. These measured values and characteristic quantities are defined in a separate ISO standard (ISO 8855 [18]).

Figure 2: Overall system "Driver – Vehicle – Environment" as closed loop

Driving-dynamics test procedures as per ISO

Steady-state circular-course driving

Performance

The "Steady-state circular-course driving" test procedure ([1], [2]) is generally carried out in such a way that the vehicle is accelerated on a circular course with a constant radius (a radius of 40 m is usually selected for passenger cars, 80 m for trucks) starting from a very slow starting speed up to the maximum attainable vehicle lateral acceleration. The longitudinal acceleration here should be significantly below 1 m/s^2 so that the driving state can be viewed as sufficiently steady-state. When semitrailer-truck or truck-trailer combinations are measured, the measurement is conducted at a number of constant driving speeds on a specified circular-course radius.

Assessment

The assessment criteria primarily used are the curves of steering-wheel angle, roll angle and float angle plotted against lateral acceleration, which are shown in Figure 3 for a passenger car and for a truck with semitrailer.

From the curve of steering-wheel angle against lateral acceleration it is possible to determine the vehicle's self-steering effect using a single-lane model (see Dynamics of lateral motion). Today's vehicles, both passenger cars and heavy-duty commercial vehicles, are basically designed as understeering. In other words, as their speed increases on a constant circular-course radius, they require a significant increase in steering angle. The limit range of an understeering vehicle is determined by the maximum transferable cornering force of the front wheels, which is recognizable from the sharply progressively rising steering-wheel angle with high lateral acceleration. It is clear from the representation that as a rule higher lateral accelerations are possible for automobiles than for trucks.

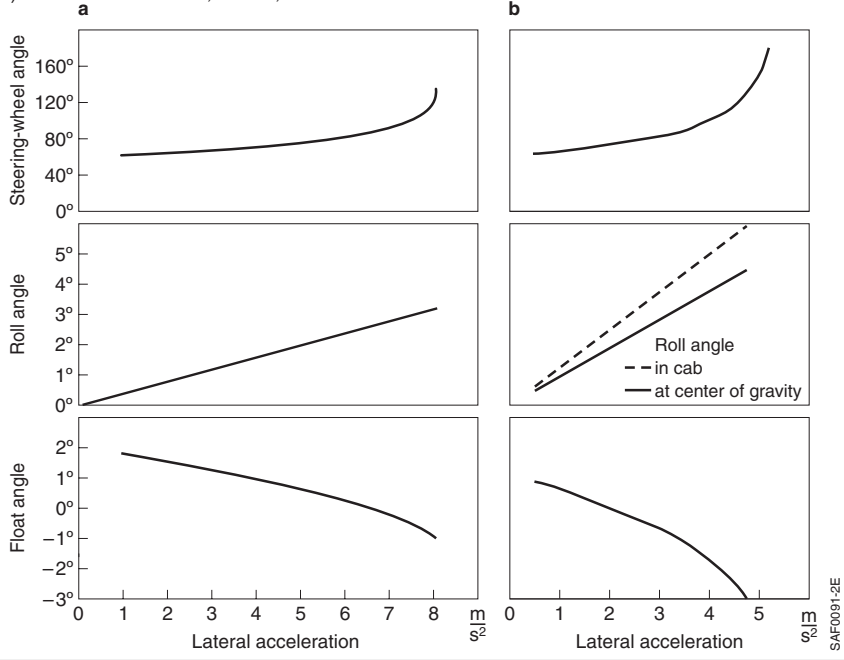
The curve of roll angle against lateral acceleration describes the lateral inclination of the vehicle that can be perceived by the driver. This is greatly dependent on the vehicle load, particularly in the case

of commercial vehicles. In the case of commercial vehicles with a high loading center of gravity, the maximum achievable lateral acceleration is for the most part determined not by the cornering force of the tires, but by the tipping limit of the vehicle.

In the case of trucks, the roll angle is additionally determined not only at the center of vehicle gravity, but also, due to the torsionally weak frame and the separate driver's cab mounting, at several fixed measuring points.

The curve of float angle against lateral acceleration is an indicator of the lateral stability of the vehicle that can be perceived by the driver. It is determined above all by the properties of the tires. In addition to the tire properties, the following vehicle parameters have a significant influence on stationary vehicle handling:
– Load and axle-load distribution.
– Stiffness of springs and stabilizers.
– Kinematic and elastokinematics movements of the wheel suspension.

Transient response



The test procedures for transient response ([3], [4]) serve to determine the vehicle response to rapid, dynamic steering stimulations, e.g.,during rapid evasion maneuvers. Procedures frequently used in tests and simulation are "Step input" and "Sinusoidal steering input and frequency response".

Step input

Performance

The "Step input" test procedure involves the vehicle, starting from straight-ahead driving at a constant speed, being turned in with a very fast steering movement from the zero steering-wheel position to a stationary steering-wheel angle. This results after the transient condition in circular driving with a defined, constant lateral acceleration. An arrangement usual for passenger cars involves turning in with a steering-wheel angle velocity of approximately 360°/s to a lateral acceleration

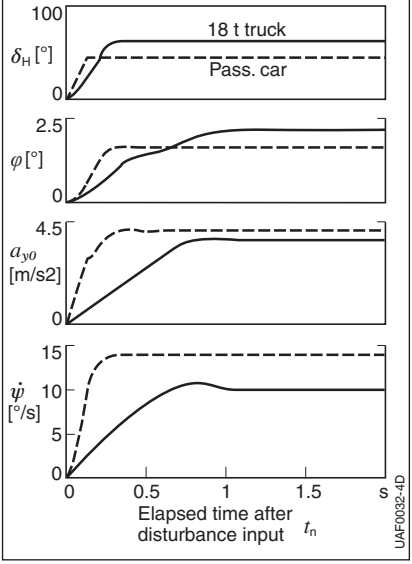


Figure 3: Steady-state circular-course driving
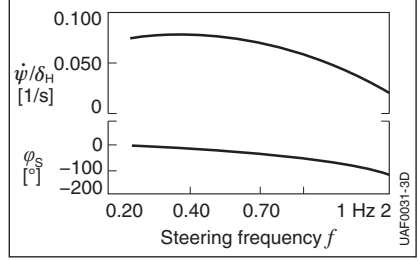
a) Passenger car, 40 m circle radius,
b) 40-ton semitrailer unit, loaded, 80 m circle radius.

of 4 m/s² at a driving speed of 80 km/h. Trucks are often driven at a speed of 60 km/h (Figure 4).

Assessment
The time delay and the overswing values with which the quantities of yaw velocity, lateral acceleration, roll angle, and float angle respond to the steering-wheel angle input are determined during this maneuver (Figure 4). The vehicle should, on the one hand, not respond too sluggishly to the steering movement and, on the other hand, not respond with excessive overswing to the steering input. Figure 4 shows that a truck reacts much more sluggishly than a passenger car.

Figure 4: Step input
(Unladen, driving speed 60 km/h.)
δ_H Steering-wheel angle,
φ Roll angle,
a_{y0} Lateral acceleration,
$\dot{\psi}$ Yaw velocity.



Sinusoidal steering input and frequency response
Performance
The "Sinusoidal steering input and frequency response" test procedure involves the vehicle being excited at a constant driving speed – for example 80 km/h – with a sinusoidal steering-wheel angle signal whose amplitude is kept constant and whose frequency is increased starting at slow steering movements of 0.2 Hz to fast steering movements up to 2.0 Hz. This makes it possible to assess the dynamic vehicle handling in the entire steering-frequency range to be excited by the driver.

The steering amplitude is kept constant during the test and is as a rule selected in such a way that the vehicle remains in the linear driving range, i.e., in the case of passenger cars in such a way that a lateral acceleration of max. 4 m/s² is obtained at the slowest steering frequency. In the case of heavy commercial vehicles, lower maximum lateral accelerations are selected for the most part.

Assessment
For assessment, the amplitudes referred to the input variable of steering-wheel angle and phase angles of the quantities of steering-wheel torque, yaw velocity, lateral acceleration, roll angle, and float angle are determined and plotted against steering frequency. Figure 5 shows such an assessment for an 18-ton truck using the example of the frequency response of

Figure 5: Sinusoidal steering-angle input
(18-ton truck, driving speed 60 km/h.)

φ_s Phase angle,
δ Amplitude of steering-angle input.

the yaw velocity. The position of the natural frequencies, the banking that occurs and the phase angles can be used as an assessment criterion for vehicle agility and stability in the case of dynamic steering excitations. Heavy banking in the curve of the yaw-velocity amplitude would for example indicate "nervous" vehicle handling at a specific steering frequency. Large phase angles and a sharply falling amplitude curve indicates on the other hand a very sluggish response by the vehicle in the case of fast steering movements.

As well as the vehicle parameters which influence the stationary handling, the damping properties and the moments of inertia of the vehicle as well as the dynamic properties of tires, steering system and wheel suspension are crucial to vehicle handling in the case of dynamic driving maneuvers.

Weave test and transition test

The "Weave test" and "Transition test" assessment procedures ([5], [6]) were developed to develop the vehicle's response to small, slow steering movements about the steering zero position. The behavior of the vehicle and steering system during the maneuvers correlates well with the driver's subjective impression of the monitorability of the vehicle in everyday driving.

Transition test

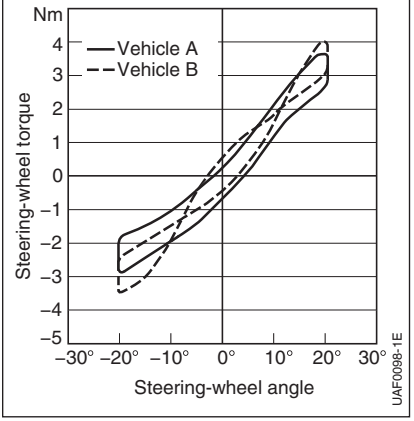
Performance

In the transition test the vehicle is turned in, starting from straight-ahead driving at a constant driving speed, with a slow steering movement (e.g., at 80 km/h with a steering-wheel angle velocity of 5 °/s) to a circular course with a low lateral acceleration of 1 to 2 m/s^2. In practice this corresponds to the operation of turning at low speed into a curve on a secondary road.

Assessment

Above all, the time characteristics of the quantities of yaw velocity and steering-wheel torque are assessed. Among others, the time after which the vehicle responds with a quantity of yaw velocity that can be perceived by the driver to the steering excitation is a suitable assessment quantity.

Weave test



Performance

In the weave test the vehicle is excited at a constant driving speed (e.g., 80 km/h) with a sinusoidal steering excitation at a slow steering frequency of 0.1 to 0.2 Hz. The maximum lateral acceleration here ranges between 2 m/s^2 (usual for trucks) and 4 m/s^2 (usual for passenger cars), i.e., the vehicle is constantly in the linear driving range.

Assessment

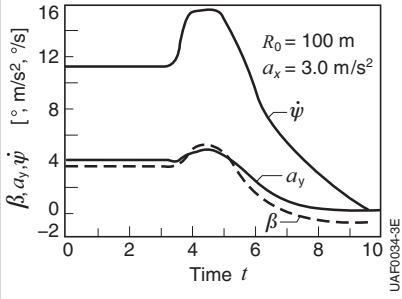
To assess the vehicle handling and steering behavior, the curves for the quantities of steering-wheel torque, yaw velocity, lateral acceleration, and float angle as a function of the input steering-wheel angle are used. The non-linearities (among others friction) in the steering system, tires and wheel suspension give rise to hysteresis loops, like the hysteresis loop of steering-wheel torque vs. steering-wheel angle shown by way of example in Figure 6. The ranges of the hystereses and the rise gradients of the curves are suitable assessment criteria. For example, the steering behavior of a vehicle which demonstrates on overlapping hysteresis loop, like vehicle B in Figure 6, is perceived by the driver to be "indifferent about the center position" and "poor in straight-running stability".

Figure 6: Steering hysteresis in weave test

Braking in a turn/curve

Performance

The "Braking in a turn/curve" test procedure ([7], [8]) is likewise geared towards a situation that occurs frequently in real driving operation. Starting out from stationary cornering on a circle with a constant radius with a lateral acceleration of between 3 m/s^2 (usual value for trucks) and 5 m/s^2 (usual value for passenger cars), the vehicle is braked with a constant steering-wheel angle and a defined deceleration, set by the brake-pedal travel required for this purpose. Several tests are carried out in which the brake-pedal setting and thus the braking deceleration are varied from light braking through to full braking.



Assessment

Figure 7 shows the time characteristics of yaw velocity, lateral acceleration and float angle of a 7.5-ton truck during a braking operation with a deceleration of 3 m/s^2. Once the braking has started (time 3.0 s), a clear banking of the driving-dynamics quantities can be made out. It shows that the vehicle turns in to the inside of the curve during the braking operation.

The extent of the banking of the driving-dynamics quantities, which are usually plotted against the varied longitudinal deceleration, are used as an assessment criterion for vehicle stability [19].

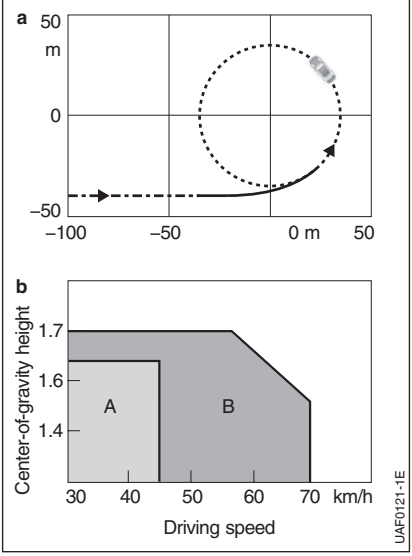
Figure 7: Time curves for braking in a turn/curve (7.5-ton truck, laden)

Vehicles runs a steady-state circular course. Braking begins at time of 3 s.
$\dot{\psi}$ Yaw velocity, β Float angle,
a_y Lateral acceleration,
a_x Longitudinal deceleration, R_0 Circle radius.

As well as the vehicle parameters which influence vehicle handling in the driving maneuvers described up to now, the braking-force distribution between front and rear axles and the design of the brake-control systems ABS and driving-dynamics control (Electronic Stability Control, ESC) have a significant influence on vehicle handling during this maneuver. It is therefore used among other things to tune the brake system and brake-control systems.

Closing curve

The "Closing Curve" test procedure [9] was developed against the backdrop of the change to the ECE regulation ECE-R13, which requires that as of 2014 virtually all heavy commercial vehicles be duly equipped with ESC systems.



Performance

This test procedure too is based on a real driving situation, namely negotiating an expressway entrance or exit at too high a driving speed. The enhanced safety afforded by the ESC control system can be gaged with this test. To this end, a trajectory leading rapidly from straight-ahead driving into a curve with a tight curve radius is defined. The course progression is created in such a way that for a certain initial speed a defined increase in the lateral acceleration is obtained, e.g., 2 m/s^2 (Figure 8a).

Assessment

The test procedure is carried out at different speeds and center-of-gravity heights, in each case with ESC activated and deactivated. The lift of the inner cornering wheels is used to assess whether the maneuver is classed as "passed". Figure 8b shows, as a function of center-of-gravity height and driving speed, the areas in which the maneuver has passed. The enhanced safety provided by ESC becomes visible.

Figure 8: Enhanced safety due to ESC in the "Closing Curve" test procedure

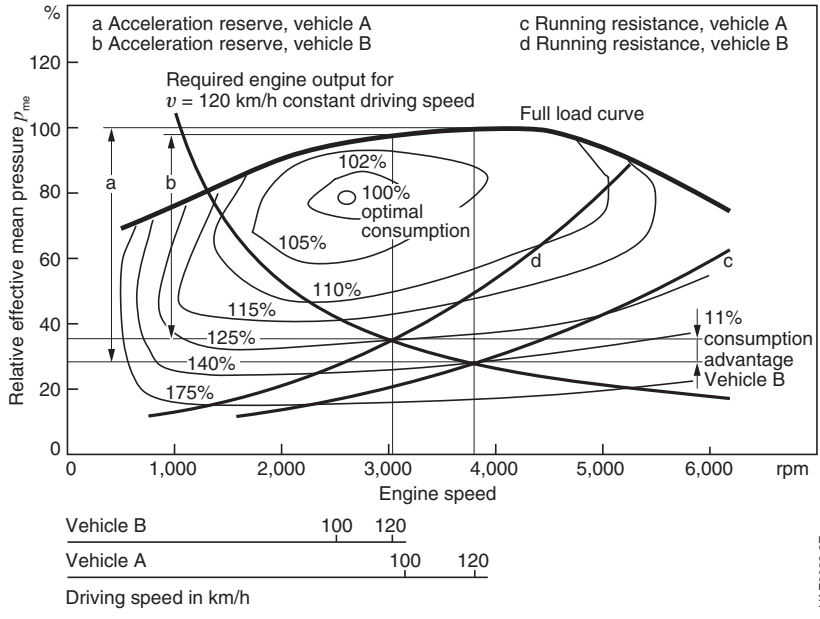
Energy demand for drives

Vehicles which draw the energy for propulsion from fossil fuels and consequently emit CO_2 while driving are subject to limits on these emissions. CO_2 emissions are proportional to fuel consumption. This also applies to mild- and full-hybrid vehicles which can run their internal-combustion engines at more fuel-efficient operating points and thus exhibit lower fuel consumption. The batteries of externally rechargeable hybrid vehicles can be charged from the power socket of the mains-supply network or from a charging post; this supplied electrical energy stored in the traction battery must therefore be taken into account in the energy demand. Electric vehicles ultimately draw all the energy required for drive purposes from the mains-supply network and thus do not emit any CO_2 locally.



Fuel consumption of internal-combustion engines

Specific fuel consumption

The most common way of presenting engine fuel-consumption maps is the "graph diagram", in which the effective mean pressure p_{me} and, as family parameters, lines of constant specific consumption (fuel throughput referred to power output in g/kWh) are plotted against the engine speed (Figure 1). This makes it possible to compare the efficiency of engines of different sizes and types.

Another way of presentation is, as a family parameter, the fuel throughput or mass flow (e.g., in kg/h). This form of presentation is particularly suitable as an input variable for CAE programs (computer-aided engineering), which can be used to simulate fuel consumption (corresponding to CO_2 emissions).

Figure 1: Engine fuel-consumption map (graph diagram)

Entered in both presentations as additional information are the full-load torque curve as the upper limiting line, the idle and breakaway speeds as limiting speeds, and often also lines of constant power P (power hyperbolas on account of $P \sim p_{me} n$, with the engine speed n).

Consumption as sum of all losses and running resistances

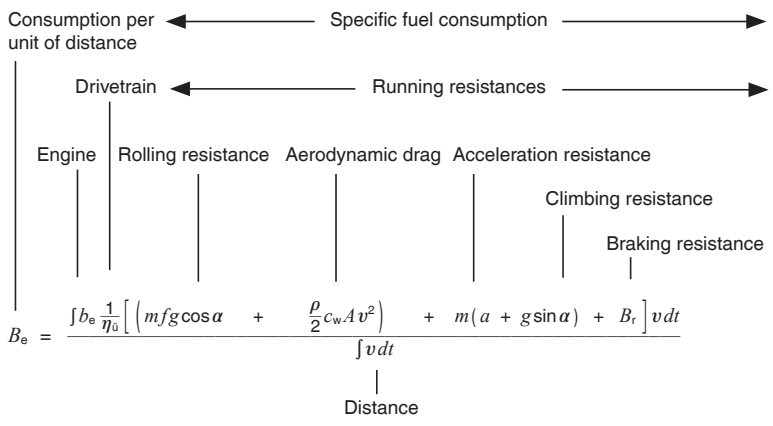
If one disregards the influence of the driver on fuel consumption, which can run to 30 %, there are, based on the consumption formula (Figure 2), three distinct groups of influencing factors:

Table 1: Quantities and units

Quantity		Unit
B_e	Distance consumption	g/m
B_e	Specific fuel consumption	g/kWh
m	Vehicle mass	kg
A	Frontal area of vehicle	m^2
f_R	Coefficient of rolling resistance	–
c_W	Drag coefficient	–
g	Gravitational acceleration	m/s^2
t	Time	s
v	Driving speed	m/s
A	Acceleration	m/s^2
B_r	Braking resistance	N
$\eta_{ü}$	Transmission efficiency of the drivetrain	–
ρ	Density of the air	kg/m^3
α	Gradient angle	°

– the engine (including belt drive and ancillaries),
– the internal running resistances of the drivetrain (e.g., transmission, differentials), and
– the external running resistances.

External running resistances



The external running resistances determine a vehicle's minimum energy demand in a specified driving profile. They can be reduced by measures such as reduced vehicle mass, lower tire rolling resistance, and improved aerodynamics. On an average production vehicle without regenerative braking, 10 % reductions in mass, drag and rolling resistance result in fuel-consumption reductions of roughly 6 %, 3 %, and 2 %, respectively.

The formula in Figure 2 distinguishes between acceleration resistance and braking resistance. This illustrates clearly that consumption per unit of distance increases above all when the brakes are subsequently applied and not the overrun fuel cutoff of the engine or even a hybrid system is used to recover some of the brake energy.

Internal running resistances

The internal running resistances are made up of the losses in the drivetrain from the crankshaft to the wheels. In Figure 1, the

Figure 2: Effect of vehicle design on fuel consumption
Quantities, see Table 1.

sum total of the internal and external running resistances are shown by curves c and d, where vehicle A shows significantly lower resistances than vehicle B.

As well as the transmission losses in the drivetrain, the overall ratio also affects fuel consumption. This is calculated from the product of the transmission and differential ratios. The choice of overall ratio results in different operating points in the engine fuel-consumption map for a specific driving speed. A “longer” ratio, i.e., a smaller overall ratio, will generally move the operating points to map areas corresponding to lower fuel consumption. At the same time, it must be noted that the accelerating performance is reduced and the NVH behavior worsens (“Noise Vibration Harshness”, impacting on driving comfort). A useful choice of ratio is therefore only possible within limits.

Determining the distance-specific fuel consumption of conventional drives
The official data for standard fuel consumption are determined on the basis of dynamometer tests conducted on exhaust-emission test benches in which statutory test cycles (e.g., NEDC for Europe, FTP 75 and Highway for the USA and JC08 for Japan) are run. WLTC (World Light-duty Test Cycles), intended to deliver more realistic consumption figures, have been applied since 2017 and 2018 in Europe and Japan. The exhaust gas is collected in sample bags and its constituents HC, CO and CO_2 are subsequently analyzed for the purpose of determining consumption (see Exhaust-gas measuring techniques). The CO_2 content of the exhaust gas is proportional to the fuel consumption.

The following reference values apply to Europe:
Diesel: 1 *l*/100 km ≈ 26.3 g CO_2/km.
Gasoline:
(Euro 4): 1 *l*/100 km ≈ 24.0 g CO_2/km.
(Euro 5, E5): 1 *l*/100 km ≈ 23.4 g CO_2/km.
(Euro 6, E10): 1 *l*/100 km ≈ 22.8 g CO_2/km.

The change from Euro 4 to Euro 5 and Euro 6 is based on a 5 % admixture of ethanol in gasoline (E5) and a 10 % admixture for Euro 6 (E10).

Vehicle masses are simulated on the test bench as an alternative by test masses. In today's certification cycles the test mass is, depending on the country and the curb weight of the vehicle, graded in increments of 55 to 120 kg. When the vehicle mass is allocated to the corresponding the ready-for-operation weight of the vehicle (including all the fillers, tool kit and the fuel tank filled to 90%) plus 100 kg as substitute for a driver and luggage is applied. The difference in consumption in the jump to an adjacent inertia weight class is – depending on the vehicle – between 0.15 and 0.25 *l*/100 km. In the WLTC the actual vehicle mass is applied as the test mass.

Units of fuel consumption
Standard fuel consumption is given in different units, depending on the country and the test cycle. In Europe, the figure is given in g CO_2/km or *l*/100 km, in the USA in mpg (miles per gallon), and in Japan in km/*l*.

Conversion examples:
30 mpg → 235.21/30 → 7.8 *l*/100 km,
22.2 km/*l* → 100/22.2 → 4.5 *l*/100 km.

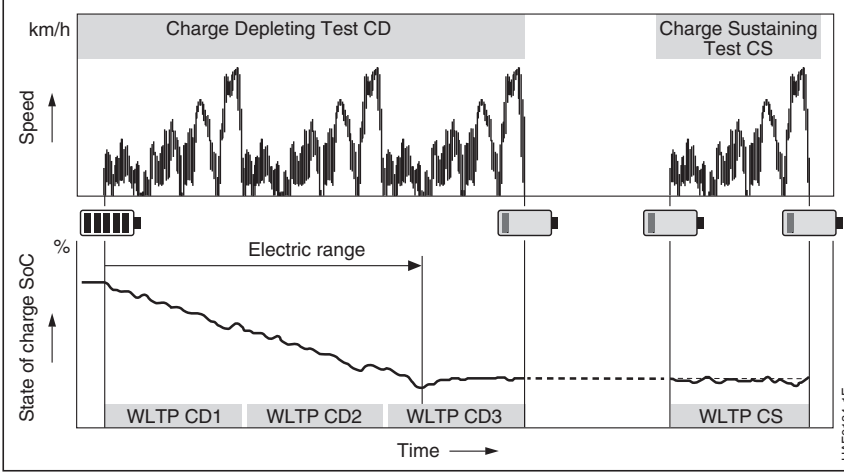
The fixed value of 235.21 used for conversion is obtained from the conversion of gallons to liters and the conversion of miles to kilometers.

Fuel consumption of hybrid vehicles

Particularities of fuel consumption of autarkic hybrids

In the dynamometer testing of autarkic hybrids (i.e., hybrids without external electric charging) the battery current is determined as well as the CO_2 value and it is ensured in all the country-specific legislation that the battery state of charge is the same before and after the test. The permitted tolerance and possible corrections differ between Europe, USA, and Japan.

In hybrid vehicles some of the vehicle's kinetic energy is converted by recuperation into electrical energy and returned to the battery, where it is available for propulsion to assist the internal-combustion engine (boost mode) or for purely electric driving. The internal-combustion engine's operating point can be moved by the electric machine into ranges in the engine map constituting lower fuel consumption (Figure 1); unfavorable part-load ranges are avoided entirely. In this way, fuel savings of 10 % to 20 % compared with conventional vehicles can be achieved.



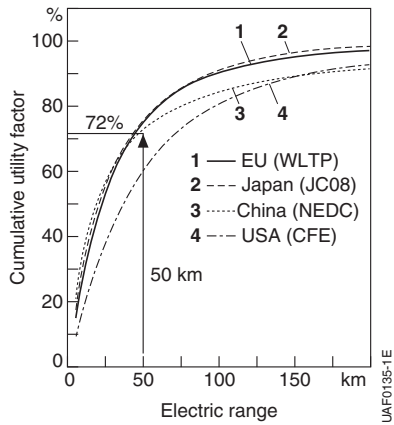
Particularities of fuel consumption of externally rechargeable hybrids

Externally rechargeable hybrids (e.g., plug-in hybrids) differ from autarkic hybrids in that the battery can be charged externally at a power socket or at a wall charging station (wallbox). Wall charging stations enable the battery to be charged at high power levels and thus reduce the charging time.

In contrast to autarkic hybrids and conventional vehicles, two dynamometer tests are performed on externally rechargeable hybrids to determine consumption and the consumption results for fuel and electrical energy from the power socket are offset with different weighting depending on the legislation. Here a test is conducted with a fully charged battery and the cycle is repeated until the electric storage device has reached its minimum charge. This is called the depleting test. A second test, the sustaining test, is performed at the minimum-charge level and is the same as the test for autarkic hybrids (Figure 3).

The utility factor (UF) weights the fuel consumption with a charged storage device (charge-depleting test, CD) and a flat storage device (Charge-sustaining test, CS) as a function of the electric range. It can be determined from field data in accordance with SAE standard J2841 [1]

Figure 3: Test procedures, example WLTC

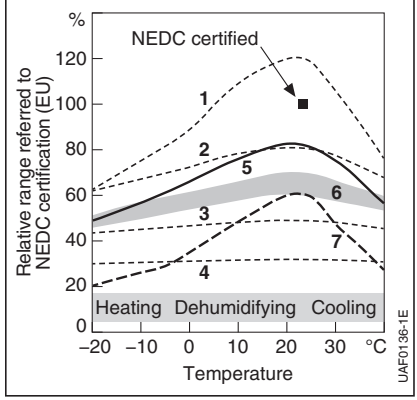


or is defined by the legislature. Figure 4 shows a comparison of the cumulative utility factors for different countries (EU, USA, China, Japan) referred to the WLTP range (Worldwide harmonized Light vehicles Test Procedure). The higher the curve, the more the fuel consumption is weighted in the CD test compared with the CS test consumption for the same range, the utility factor increases, and the certification consumption decreases. This is obtained from the product of sustaining consumption and the value (1– UF).

Figure 4 shows that for an electric range in the WLTC of 50 km the utility factor in China is 72 %, i.e., for sustaining consumption of 6 l/100 km the certification consumption would be 1.7 l/100 km.

The fuel consumption of a plug-in hybrid on the road can deviate markedly from the certification values since the share of electric driving depends, as well as on the driving style, very much on the customer's electric-charging behavior. The charging behavior is decisively influenced by the existing charging infrastructure and the operating convenience.

Figure 4: Utility factor: as a function of the electric range in the WLTC



Range and consumption of electric vehicles

Electric range

The official data for the standard range are determined on the basis of dynamometer tests on test benches in which statutory test cycles are repeatedly run. For example, for an electric range of 200 km the NEDC cycle must be run approximately 19 times. As in the dynamometer tests conducted on conventional vehicles and hybrids, secondary loads and air-conditioning influences are not taken into account here either. The latter play a large role in electric vehicles with regard to the attainable range because all the energy for heating and cooling is drawn from the battery and thus is no longer available for propulsion. Figure 5 shows the air-conditioning influence for heating, cooling or dehumidifying (reheating), represented by the temperature, and the influence of driving behavior (speed, acceleration, braking response), represented by different cycles, referred to the attainable range.

Figure 5: Relative range change as a function of temperature referred to the NEDC certification range

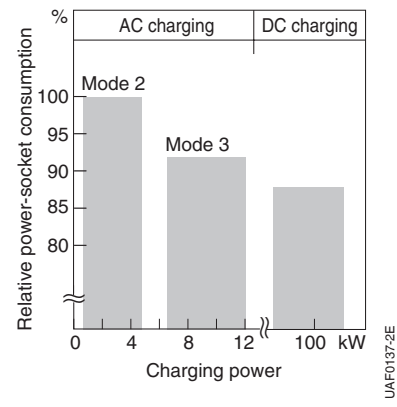
1 Constant 50 km/h,
2 Constant 100 km/h,
3 Constant 150 km/h,
4 Constant 200 km/h,
5 WLTC,
6 Long distance,
7 NYCC (urban).

The higher the energy demand from the driving task, the less the effect of the A/C secondary loads. The smallest ranges are attained in urban cycles (using the example of the New York City Cycle, NYCC) at low temperatures. Constant-speed driving at temperatures around 20 °C provide for the largest ranges.

Power-socket consumption

After the end of the range test the traction battery of each electric vehicle is recharged at a power socket or a wall charging station and the energy required for this is determined. Referring this energy to the previously determined range produces the power-socket consumption in Wh/km or kWh/100 km. While the terminal consumption, which can be measured at the battery terminal, is only dependent on the vehicle and the test cycle, the power-socket consumption additionally varies as a result of the charging procedure used. Figure 6 plots the dependence of the power-socket consumption on charging power and charging mode (charging procedure) for a concrete pair of vehicle and driving cycle. The different charging modes are alternating-current charging (AC) with Mode 2 (charging from domestic power socket, with max. 32 A) and Mode 3 (charging e.g. from charging post or wall charging station) and direct-current charging (DC). The higher the charging power, the lower the power-socket consumption and the higher the charging-system efficiency η. This is calculated as follows:

$$\eta = \frac{\text{power-socket consumption in } \frac{\text{kWh}}{100\ \text{km}}}{\text{terminal consumption in } \frac{\text{kWh}}{100\ \text{km}}}$$



The charging-system efficiency is affected by the losses from ancillary components (e.g., pumps, fans, and ECUs), the losses from the on-board charger during AC charging, and those from the wall charging station. The on-board charger here has the task of converting the alternating current from the charging network into direct current with the right voltage for the battery.

Driving performance of electric vehicles

The driving performance of electric vehicles is much more heavily dependent on temperature and the charge state of the energy accumulator than that of conventional vehicles. As the temperature decreases and with a low battery state of charge (SoC), the electric drivetrain delivers less power and consequently the top speed decreases and the acceleration time increases. At temperatures below freezing and with the battery at 50 % charge the maximum speed decreases to approximately 50 % of the nominal top speed, and the acceleration time from 0 to 100 km/h doubles.

Figure 6: Electrical power-socket consumption as a function of charging power and charging procedure

Relative power-socket consumption is referred to the consumption at 1.4 kW charging power.

Well-to-Wheel analysis

In a Well-to-Wheel analysis the energy consumption and the greenhouse-gas emissions which are caused by the manufacture, provision and use of a fuel are analyzed. The analysis is divided into two steps (Figure 7):

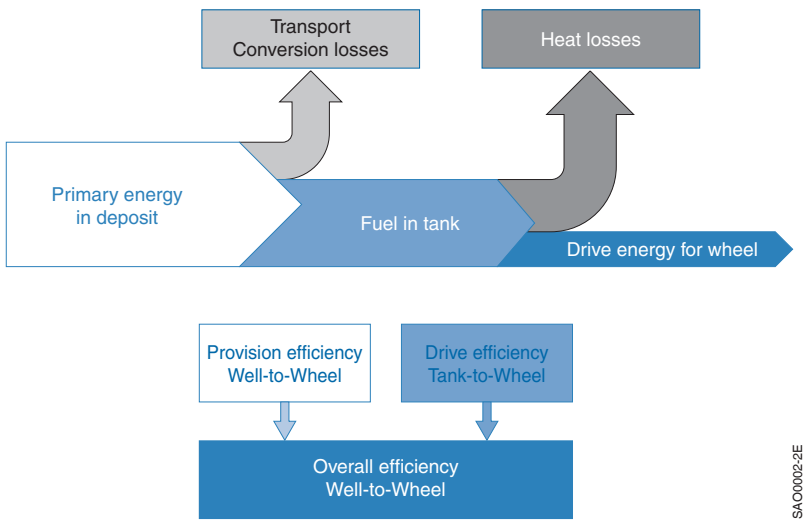
– The Well-to-Tank path describes the provision of fuel.
– The Tank-to-Wheel path describes the use of the fuel in the vehicle.

Provision

The Well-to-Tank path (WtT, provision path) comprises the extraction of the primary sources of energy, the transportation of the raw materials, the manufacture of the fuel, and its distribution onward to the vehicle tank. Both energy losses and greenhouse-gas and exhaust emissions arise in this step.

The Well-to-Tank efficiency (provision efficiency) is the ratio of energy content of the fuel in the tank to the energy content of the source of energy in the deposit. The amounts of energy required for the individual process steps arise as conversion losses (examples, see Table 2).

Different processes must be taken into account here, depending on the fuel. If there are different manufacturing paths for a fuel (e.g., hydrogen), the balance crucially depends on which manufacturing path is chosen. In other words, a fuel cannot be evaluated independently of how it is manufactured. The following examples show specific influencing factors for some fuels.



Fossil gasolines and diesel fuels

For the provision of gasoline and diesel fuel the analysis includes above all the energies and emissions which are required for extracting the crude oil, for transporting, processing and refining the oil, and for distributing the fuel.

Biofuels

In the case of biogenous fuels, energy consumption and greenhouse-gas emissions arise during cultivation provided the biomass is cultivated specifically for energy use (cultivated biomass). Particularly crucial here are the manufacture and use of nitrogenated fertilizers as well as diesel consumption for working the cultivated areas. Agricultural production is not taken into account in the biofuels are produced from recyclings.

Figure 7: Energy flow, Well-to-Wheel for an internal-combustion engine (shown as a Sankey diagram)

In the case of fuels produced from biomass, the amount of CO_2 taken by the plants from the atmosphere as they grow are taken into account in the balance as a negative value. In this way the total amount of CO_2 which is attributed to provision is reduced.

Credits
During the production of biofuels by-products are obtained from time to time which can be used for other purposes, e.g., glycerin in the manufacture of biodiesel or animal feed in the manufacture of bioethanol from grain. Provided the by-products replace conventionally created products, saved emissions and energy consumption for the conventional manufacture of the product are credited to the biofuel. In this way energy consumption and emissions which are attributed to the biofuels are reduced. All in all, therefore, negative values can also be obtained for the CO_2 emissions.

In the case of residual biomass, it must be borne in mind that this biomass under certain circumstances could have been used for other purposes (e.g., used frying oil as animal feed, offal timber for generation of energy). This lost alternative use reduces the advantages of the biofuel in the balance.

Natural gas
The provision path of natural gas is essentially described by the extraction, long-distance transportation and compression of the gas to 200 bar at the filling station.

Electricity
If electricity is used directly for the vehicle drive or indirectly to create hydrogen or synthetic fuels, the current-generation emissions are attributed to the fuel.

Hydrogen
Hydrogen can be obtained by steam reformation from natural gas. What must be taken into account in particular here are the long-distance transportation of the natural gas, steam reformation, and compression of the hydrogen at the filling station.

If, however, hydrogen is obtained by electrolysis from water, the electrical energy used must be taken into consideration. The balance is then very much dependent on how the electrical energy is generated, since the emissions from energy generation are attributed to the hydrogen.

Table 2: Conversion losses and provision efficiencies for diesel, gasoline, CNG (compressed natural gas), and H_2 (compressed hydrogen) from two different production paths (gray hydrogen from CNG by means of steam reformation, green hydrogen from wind power by means of electrolysis). Source: [2]

Losses and overall efficiency referred to source energy		Diesel fossil (EU mix)	Gasoline fossil (EU mix)	CNG fossil (EU mix)	H_2 from CNG (Russia)	H_2 Electrolysis (wind power)
Losses	Extraction, energy generation, processing	10 %	10 %	2%	2%	0 %
	Long-distance transportation	1 %	1 %	4 %	8 %	0 %
	Conversion (refinery, steam reformation, electrolysis)	8 %	7 %	0 %	26 %	32 %
	Domestic distribution	1 %	2%	7 %	10 %	15%
Overall provision efficiency		79 %	81 %	87 %	54 %	54 %

Synthetic fuels
The synthesis of hydrogen into gaseous or liquid fuels can essentially be performed in one of two processes: methanation or by way of a Fischer-Tropsch process. If for these processes CO_2 is filtered out of the air and the hydrogen is obtained from regenerated electricity, the fuel produced can in the best case be greenhouse-gas-free.

The generation of the starting substances hydrogen and CO_2 or CO and the number of subsequent synthesis steps determine the energy losses which arise during the production of the various synthetic fuels (e-fuels).

Drive
The fuel used and the drive efficiency are decisive for the fuel consumption and the local CO_2 emissions of a vehicle. This is referred to as the Tank-to-Wheel efficiency and describes the ratio of drive energy which is output to the wheels (Tank-to-Wheel path, drive path) to the energy content of the fuel consumed.

Defined driving cycles are used to compare the fuel consumption and the emissions of different drive concepts. This is in effect a driving profile with defined driving speeds and acceleration phases. For a standardized driving cycle the respective drive efficiency and the emissions can be determined for the different drive concepts.

Overall examination
The provision path and the drive path are brought together in the Well-to-Wheel analysis (WtW) (see Figure 7). Here in each case the energy expenditure and the greenhouse-gas emissions of the two sub-paths are added. The overall examination thus comprises both fuel provision and vehicle use. In the energy balance the sum total of exhaustible primary energies is given in MJ/km (i.e., fossil and nuclear energy). In the greenhouse-gas balance the sum total of greenhouse-gas emissions is given as a CO_2 equivalent in g/km.

The CO_2 equivalent takes into account as well as carbon dioxide further greenhouse gases, which are weighted according to their specific greenhouse effect. Reference vehicles and driving cycles are used as the basis for the balances.

When the different fuels are compared with each other, it becomes clear that a relatively high expenditure for fuel provision (energy used and emissions caused) can be compensated for by a high drive efficiency and low direct emissions during the combustion of the fuel. It is therefore not possible to evaluate a fuel without also analyzing the associated drive technology.

Figure 8 shows by way of example for different fossil and regenerative fuels the CO_2 emissions which result from fuel provision (WtT) and from fuel use (TtW). It must be borne in mind here, however, that the CO_2 balance is very much dependent on the boundary conditions of fuel production and use such that the specified values are in no way generally applicable to the fuel in question.

Life-cycle examination
A further analysis of greenhouse-gas emissions and energy consumption moves the focus of examination from the fuel to the vehicle. A life-cycle examination for the vehicles takes into consideration, aside from operation of the vehicle, energy consumption and greenhouse-gas emissions that arise during the manufacture of the vehicle. Starting with raw-material extraction, transportation, refinement, and processing, here too recycling is taken into consideration at the end of the vehicle's life (“cradle to grave”). The results of this examination are very much dependent on the process paths used.

A more comprehensive examination of the environmental impacts is offered by a life-cycle analysis (LCA). Such an analysis takes into account, as well as energy consumption and greenhouse-gas emissions, numerous additional environmental impacts such as for example land consumption, water consumption, and water pollution.

Vehicle aerodynamics

Aerodynamic forces

Vehicle aerodynamics concerns all phenomena that arise as a surrounding medium (air) flows around or through moving vehicles and their components. The drag, forces and moments (see Table 1) are evaluated and usually optimized by changing the shape of the vehicle.

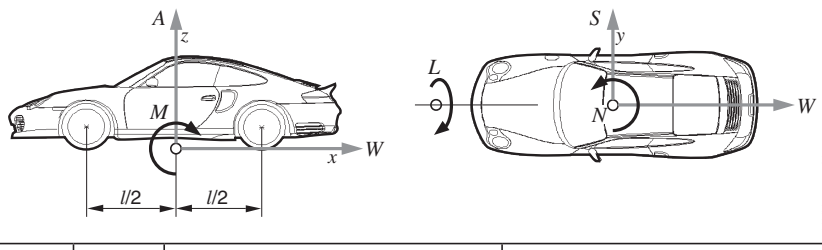
Aerodynamic drag
Aerodynamic drag W_L is given a lot of attention in developing motor vehicles, because it has a direct impact on the vehicle performance and fuel consumption. A critical variable here is the drag coefficient c_W, which describes the aerodynamic quality of the shape of a body in a flow. The aerodynamic drag is also influenced by the frontal area A_{fx} and the dynamic pressure q of the flow, which depends on the air density ρ and the airflow velocity v.

Dynamic pressure is described by this equation:

$$q = 0.5\ \rho\ v^2.$$

Aerodynamic drag is calculated as (also refer to fluid mechanics):

$$W_L = \frac{\rho}{2}\, v^2 c_W A_{fx}.$$



Aerodynamic drag is composed of the skin friction drag and form drag:

$$W_L = W_R + W_D.$$

Skin friction drag W_R
Skin friction drag arises due to shear stress τ_w on the walls as the air flows by. Figure 1 shows an example of this on a wing. Skin friction drag is calculated as an integral of the shear stress over the surface:

$$W_R = \int \tau_w \cos\varphi\, dF.$$

Table 1: Aerodynamic forces and moments
q Dynamic pressure, ρ Air density, v Airflow velocity, A_{fx} Frontal area,
c_A Lift coefficient, l Wheelbase.
$c_{AV} = 0.5\ c_A + c_M$ (relative to the front axle),
$c_{AH} = 0.5\ c_A - c_M$ (referred to rear axle).

Quantity	Unit	Meaning	Coefficient with definition
W	N	Drag in the x direction	$c_W = W/(q\,A_{fx})$
S	N	Side force in the y direction	$c_S = S/(q\,A_{fx})$
A	N	Lift in the z direction	$c_A = A/(q\,A_{fx})$
L	Nm	Rolling moment around x	$c_L = L/(q\,A_{fx}\,l)$
M	Nm	Pitching moment around y	$c_M = M/(q\,A_{fx}\,l)$
N	Nm	Yawing moment around z	$c_N = N/(q\,A_{fx}\,l)$

Form drag W_D
Form drag arises through pressure changes on blunt bodies caused by shedding. It is calculated as an integral of the pressure over the surface:

$$W_D = \int p \sin\varphi \, dF.$$

Figure 2 shows the flow pattern for flow around a wing and a hemisphere. Shedding results in vortices, and therefore pressure differences. Form drag is predominant for blunt bodies. For streamlined bodies, the friction component dominates; there is no turbulent shedding from the body's surface.

For the c_W values for different bodies and car body shapes, refer to the various tables (see Drag coefficients, Fluid mechanics and Drag coefficients, Motor-vehicle dynamics).

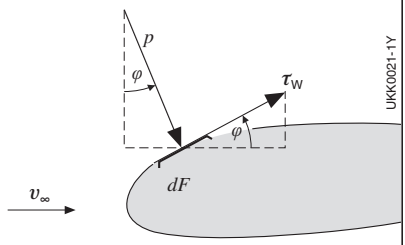
dF Surface element.



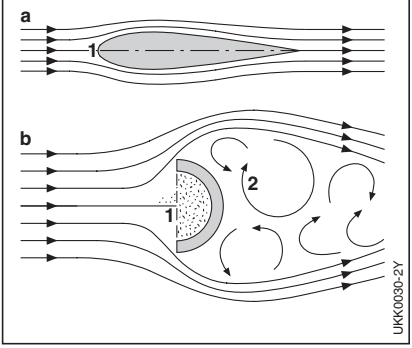


Figure 2: Flow conditions for various bodies
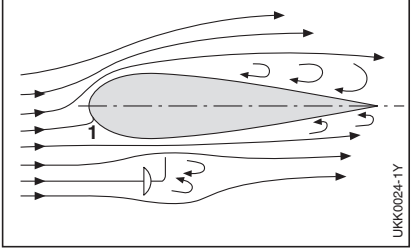
a) Streamlined body (wing),
b) Blunt body (hemisphere).
1 Stagnation point,
2 Separated flow, vortices.



Induced drag
The difference in pressure above and below a vehicle in flow lead to superimposition of the main horizontal flow around the body. A vertical flow component arises through pressure equalization via the body sides, and wake turbulence develops, which causes the induced drag.

Internal drag
Internal drag arises from pressure loss as air flows through the engine compartment.

Interference drag
Interference drag is produced by the interaction of attachments (such as the wheel suspension, wheels, exterior mirrors, antennas, windshield wipers, spoilers, vanes). The total drag is not the sum of the drag forces of the individual parts, because the mutual interference has to be taken into account. Thus attachments can also cause the c_W value to drop.

The impact of an exterior rearview mirror on the car body is shown here as an example (Fig. 3). It causes the stagnation point to move toward the attachment; this results in asymmetrical flow around the car body. Consequently, there is a greater risk of shedding vortices, and that leads to an increasing c_W value.

Figure 3: Influence of an exterior mirror on a car body (model)
1 Stagnation point.

Buoyancy force
The curvature of the car's top surface causes the air to flow faster above the vehicle than under it, which generates an undesirable lift force (Fig. 4). This reduces the tire contact forces and thereby has a negative impact on the directional stability.

The lift coefficient c_A is the sum of the lift coefficients on the front axle c_{AV} and the rear axle c_{AH}. The difference between the lift on the front and rear axles is referred to as "lift balance" and is a variable influencing directional stability.

The pitching moment M, which acts around the y-axis, is often used as a design variable instead. A positive pitching moment requires understeer, and a negative pitching moment requires oversteer. The rolling moment L around the x-axis is disregarded with respect to aerodynamics.

Lateral force
A car has an almost symmetrical shape when viewed from the front, which means that side forces generated by air flows are small. As soon as the approaching air flow deviates from the x-axis (i.e. in a crosswind), the airflow generates side forces that can affect vehicle behavior considerably (Fig. 5).

The yawing moment N, which acts around the z-axis, is also used as an indicator for crosswind sensitivity. This value is used to derive the yaw-angle velocity and yaw angular acceleration, which provide information about the negative impact of crosswind.

Tasks of vehicle aerodynamics

Aerodynamics has other tasks besides reducing the c_W value (Fig. 6).

Motive power

Impact of velocity on tractive resistance

In order to set the vehicle in motion and keep it moving, the engine has to produce a tractive force Z. This is composed of the aerodynamic drag W_L, rolling resistance W_R, climbing resistance W_S, drag during acceleration W_B and losses in the powertrain W_A. This results in the tractive resistance equation:

$$Z = W_L + W_R + W_S + W_B + W_A.$$

Climbing resistance and acceleration resistance are zero during constant motion on a level stretch. The mileage is substantially determined by the aerodynamic drag, because it increases quadratically with the velocity and surpasses the other tractive resistances as of 80 km/h (Fig. 7).

The lower the product of the c_W value and frontal area A_{fx} ($A_{fx} \cdot c_W$ is often called the drag area), the faster a vehicle can move with a suitable transmission ratio. At a constant velocity, a smaller drag area leads to lower fuel consumption. Consequently, the vehicle produces fewer emissions.

As a function of the low driving speeds in the New European Driving Cycle (average speed of 33.4 km/h, see European test cycle), however, the influence of the aerodynamic drag is greatly underestimated in the manufacturer/consumption data, which can lead to higher fuel consumption in everyday operation for the average driver.

UKK0027-3E

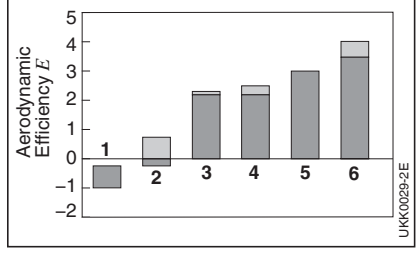
Directional stability
Directional stability, sensitivity of the steering behavior, lane-change behavior, handling and crosswind sensitivity are critically influenced by the lift and side forces. The forces that can be transferred from the wheels to the road in the longitudinal and transverse directions can be no larger than the vertical force (normal force).

The lift acts against the vertical forces resulting from the weight. Consequently, the forces that can be transferred from the tires, above all during motion in a curve, can be reduced until there is a total loss of directional stability, depending on the driving speed and lift. The transferable braking forces also depend on the vertical wheel load, and therefore on the aerodynamic lift.

The task of aerodynamics is therefore to minimize the lift forces through means such as spoilers on the front and rear of a vehicle. For sports cars it can even happen that downforces (i.e. negative lift forces) greater than the weight are produced.

Figure 8: Cornering behavior
a) Understeering behavior,
b) Oversteering behavior.
1 Correct trajectory,
2 Trajectory of an understeered vehicle,
3 Trajectory of an oversteered vehicle.

Lift balance
If the lift balance has a lift coefficient c_{AV} on the front axle greater than c_{AH} on the rear axle, there is a positive pitching moment and the design produces understeering driving behavior. Then if the speed in a curve is too high it will be noticed immediately when the steering angle is too high; the vehicle should be stabilized again by backing off the accelerator (Fig. 8a).



If c_{AV} is less than c_{AH}, a negative pitching moment is produced and there is an oversteering design (Fig. 8b). Then if the speed in a curve is too high it will be perceived not through the steering wheel, but through the seat. Backing off the accelerator makes the vehicle unstable; it can be kept in the lane only with targeted countersteering and depressing the accelerator.

Aerodynamic efficiency
A significant reduction of the lift forces usually comes at the expense of a favorable c_W value. The smaller this impact, the greater the aerodynamic efficiency E. It describes the relationship between the lift and drag coefficients:

$$E = \frac{c_A}{c_W}.$$

Figure 9 shows a comparison of the values for the aerodynamic efficiency of different vehicles. Due to the freedom of body design and the very fast racetrack, current Le Mans prototypes have the best

Figure 9: Aerodynamic efficiency for various vehicle types
1 Passenger car,
2 Sports car,
3 Formula 3 racecar,
4 Indy car series,
5 Formula 1 racecar,
6 Le Mans racecar.

efficiency (E = 3.5 to 4). Despite a high downforce, a low c_W value is achieved.

Due to the fuel consumption advantages, passenger cars usually have very low c_W values, but positive lift, and therefore a negative efficiency down to $E = -1$.

Cooling and ventilation

The responsibility of aerodynamics consists in requirements-based air intake, so that the heat generated by operating the vehicle is dissipated to the environment (see Engine cooling).

An intensive flow of cooling air can lead to a high internal drag, and therefore increase the aerodynamic drag. Therefore a great deal of attention is given to achieving an optimum balance between cooling requirements and aerodynamics (Fig. 10). To optimize the air intake, air inlets and outlets are located on the vehicle in zones with the greatest possible pressure difference for propulsion. The flow of cooling air can be controlled and adapted by changing the size of the respective openings. The cooling air is conducted through channels to the radiators, which should be designed to be as free of pressure loss and leaks as possible.

The same criteria also apply to an exhaust air duct up to the air outlet. The air outlet should be positioned downstream with the least possible pressure loss. If it can be placed in a zone where there are already aerodynamic losses, these can be favorably reduced by the arising interference. For example, blowing out the cooling air ahead of the front wheel can form an air cushion and thereby guide the flow around the wheel with fewer losses, which nearly equalizes the cooling air drag (Fig. 11).

The aerodynamic pressure losses can also be controlled by choosing suitable radiator cores and their dimensions, as well as fans and their frames. To entirely prevent cooling air drag with a low power requirement, electrically closable radiator shutters were introduced in series production back in 1987 (for the Porsche 928). Today this measure is widely used in the premium class.

Comfort and convenience
Aerodynamics helps provide the passengers with comfort primarily by reducing wind noise (aeroacoustics), dirt and drafts.

Aeroacoustics
Wind noise in the passenger compartment of a car is the primary noise source for speeds over 120 km/h; above 200 km/h it is approximately 6 dB(A) louder than all other acoustic sources (Fig. 12). This corresponds to four times the sound power.

The term "aeroacoustics" refers to the production of noise from
– Flow around the body (flow separation, broadband noise from unsteady pressure fluctuations, noise with discrete frequencies such as from antennas and exterior mirrors),
– Component excitation with low-frequency noise excitation due to large surfaces in a flow (such as convertible top, roof, door and cover panels),
– Overflow with noise created by a Helmholtz resonance (such as with open windows, sliding sunroof),
– Leakage due to pressure differences between the passenger compartment and flow around the body as the result of aerodynamic and mechanical component loads.

Improvement of the aeroacoustics
By giving the basic body an aerodynamic shape you can reduce the local flow velocities, influence the flow direction, and prevent or limit turbulent shedding. Generally speaking, whatever reduces the c_W value also leads to lower wind noise.

Freestanding attachments (such as mirrors, wipers, antennas, roof transport system) disrupt the flow around the basic body by creating additional flow separation. Therefore they should be positioned where they will produce the least possible disruption and their shape should be optimized. With component excitation, aerodynamics analyses the necessity and placement of reinforcement plates or damping measures.

In the case of flow over cavities (such as an open sliding sunroof), low-frequency pulsing of the air volume in the passenger compartment can occur (humming). That is the resonance case of periodic oscillation of the shear layer between the air overflow and the static air in the passenger compartment (Fig. 13) with the natural frequency of the passenger compartment (Helmholtz resonator principle). As an aerodynamic measure, the shear layer buildup is upset by interference flows, for example, using a wind deflector on the sliding sunroof.

Figure 12: Wind noise components in total noise

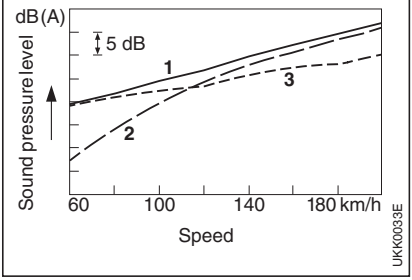
2 Wind noise,
3 Other noise.



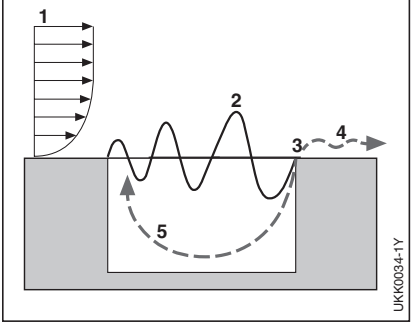


Figure 13: Feedback mechanism
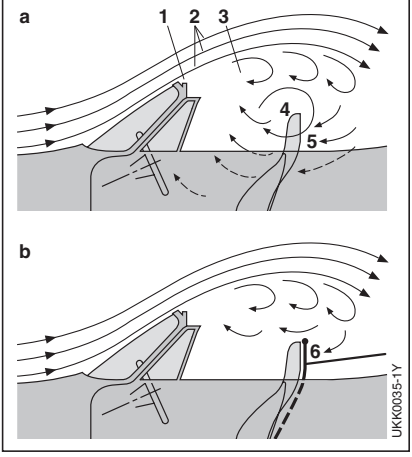
1 Turbulent oncoming flow,
2 Shear layer oscillation,
3 Rear edge of cavity,
4 Vortex,
5 Pressure wave.



The aeroacoustic quality is evaluated not only by the spectral analysis, but also by taking into account psychoacoustic parameters. These parameters measure higher-frequency noise components; consequently, subjective perception (loudness, sharpness) and speech intelligibility are taken into account better. The sharpness is evaluated independently from loudness and roughness. The articulation index is a measure of speech intelligibility.

Dirt

The wheels of your own vehicle kick up dirt particles, which settle on the surface of your vehicle (self-caused dirtying) or they mix with the turbulent wake and settle on following vehicles (extraneously caused dirtying). The magnitude and intensity of the contaminated surfaces are caused by local wake turbulence of the surrounding flow. The task of vehicle aerodynamics is to identify such turbulence and reduce it or transpose it to unproblematic zones. Great care is given to avoiding impaired visibility by keeping the windows and exterior mirrors free of dirt buildup.

Figure 14: Reduction of drafts for a convertible by using a windbreak

2 Flow around vehicle,
3 Unsteady vortex sheet,
4 Vortex direction of rotation in passenger compartment,
5 Airflow between the seats and between the seats and side panels,
6 Windbreak for reducing airflow between the seats.

Draft prevention

Usually there are bothersome drafts when driving with the windows and roof open. This can be clearly observed in a convertible when the top is open, because there is shedding of the flow over a large area behind the windshield frame. A low-pressure region behind the windshield is filled by a backflow. Backflows and turbulence cause the bothersome drafts (Fig. 14).

The vortices can be damped and significantly reduced by the mesh fabric of a windbreak. The task of vehicle aerodynamics is to determine the size and shape of this component as well as its mesh density.

Component forces

Component forces arise from the pressure forces produced by the flow around the body (measured quantity is the c_p value), which vehicle aerodynamics has to determine empirically and increasingly also through calculations. The positive or negative pressure forces acting perpendicular to the outer skin increase along with the airflow velocity and act as a load on the components located there.

In areas where there is shedding (such as A-pillars, exterior mirrors, rear window, rear spoiler), the turbulence results in stochastically varying loads, which have to be taken into account for determining the function and durability of the components.

Vehicle wind tunnels

Application

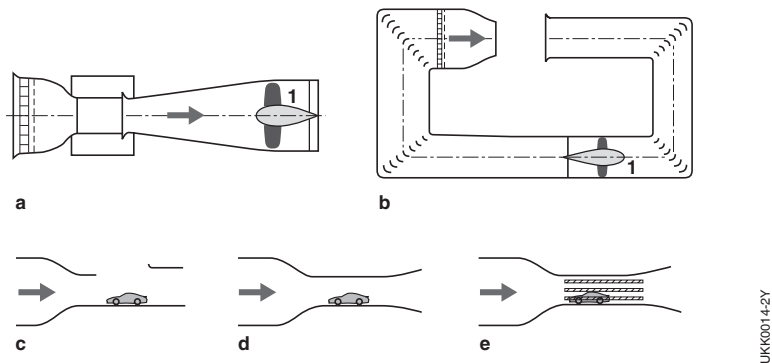
Aerodynamic measurements on roads are difficult, because the environmental conditions are neither uniform nor steady. The direction and steadiness of the conditions are constantly changing due to factors such as natural wind, buildings, and traffic. A vehicle wind tunnel is used to represent the air flow affecting a vehicle traveling on the road in an environment that is as realistic and reproducible as possible.

The advantages of using a vehicle wind tunnel as an experimental development tool compared with road measurements are the reproducibility of test conditions, the uncomplicated, reliable, and fast measuring technology, and the ability to disassociate effects (such as driving noise) that occur only in conjunction with road travel. Design prototypes that are not yet roadworthy can be optimized aerodynamically in a wind tunnel with guaranteed secrecy.

Wind tunnel designs

Types of wind tunnel

Aerodynamic parameters are calculated in wind tunnels. They vary in the type of air guidance, test section, size, and road-surface simulation (Table 2). Closed-circuit (closed return) wind tunnels are referred to as "Göttingen type", while open-circuit (no return) wind tunnels are referred to as "Eiffel type" (Figure 15). For vehicle aerodynamics, Göttingen wind tunnels with an open test section or with slotted walls are used predominantly.



Standard wind tunnel equipment

The test section design can be open, have slotted walls, or be closed. It is characterized by the outlet cross-section of the nozzle, the cross-section of the collector, and the length of the test section (Fig. 19, Table 2).

Obstruction $\Phi_N = A_{fx}/A_N$ is also an important parameter. This is the ratio between the frontal area of the vehicle A_{fx} and the nozzle cross-section A_N. On the road, this ratio is $\Phi_N = 0$, therefore it should also be as small as possible in the wind tunnel. Taking the construction and operating costs of a wind tunnel into account, $\Phi_N = 0.1$ is a common figure in practice. This corresponds to a diffuser cross-section of approx. 20 m^2.

The contraction and contours of a diffuser determine the velocity and steadiness of the wind-tunnel air flow. A large contraction ratio κ of the cross-sectional areas of the prechamber to the nozzle outlet ($\kappa = A_V/A_D$) leads to uniform velocity distribution and low turbulence, as well as to fast acceleration of the airflow.

Figure 15: Wind-tunnel designs

c) Open test section,
d) Closed test section,
e) Test section with slotted walls.
1 Fan.

The diffuser contour can influence the steadiness of the velocity profile at the diffuser outlet in the test section, and parallelism in relation to the geometrical tunnel axis.

The settling chamber or prechamber is positioned upstream of the nozzle and in the largest cross-sectional area of the wind tunnel. The prechamber contains flow rectifiers, filters, and heat exchangers that improve the quality of the air flow in terms of steadiness and direction, and keep the channel temperature constant.

The fan in most wind tunnels can generate wind speeds of well over 200 km/h. Speeds of this size are only rarely used, for example, for testing the functional safety and stability of body components under wind loads. This is because such tests require the full fan capacity of up to 5,000 kW. Normal measurements are taken at 140 km/h. At this speed, the aerodynamic coefficients can be determined reliably and at low operating cost. The wind speed is regulated either by changing the fan speed, or by adjusting the fan blades at a constant speed (Table 3).

A wind tunnel balance records the aerodynamic forces at work on the test vehicle and the moments of all four tire contact surfaces; it breaks these forces into x, y, and z components to calculate the aerodynamic parameters.

A wind tunnel balance is normally positioned below a turning platform, which is used to turn the vehicle in relation to the wind direction, and thus simulate the effect of side winds.

In contrast to a real situation, a vehicle in a wind tunnel is stationary and has air blown toward it. The influence of the relative movement between the vehicle and

Table 2: Vehicle wind tunnels in Germany (examples)

Wind tunnel operator	Nozzle cross-section	Collector cross-section	Test section length	Test section design	Simulation of the moving road
Audi	11.0 m²	37.4 m²	9.5 to 9.93 m	Open	with 5 moving belts
BMW	18.0 to 25.0 m²	41.4 m²	17.9 m	Open	with 5 moving belts
BMW Aerolab	14 m²	25.9 m²	15.7 m	Open	1 conveyor belt, width greater than vehicle width
Daimler	28.0 m²	61 m²	19 m	Open	with 5 moving belts
IVK Stuttgart	22.5 m²	26.5 m²	9.9 m	Open	with 5 moving belts
Ford	20.0 m²	28.2 m²	9.7 m	Open	–
Porsche	22.3 m²	37.7 m²	13.5 m	Slotted walls, open	–
Volkswagen	37.5 m²	44.8 m²	10.0 m	Open	–

Table 3: Wind-tunnel fans

Wind tunnel	Drive power	Fan diameter	Wind velocity	Control
Audi	2,600 kW	5.0 m	300 km/h	Revolutions per minute
BMW	4,140 kW	8.0 m	300 km/h	Revolutions per minute
BMW Aerolab	3,440 kW	6.3 m	300 km/h	Revolutions per minute
Daimler	5,200 kW	9.0 m	265 km/h	Revolutions per minute
IVK Stuttgart	3,300 kW	7.1 m	260 km/h	Revolutions per minute
Ford	1,950 kW	6.3 m	185 km/h	Revolutions per minute
Porsche	2,600 kW	7.4 m	220 km/h	Revolutions per minute
Volkswagen	2,600 kW	9.0 m	180 km/h	Blade adjustment

the road cannot be taken into account. Therefore, in addition to wind tunnels with a stationary floor, there is now increased use of wind tunnels with moving belts incorporated into the floor to imitate motion of the car over the road and rotating wheels (Figure 16). The quality of the air flow between the vehicle and the road can thus be improved and made significantly more realistic.

Wind-tunnel auxiliary systems

Frontal-area measuring system

The frontal-area measuring system (laser or CCD system) measures the frontal area of the vehicle by optical means. The results are then used to calculate the aerodynamic coefficients from the forces measured in the wind tunnel.

The ideal pressure transducer system of a wind tunnel can simultaneously record the pressure curve at up to 100 pressure measuring points, for example, using the flat sensors affixed to the car body surface for the pressure distribution. The miniature pressure sensors used for each measuring point have no wearing parts

Figure 16: Turning platform on test section floor with flat belts incorporated

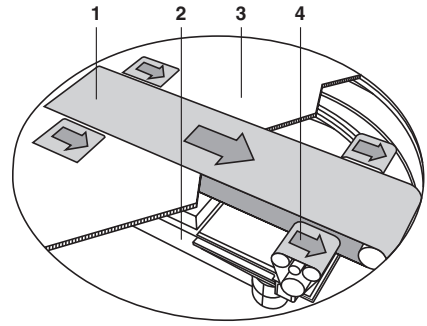

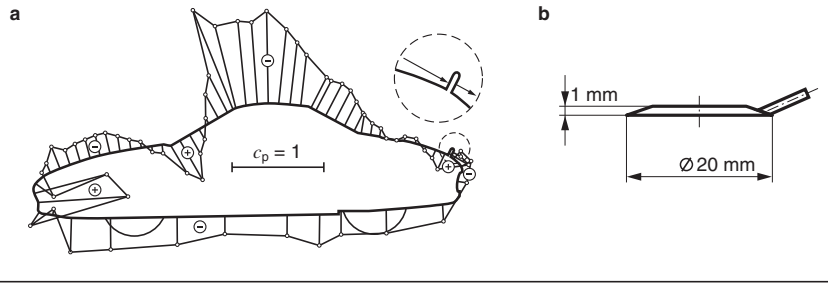

Figure 17: Measurement of pressure distribution (application example)

a) Pressure distribution on midsection of vehicle surface (y = 0), measured using 63 flat sensors,
b) Flat sensor.
The lines show the static pressure acting perpendicular to the measurement point.
The arrow length indicates the magnitude of the pressure.
The line under c_p = 1 shows the scale.
c_p is a dimensionless pressure coefficient;
it describes the pressure p_∞ at any point on the vehicle at the velocity v_∞ with respect to the dynamic pressure p prevalent at this velocity.

$$c_p = \frac{p - p_\infty}{0.5 \cdot \rho \cdot v_\infty^2}.$$

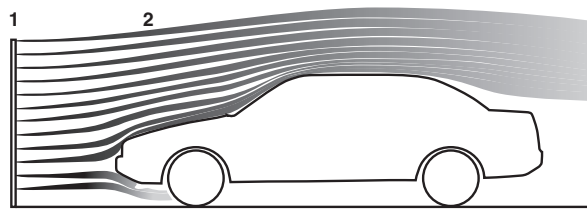
and can therefore electronically scan at a high frequency (Figure 17).

Traversing cradle
The traversing cradle allows the measurement of the complete vehicle airflow field. Each position in the test section can be located by coordinates and reproduced. According to the sensors present at each point, the pressure, velocity, or noise sources at each location can then be determined.

Smoke tubes
Smoke tubes are used to visualize the airflow, which would otherwise be invisible. The smoke pattern enables detection of flow separation, the vortices of which worsen the coefficients (Fig. 18). The nontoxic "smoke" is usually created by heating a glycol mixture in an oil-vapor generator. Other methods for visualizing the air flow include:
– Tufts on the vehicle surface,
– Tuft sensors,
– Photographs of flow patterns with quick-drying liquid mixture of kerosene or talc,
– Helium bubble generator,
– Laser sheet.

Pollutant dispersion system
The pollutant dispersion system can be used to spray the vehicle in the wind tunnel with water ranging from light mist to heavy rain. The flow patterns can be visualized and documented by mixing chalk or a fluorescent agent to the pollutant.

Hot-water unit
The hot-water unit provides heated water at a constant rate for measuring radiator cooling capacity in prototypes that are not yet roadworthy.



Wind tunnel variants
A vehicle wind tunnel is a major investment. This investment, combined with high operating costs, make it an expensive test environment with a high hourly rate. Only very frequent utilization of vehicle wind tunnels for aerodynamic, aeroacoustic, and thermal experiments can justify the construction of several wind tunnels specialized for different tasks.

Model wind tunnel
A model wind tunnel can considerably reduce operating costs, due to the lower construction requirements and technical complexity. Depending on the scale (1:5 to 1:2), it is easier, faster, and more cost-effective to change the shape of vehicle models.

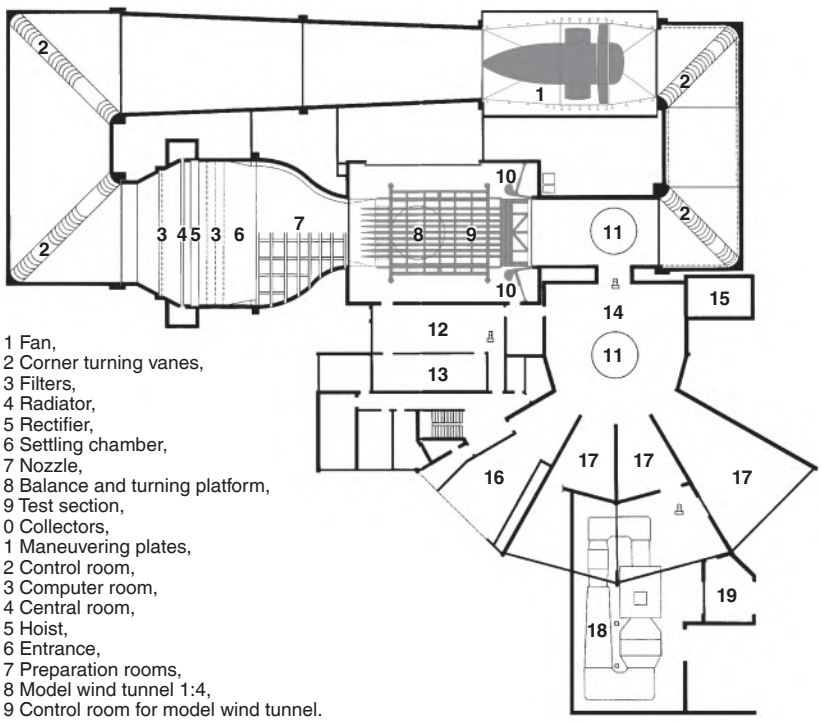
Model tests are primarily used in the early development phase for optimizing the basic aerodynamic shape. With the support of designers, plasticine models are used in a wind tunnel to optimize shapes or develop complete alternative shape variants and establish their aerodynamic potential.

Once there is a data set, new production methods (such as rapid prototyping) can be used to quickly produce models to any scale with accurate details. This allows for important investigations of the models in order to optimize details, even after the shaping phase.

Figure 18: Use of a smoke rake consisting of smoke tubes to make the airflow visible
1 Rake,
2 Smoke stream.

Acoustic wind tunnel
In an acoustic wind tunnel, extensive sound insulation measures mean that the sound pressure level is approximately 30 dB(A) lower than in a standard wind tunnel. This provides a sufficiently large signal-to-noise ratio of more than 10 dB(A) from the useful signal of the vehicle to allow identification and evaluation of wind noises generated by the air circulation and throughflow.

Climate-controlled wind tunnels
Climate-controlled wind tunnels are used for thermal analysis and protection of vehicles in defined temperature ranges at different load conditions.



Large-scale heat exchangers are used to set a temperature range, e.g. from –40 °C to +70 °C at a low control tolerance limit of approx. ± 1 K.

The vehicle is positioned on dynamometer rollers and driven at the required load condition or load cycle. Wind speed and roller speed must be exactly synchronized, even at low speeds. If necessary, uphill or downhill gradients can be simulated to introduce realistic road factors to the vehicle operating cycle.

There is also the option of regulating the air humidity or simulating solar radiation (using a bank of lamps).

The extensive aerodynamic challenges in vehicle design are not all covered by enhanced test-bench simulations as described above. In addition to experimental testing, manufacturers are therefore making increasing use of CFD models (Computational Fluid Dynamics). They allow preliminary decisions to be made to reduce the test workload.

Vehicle acoustics

Vehicle acoustics deals with all vibrational excitations and their transmission in the vehicle and in airborne noise. The primary sources here are the engine, excitation of the tires and chassis due to the texture and irregularities of the road, as well as excitation due to the airflow around the vehicle with increasing driving speed.

Table 1: Limits in dB(A) for noise emission from motor vehicles as per [1]

Vehicle category	since October of 1995 dB(A)
Passenger cars	
With spark-ignition or diesel engine	74
– with direct-injection diesel engine	75
Trucks and buses	
Permissible total weight below 2 t	76
– with direct-injection diesel engine	77
Buses	
Permissible total weight 2 t to 3.5 t	76
– with direct-injection diesel engine	77
Permissible total weight above 3.5 t:	
– engine power output up to 150 kW	78
– engine power output above 150 kW	80
Trucks	
Permissible total weight 2 t to 3.5 t	76
– with direct-injection diesel engine	77
Permissible total weight above 3.5 t (German Road Traffic Licensing Regulations: above 2.8 t):	
– engine power output up to 75 kW	77
– engine power output up to 150 kW	78
– engine power output above 150 kW	80
Off-road and four-wheel drive vehicles These vehicles are governed by higher additional limit values for engine brake and compressed-air noises.	

Legal requirements

Noise emission from vehicles and its testing

Test procedures used to monitor compliance with legal requirements are concerned exclusively with exterior-noise levels. The EC Directive 70/157/EEC enacted in 1970, together with its last revision 2007/34/EC [1], defines measurement procedures for noise emissions from stationary and moving vehicles, as well as limit values for noise emissions from moving vehicles (Table 1) for various vehicle categories. On account of the inadequate effectiveness of these statutory provisions in real traffic, the measurement method has been revised with the aim of better reproducing urban traffic in the test procedure.

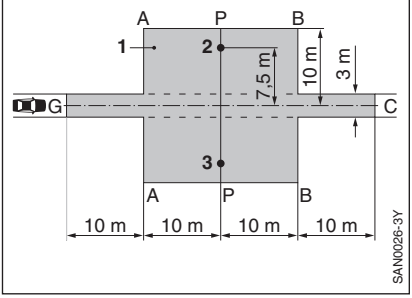
The new EU noise legislation – Regulation 540/2014/EC [2] – has been in force since April 2014 and its application has been mandatory for new homologations of vehicles since July 2016. The UN Regulation UN R51.03 [3] applied in parallel in the EU has been in force since January 2016 and follows the same timeline as the EU Regulation. For the old legislation there are transitional provisions until July 2022 (until July 2023 for N2 category vehicles).

In addition, tread noise requirements were defined in the regulation 661/2009/EC [4]. Depending on the tires, the test area is 70 or 80 km/h.

Measuring noise emissions from moving passenger cars and trucks up to a permissible total weight of 3.5 t

The vehicle approaches line AA, which is located up to 10 m from the microphone plane, at a constant velocity of 50 km/h (Figure 1). After the vehicle reaches line AA, it continues under full acceleration as far as line BB (placed 10 m behind the microphone plane), which serves as the end of the test section. Passenger cars with manual transmissions and a maximum of four forward gears are tested in second gear. Consecutive readings in second and third gear are employed for

vehicles with more than four forward gears, while sports cars are tested in third gear in accordance with the definition in the Directive. Vehicles with automatic transmissions are tested in the D position.



The noise-emissions level is defined as the maximum occurring sound level which is measured on the left and right sides of the vehicle at a distance of 7.5 m from the center of the lane. In a test in two gears, the noise-emissions level is the arithmetic mean from the measurement of both gears.

Measuring noise emissions from moving trucks starting from a permissible total weight of 3.5 t

The vehicle approaches line AA, which is located up to 10 m from the microphone plane, at a constant velocity (Figure 1). After the truck reaches line AA, it continues at full acceleration as far as line BB (also placed 10 m from the microphone plane), which serves as the end of the test section. The driving speed adopted is dependent on the gear tested and the rated engine speed. The choice of gears selected is based on the fact that at least the rated speed must be reached within the test section, however, the vehicle must pass through the test section without reaching the engine-speed limitation. The noise-emissions level is defined as the maximum occurring sound level from all the measurements.

Figure 1: Test layout for driving-noise measurement

1 Road surface as specified by ISO 10844 [5],
2 Left microphone,
3 Right microphone.

Measuring noise emissions from stationary vehicles

Following noise approval of a vehicle, measurement of noise emissions from stationary vehicles makes it possible to determine a reference noise value for the noise emissions of the vehicle in traffic when in “proper” condition. This makes it easier for the vehicle’s noise emissions to be checked, for example, by the police or regulatory official. Noise emission from stationary vehicles is measured at a distance of 50 cm from the exhaust outlet at a horizontal angle of 45° ± 10° relative to the direction of exhaust flow. During the measurement, the engine has to be brought up to a speed dependent on its nominal speed. Upon reaching this test speed, it is to be maintained for 3 sec. and then the throttle response switch is to be quickly moved to the idle position. The maximum A-weighted sound pressure level determined during this measurement is entered in the vehicle documentation with the suffix P´ (to distinguish it from data of earlier test procedures).

A maximum deviation of 5 dB from the entered reference value is permitted for tests in traffic.

Minimum noise from vehicles

When quiet electric motors began being widely used as a drive source for vehicles, it became a problem for pedestrians: They have great difficulty recognizing these vehicles in traffic in a timely manner. Investigations have shown that this is particularly the case in the low-speed range up to about 20 to 30 km/h. To reduce the danger of collisions between vehicles and pedestrians, work is currently being done to specify an international standard for minimum noise emissions. These provisions are mandatory from July 2019 for the new homologation of vehicles and mandatory from July 2021 for all newly approved vehicles.

Development work on vehicle acoustics

Measuring equipment for acoustics
The measuring techniques listed in the following are used to measure and evaluate not only the exterior noise level, but also the interior noise level and in particular the various vehicle vibrations [6]:
– Sound-pressure recording is performed with capacitor microphones, e.g. using sound-level meters, in dB(A).
– The dummy-head measurement technique enables noise to be recorded by microphones built into the ears of an artificial head. Artificial- or dummy-head technology provides the opportunity of making realistic recordings, so that they can be compared with other similar recordings at a different place and time.
– Measuring rooms for standard sound measurements are generally equipped with highly sound-absorbent walls. Depending on the objective, these rooms can be equipped with chassis dynamometers, so that a vehicle can be evaluated even while in driving mode.
– For vibrations and structure-borne noise acceleration, sensors (mass partly under 1 g) are used which operate, for example, according to the piezoelectric principle. Laser vibrometers are used for rapid, non-contact measurements based on the Doppler principle.
– Position measuring devices are used, for example, to record movement of the shock absorbers and chassis relative to the body.
– Vibration test benches provide the option of measuring the various cases of vibrational excitation in the overall vehicle, the body, or individual components. Hydropulsers permit excitation of low frequencies smaller than 150 Hz with large vibration paths for simulating road excitation. Shakers, on the other hand, permit high frequencies up to 2 kHz for simulating engine excitation.
– Ride comfort segments simulate various kinds of road excitation, ranging from different kinds of asphalt to manhole covers or concrete transverse joints.
– Reverberation rooms enable the sound insulation of individual materials or components to be determined, for example, for doors or whole bulkheads in the engine compartment.

Calculating methods in acoustics
Vibrations and oscillations
Natural-vibration calculations are performed using the finite-element method (FEM). Model adjustment with experimental modal analysis or modeling of forces acting during operation enables the calculation of real operational vibration shapes. In this way, structures can be optimized in early design phases with regard to their vibration response and sound radiation.

Airborne noise and fluid-borne noise
Sound-field calculations, for example of cabinet radiation or in cavities, are carried out using the finite-element method (FEM) or boundary-element method (BEM) ([7]).

Ride comfort simulation
Effects of vibration from the road on the chassis and body can be simulated by using rigid body models in combination with the road excitation. What is interesting here is that it is also possible to connect the drive unit via the engine mount and transmission mount. Such models enable variable coordination of the chassis mount and power train mount, typically in the frequency range up to 50 Hz.

Sources of noise

Engine and transmission acoustics
Engine noises are caused primarily by the mechanical movement of components. Even the combustion process in the cylinders causes excitations of the engine structure. In all cases, the vibrations are, on the one hand, directed through the structure and, on the other hand, radiated as airborne noise. In the process, noises can also occur dominantly at a clear distance from the excitation location. This is determined by the sensitivity of the membrane surfaces and the natural-vibration response of the local structure.

Important sources of noise on the engine are the crankshaft drive, the camshaft drive, the crankcase, the oil pan, the cylinder-head cover, the auxiliary power take-offs (e.g. alternator and water pump), and the belt drives. All of these elements together shape the basic acoustic character of the unit (engine/transmission combination).

The objective of the acoustician is to achieve harmonization of the vibration and noise behavior in the power train by means of suitable technical modifications. Some of the important influencing factors to take into account include the following:
– Tolerances, clearances and structures,
– Thermal expansion in clearances,
– Avoiding resonances,
– Choice of materials,
– Vibration shapes of the engine/transmission unit,
– Muffler design.

Here, most of these are in a conflict of interests with other development disciplines, particularly space design (package), energy management and driving dynamics. Thus, in a four-cylinder engine, the often dominant second engine order, which is frequently perceived as humming, can be significantly reduced with balancer shafts and very rigid units. But this comes at the expense of additional weight, more complicated structures and a considerable dip in performance.

Engine and transmission acoustics also has the task of largely reducing the transmission of rigid-body sound vibrations to the body and the airborne noise. Starting points for this are the design of the power train mount with respect to insulation, low-vibration designs, short, compact connections of auxiliary units, and prevention of large, smooth vibration surfaces by means of ribbing or additional damping materials.

The engine mount deserves special attention. Stiff assembly bearings improve driving dynamics, but convey to the driver a very raw engine noise and increase the vibration input into the body. If the bearings are too soft, it means the engine can move large distances, which can lead to unpleasant bucking motion of the whole vehicle. Highly insulating, hydraulically damped elements can be used to bring about a certain softness with good vibration comfort for the whole vehicle.

Gas exchange noise
(exhaust and intake system)
The energy transmitted by the combustion processes to the inducted air is output in time with the ignition processes and the valve movements via the exhaust-gas system to the surroundings again. The design of the exhaust manifolds, the exhaust pipes and the mufflers decisively affects which frequency components are radiated with which levels. Here, the sound output, not only at the orifice but also at the surface of all the components, is important. The noise dynamics of this acoustic source are enormous, easily reaching 15 dB and higher when the level difference is considered between idle and full load. On the basis of these dynamics, this source is ideally suitable for sound designs.

Chassis acoustics
Excitation from the road introduces vibrations into the chassis. These are strongly attenuated at first by the damping of the tires, but vibrations can still be transmitted in the chassis and into the body. Moreover, the road can incite natural resonance in the chassis, which can reach the passenger compartment in the form of unpleasant droning if the body has a certain sensitivity. Chassis acoustics has the task of finding an optimum acoustical configuration of the chassis without impairing the dynamic handling characteristics of the vehicle.

Body acoustics
The body is the interface between the chassis, power train and mounts of many auxiliary drives. These include, for example, fans, servomotors and even loudspeakers. The body, however, is also a point of attack for airflow forces. It surrounds the driver and passengers and protects them from external influences. But it also transmits vibrations and introduces them to the passenger compartment, where the occupants can both feel and hear them.

Body acoustics deals specifically with minimizing the transmission of sound and preventing airborne noise excitations, which, along with resonance in the passenger compartment, can lead to unpleasant droning noise. It also deals with optimizing the natural-oscillation characteristics of the body, because the body's eigenmodes – such as the torsion of the basic body or the first bending mode of the front end – can lead to shaking of the vehicle, which feels like when the vehicle is very fluttery on the road.

High rigidity of the attachment points for the chassis and engine provide for low excitation, sealing the byways reduces the conduction of sound within the body, and damping materials provide for sufficient insulation.

Body acoustics also includes aeroacoustics, in which optimized transitions at vehicle edges and flows around components should prevent turbulent flows from developing. These can make themselves apparent as unpleasant interior and exterior noise at high speeds.

Ride comfort
Ride comfort concerns all of the ride-related components that the driver and passengers touch. In particular these include the steering wheel, shift lever, pedals, and of course the seat. Excitations can come from the road, body, or engine and are in the frequency range under 50 Hz. The objective is to minimize all vibrations.

Dynamic strength
All vehicle components are subject to vibrational excitation, and therefore to dynamic loads. To ensure that all components have a sufficient dynamic load capacity over a long time period, they have to be investigated with respect to their dynamic strength. To do so, individual components as well as entire assemblies are subjected to continuous loading on test benches by electrodynamic shakers or hydraulic punches. The excitation profiles are gained from load measurements from real driving profiles. If necessary, the components can also be tested with climatic adaptations, such as low or extremely high temperatures. Exhaust systems can, for example, have hot gases pumped through them to simulate the engine exhaust gases. These tests provide valuable indications for optimizing details, as a result of which materials, flanges or ribs are often optimized again.

Sound design

Definition of sound design
Sound design is the active and specific matching of a product to a desired noise behavior. The aim is to lend the product a typical "sound" expected by the customer and corresponding to the brand identity and to arouse quite specific emotional associations with the product.

The most well-known field is the automobile sector, where both customers and the press show great interest in the result of the sound development of products. However, intensive work is also being carried out on the sound of products in many other fields, such as, for example, household appliances (vacuum cleaners and washing machines) and even foods (the "crunch" of potato chips).

Terms other than sound design are also commonly encountered. Sound engineering is, as a rule, the concrete technical realization on the product, i.e. the specific technical implementation of a target sound elaborated in sound design.Sound cleaning is the suppression of unwanted noise to achieve an optimally neutral noise behavior. This is often carried out for luxury vehicles as a starting point for developing a discreet sound.

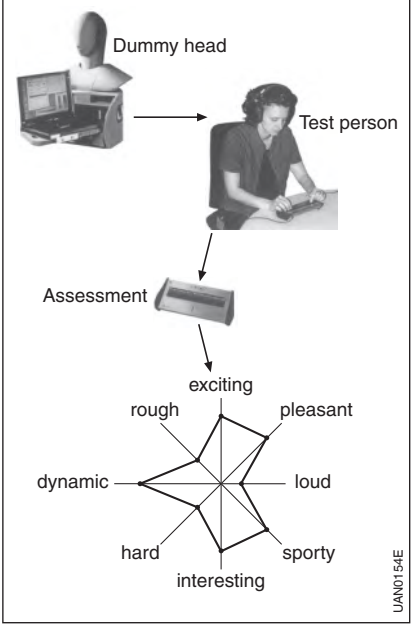
Sound at the vehicle
The steps for implementing sound at a product, are generally speaking, always the same. For clarification purposes, this is explained by reference to the automobile sector.

Sound is the audible feedback of the vehicle at a specific operating state arrived at by the driver using the accelerator pedal and choosing a gear. Sound is accordingly described by the engine's operating point with regard to engine revs and load, as well as their time variance – i.e. acceleration, steady-state driving or deceleration. Starting and idle noises are added.

Depending on the design, the subjective perception of the throttle response is "spontaneous" or "sluggish", regardless of the real physically measurable acceleration.

A distinction is made between a vehicle's interior and exterior noises. Exterior noise is shaped by the airborne noise radiation of all the components, primarily by the engine and the exhaust-gas and air-intake systems and their orifices. In addition to these, there is disruptive noise from rolling and the wind. The acoustic conditions in the passenger compartment are additionally influenced by the structure-borne noise and the acoustic transfer paths through the body.

Sound quality
Sound quality refers to discrete components that can be actively moved or changed, such as switches, levers, servomotors, or flaps. Here, the actuating noise is intended to underline the quality and the soundness of the product. Opening and closing doors and hoods also has to sound good and must not be jarring. Moreover, sound quality also includes prevention of rattling, grinding and squeaking noises produced by components touching and rubbing against each other.



Assessment methods
Psychoacoustics
Sound cannot be assessed with the standard assessment method based on loudness, roughness or tonality. When the sound of a vehicle is mentioned, for the most part terms such as "sporty", "sonorous", "aggressive" or "inspiring" are used. These must be translated into a technical language so that the development engineers know at a later stage what spectral content, what dynamics and what time variances are responsible for them. For this reason, these subjective factors are being increasingly brought into play and

structured in order to establish assessment criteria from them. In the practical course of a psychoacoustic assessment (Figure 2), sound samples are assessed according to antagonistic value pairs (such as good – bad, loud – quiet, weak – strong) so as to arrive at a characterization of the sound.

Virtual prototyping
Analyses and measurements conducted on components can be used to make predictions about sound behavior and the leeway for making modifications. Vehicle measurements are also made using artificial-head technology. Variations can then be simulated in a narrow range with modern computer technology, always with a view toward whether a "virtually created sound" can also be technically realized.

Now the virtual sounds processed using computer technology can be evaluated by test subjects with respect to previously developed evaluation criteria. From this, it is possible to derive assessor preferences, which are now, however, technically stored and provide indications as to which frequency elements are necessary or offending and which components come into consideration.

Figure 2: Psychoacoustic assessment

Active sound
Of course, missing sound elements can also be provided with active speaker systems inside and outside the vehicle. This technology is currently gaining ever more importance, because electric vehicles and hybrid vehicles in electric driving mode are frequently evaluated as being too quiet. Significant improvements can be achieved here by adding electronic sound.These provisions are mandatory from July 2019 for the new homologation of vehicles and mandatory from July 2021 for all newly approved vehicles (see Minimum noise from vehicles).

Lubricants

Terms and definitions

Lubricants
Lubricants provide mutual insulation for components in a state of relative motion. The lubricant's function is to prevent direct contact between these components, thereby reducing wear and minimizing friction. Lubricants serve as coolants, friction-surface sealants, and corrosion inhibitors, and can also reduce running noise. Lubricants may be solid, consistent, liquid, or gaseous in form. Specific lubricants are selected with reference to design characteristics, materials combinations, the ambient conditions, and the stress factors encountered at the friction surface ([1], [2], [3]).

Additives
Additives are substances mixed into the lubricant in order to improve specific properties. These substances modify either the lubricant's physical characteristics (e.g. viscosity-index improvers, pour-point depressors) or its chemical properties (e.g. oxidation inhibitors, corrosion inhibitors). In addition, the properties of the friction surfaces themselves can be modified by additives which change the friction characteristics (friction modifiers), protect against wear (anti-wear agents), or provide protection against scoring and seizure (extreme-pressure additives). Great care must be exercised in order to ensure that the additives are correctly matched with each other and with the base lubricant.

ATF
ATF (automatic transmission fluids) are special-purpose lubricants specifically formulated to meet stringent requirements for operation in automatic transmissions.

Ash
Ash is the mineral residue which remains after oxide and sulfate incineration (DIN 51575, [4]).

Bleeding
Bleeding is the separation of base oil (lube oil) and the thickener in a lubricating grease (oil separation, DIN 51817 [5]). During this process the lube oil is released to the lubricating surroundings.

Bingham bodies
Bingham bodies are materials whose flow characteristics differ from those of Newtonian fluids (see Rheology, Newtonian fluids).

Fire point and flash point
The lowest temperature (referred to 1,013 hPa) at which a gaseous mineral product initially flashes is known as the flash point. The fire point is the temperature at which it continues to burn for at least 5 s (DIN EN ISO 2592 [6]).

Cloud point
The cloud point is the temperature at which mineral oil becomes opaque due to the formation of paraffin crystals or precipitation of other solids (DIN ISO 23015 [7]).

Detergents
These additives prevent paint- and carbon-like deposits on hot components (e.g. pistons). They serve as cleaning agents which like a tenside contain both hydrophilic and hydrophobic areas.

Dispersants
Dispersants prevent (disperse) sludging and sedimentation, particularly at low temperatures (solid substances are held finely distributed in suspension).

EP lubricants
See High-pressure lubricants (EP, Extreme Pressure).

Flow pressure
The flow pressure is the pressure required to press a consistent lubricant through a standardized test nozzle (Kesternich method, DIN 51805 [8]). The flow pressure is an index of a lubricant's starting flow characteristics, particularly at low temperatures.

Yield point
The yield point is the shear stress at which a substance begins to flow. Above the yield point, the rheological characteristics of plastic substances are the same as those of liquids (DIN 1342-3 [9]).

Friction modifiers
Friction modifiers are polar lubricant additives which reduce friction in the mixed-friction range (see Mixed friction) and increase bearing capacity after adsorption on the surface of the metal. They also inhibit stick-slip behavior.

Gel-type greases
Gel-type greases are lubricants with inorganic gelling agents (e.g. Bentonites, silica gels).

Anti-friction coatings
Anti-friction coatings are solid lubricant combinations which a binding agent holds in place on the friction surfaces (AFC, anti-friction coating).

Graphite
Graphite is a solid lubricant with layer-lattice structure. Graphite provides excellent lubrication when combined with water (e.g. high atmospheric humidity) and in carbon-dioxide atmospheres or when combined with oils. It does not inhibit friction in a vacuum.

Borderline pumping temperature
The borderline pumping temperature is the application limit for oil throughput through engines after cold starting. Below the borderline pumping temperature oil can no longer flow of its own accord to the oil pump, and thus a sufficient supply of oil can no longer be guaranteed.

High-pressure lubricants
High-pressure lubricants (EP, Extreme Pressure) contain additives to enhance load-bearing capacity, to reduce wear, and to reduce scoring (generally provide good performance in steel-to-steel and steel-to-ceramic applications).

Hydro-crack oils
Hydro-crack oils are refined mineral oils with increased viscosity index (VI 130 to 140). They are produced by hydrogenating mineral oils and are thus more thermally stable and have improved viscosity-temperature characteristics.

Induction period
The induction period is the time which elapses before substantial changes occur in a lubricant (e.g. aging of an oil containing an oxidation inhibitor).

Inhibitors
Inhibitors are active system-protecting ingredients which slow down the chemical decomposition of lubricants (e.g. due to oxidation) or protect against corrosion (corrosion inhibitors).

Low-temperature sludge
Low-temperature sludges are the products of oil degradation which form in the engine crankcase due to incomplete combustion and condensate at low engine load. Low-temperature sludge increases wear and can cause engine damage. Modern high-quality engine oils inhibit its formation.

Cold-starting reliability
Cold-starting reliability is a temperature value and based on experience is approx. 5 °C above the borderline pumping temperature.

Consistency
Consistency is a measure of the ease with which lubricating greases and pastes can be deformed (DIN ISO 2137 [10]). A standardized cone is dropped into a flattened grease sample and then the penetration depth is measured in 1/10 mm (Figure 2, see also Penetration and Table 5).

Doped lubricants
Doped lubricants contain additives for improving specific properties (e.g. aging stability, wear protection, corrosion protection, viscosity-temperature characteristics).

High-lubricity oils
High-lubricity oils are lubricating oils with multigrade properties, low cold viscosity, and special anti-friction additives. Extremely low engine friction under all operating conditions reduces fuel consumption.

Longlife engine oils
Longlife engine oils are oils for significantly extended oil-change intervals.

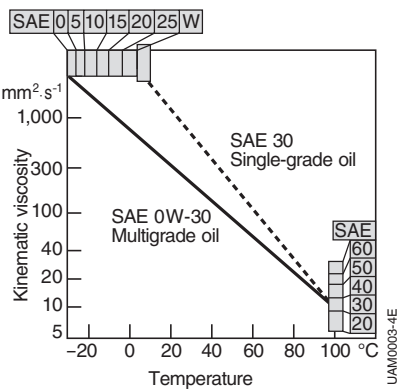
Multigrade oils
Multigrade oils are engine and transmission oils with good resistance to viscosity-temperature change (high viscosity index VI, Figure 1, see Viscosity). They often contain polymers which change their solid structure as a function of temperature. When the oil is cold, the molecules in the oil are "bunched together". As the temperature increases, the molecules stretch and thereby increase the friction between the particles. The viscosity of the oil increases, thereby guaranteeing a stable lubricating film even at high temperatures. Multigrade oils reduce friction and wear, and during cold starting ensure that all the engine components are quickly lubricated. These oils are formulated for year-round use in motor vehicles; their viscosity ratings extend through several SAE grades.

Metal soaps
Metal soaps are reaction products from metals or from their compounds with fatty acids. They are used as thickeners for grease and as friction modifiers.

Mineral oils
Mineral oils are distillates or raffinates produced from petroleum or coal. They consist of numerous hydrocarbons in various chemical compositions. Classification is according to the predominant component: paraffin-based oils (chain-shaped saturated hydrocarbons), naphthene-based oils (closed-chain saturated hydrocarbons, generally with five or six carbon atoms per ring) or aromatic oils (e.g. alkylbenzene). These substances are distinguished by major variations in their respective chemical and physical properties.

Molybdenum disulfide
Molybdenum disulfide (MoS_2) is a solid lubricant with layer-lattice structure. Only low cohesive forces are present between the individual layers, so their mutual displacement is characterized by relatively low shear forces. A reduction in friction is only obtained when MoS_2 is applied in suitable form to the surface of the metal (e.g. in combination with a binder such as MoS_2 anti-friction coating).

Figure 1: Viscosity/temperature curves for single- and multigrade engine oils



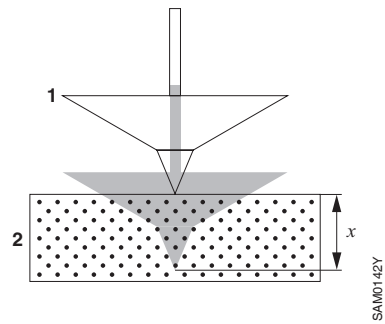


Figure 2: Determining cone penetration
1 Standardized cone,
2 Consistent lubricant at defined temperature.
x Penetration depth.

Penetration
Penetration denotes the depth (in 10^{-1} mm) to which a standardized cone penetrates into a consistent lubricant within a defined period and at a specified temperature (Figure 2). The larger the number, the softer the lubricant (DIN ISO 2137 [10]).

Polar substances
Dipolar molecules are easily adsorbed onto metal surfaces. They enhance adhesion and bearing capacity, thus reducing friction and wear. This category includes, for example, diester oils, ethers, polyglycols, and fatty acids.

Pour point
Pour point is the lowest temperature at which an oil continues to flow when cooled under defined conditions (DIN ISO 3016 [11]).

PTFE
PTFE (polytetrafluoroethylene, Teflon) is a thermoplastic with outstanding properties as a solid lubricant, particularly at very low sliding velocities (< 0.1 m/s). PTFE only becomes brittle below approx. -270 °C. The upper service temperature for use is approx. 260 °C. Above this level, it decomposes with toxic cleavage products.

Rheology
Rheology is the science dealing with the flow characteristics of materials. These are generally represented in the shape of flow curves (Figure 3). In the diagram shear stress τ is plotted against shear rate $\dot{\gamma}$.

Shear stress and shear rate
Shear stress is defined as the shear force per shear area, shear rate as the quotient of velocity v and gap height h (Figure 4).

Shear stress $\tau = F/A$ (in N/m^2 = Pa),
F shear force, A area vs. shear rate.

Shear rate $\dot{\gamma} = v/y$ (in s^{-1}),
v velocity, y thickness of lubricating film.

The flow curves are usually measured in a plate-cone measuring system. The sample to be measured is located between the plate and the cone; the torque is proportional to the shear stress and the rotational speed proportional to the shear rate.

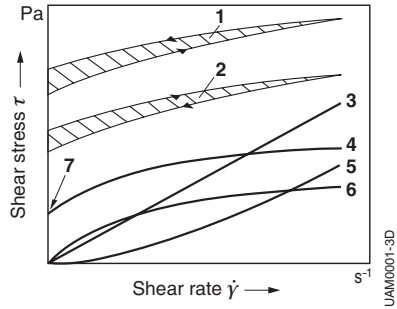
Shear stress τ can be illustrated using the two-plate model (Figure 4). The fluid is located between the two plates. The bottom plate is fixed, the top plate moves with shear area A by means of shear force F.

Shear viscosity
Shear viscosity η is in liquids of ideal viscosity and constant temperature the ratio of shear stress τ to shear rate $\dot{\gamma}$:

$$\eta = \frac{\tau}{\dot{\gamma}}.$$

The term “dynamic viscosity” is also used for η. The former unit centiPoise (cP) is equal to the unit mPa · s.

Figure 3: Flow curves
1 Rheopexic, 2 Thixotropic, 3 Newtonian, 4 Plastic, 5 Dilatant, 6 Intrinsically viscous, 7 Yield point.



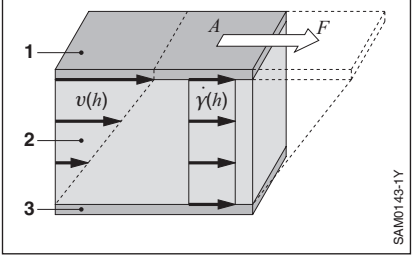


Figure 4: Velocity distribution and shear rate in the lubricating gap
1 Moving plate, 2 Fluid, 3 Fixed plate.
A Shear surface, F Shear force, h Height, v Velocity, $\dot{\gamma}$ Shear rate.

Midpoint viscosity
Each viscosity grade in accordance with DIN ISO 3448 [12] is defined by a viscosity range at a temperature of 40 °C (see Table 1). The permissible limit is ±10 %. Thus, for example, viscosity grade ISO VG 10 has the limits 9 and 11 mm^2/s at a midpoint viscosity of 10 mm^2/s.

HTHS viscosity
The HTHS viscosity (High Temperature High Shear) specifies the shear viscosity at a temperature of 150 °C and a shear rate of $10^6\ s^{-1}$.

Kinematic viscosity
The kinematic viscosity ν is usually determined in vertical, narrow glass tubes. The time the fluid needs at a defined temperature to flow through a specific section of the tube is measured. If density ρ is known, it is also possible to calculate the shear viscosity η from it.

$\nu = \frac{\eta}{\rho}$, (ν in mm^2/s; ρ in kg/m^3).

The former unit "centiStokes" (cSt) is equal to the unit mm^2/s.

Newtonian fluids
Newtonian fluids display a linear relationship between shear stress τ and shear rate $\dot{\gamma}$ in the shape of a straight line through zero, with the slope increasing as a function of viscosity (Figure 3).

All materials not characterized by this kind of flow behavior are classified as non-Newtonian fluids.

Intrinsically viscous flow behavior
Intrinsically viscous flow behavior is the capacity of a fluid to show decreasing viscosities with increasing shear rate (Figure 3, e.g. liquid greases, multigrade oils with viscosity-index improvers).

Dilatant flow behavior
Dilatant flow behavior is the increase in viscosity with increasing shear rate (Figure 3).

Plastic flow behavior
A plastic substance is a substance whose rheological behavior is characterized by a yield point (according to DIN 1342-1 [13]). Plastic flow behavior is the formability of an intrinsically viscous fluid supplemented by yield point (Figure 3, e.g. lubricating greases).

Thixotropy
Thixotropy is a characteristic of those non-Newtonian fluids that display an decrease in viscosity proportional to shear time, and only gradually recover their original viscosity once shearing ceases (Figure 3).

Rheopexy
Rheopexy is a characteristic of those non-Newtonian fluids that display an increase in viscosity proportional to shear time, and only gradually recover their original viscosity once shearing ceases (Figure 3).

Table 1: Viscosity grades for industrial lubricating oils acc. to ISO 3448 [12]

ISO viscosity grade	Medium viscosity at 40 °C in mm^2/s	Limits of kinematic viscosity at 40 °C in mm^2/s	
		min.	max.
ISO VG 2	2.2	1.98	2.42
ISO VG 3	3.2	2.88	3.52
ISO VG 5	4.6	4.14	5.06
ISO VG 7	6.8	6.12	7.48
ISO VG 10	10	9.00	11.0
ISO VG 15	15	13.5	16.5
ISO VG 22	22	19.8	24.2
ISO VG 32	32	28.8	35.2
ISO VG 46	46	41.4	50.6
ISO VG 68	68	61.2	74.8
ISO VG 100	100	90.0	110
ISO VG 150	150	135	165
ISO VG 220	220	198	242
ISO VG 320	320	288	352
ISO VG 460	460	414	506
ISO VG 680	680	612	748
ISO VG 1000	1,000	900	1,100
ISO VG 1500	1,500	1,350	1,650
ISO VG 2200	2,200	1,980	2,420
ISO VG 3200	3,200	2,880	3,520

Dropping point
The dropping point is the temperature at which a lubricating grease attains a specified viscosity under specified test conditions (DIN ISO 2176 [14]).

Stribeck curve
The Stribeck curve portrays friction levels between two liquid- or grease-lubricated tribological systems separated by a narrowing gap (e.g. lubricated plain or ball bearings) as a function of sliding velocity (Figure 5). As the relative speed increases, so too does the hydrodynamic pressure in friction contact.

Solid-body friction
In the case of solid-body friction, the height of the lubricating film is lower than that of the roughness protrusions in the material's surface. This causes wear.

Mixed friction
In the case of mixed friction, the height of the lubricating film is approximately equal to that of the roughness protrusions. This still means increased wear because the roughness protrusions are in contact with each other.

Hydrodynamics
In the case of hydrodynamics, there is complete separation between the primary body and the opposed body, e.g. when aquaplaning (virtually wear-free condition).

Synthetic oil
Synthetic oil is manufactured in a process of chemical synthesis from smaller molecules. For example, synthetic hydrocarbons in the form of poly-α-olefins, which are manufactured by the polymerization and subsequent hydrogenation of ethylene. Further synthetic oils are polyglycols, diester oils, silicone oils, and perfluoropolyether oils.

Viscosity
Viscosity is a measure of the internal friction of substances (DIN 1342 [13], DIN EN ISO 3104 [15]). It is caused by the resistance (internal friction) with which the substance's molecules oppose displacement forces (see Rheology). As the temperature decreases, the viscosity increases and the oil becomes more viscous. At low temperatures the viscosity must not be too high so that the oil in the bearings does not exert too excessive a resistance on the rotational motion of the engine or transmission. At high temperatures the oil must still be sufficiently viscous to maintain the lubricating film.

Viscosity index
The viscosity index (VI) is a mathematically derived number expressing the change in a mineral-oil product's viscosity relative to its temperature. The greater the viscosity index, the lower the effect of temperature on the viscosity (DIN ISO 2909 [16]).

Viscosity grades
Oils are classified within specific viscosity ranges in viscosity grades:
– ISO viscosity grades (DIN ISO 3448 [12]): see Table 1.
– SAE viscosity grades (SAE J300 [17], SAE J306 [18]): see Table 2 and Table 3.

Worked penetration
Worked penetration is the penetration of a grease sample after it has been processed in a grease kneader (DIN ISO 2137 [19]).

Figure 5: Stribeck curve
R Surface roughness, F_N Normal force,
d Distance between primary and opposed body.
Range a: Solid-body friction, high wear.
Range b: Mixed friction, moderate wear.
Range c: Hydrodynamics, no abrasive wear.

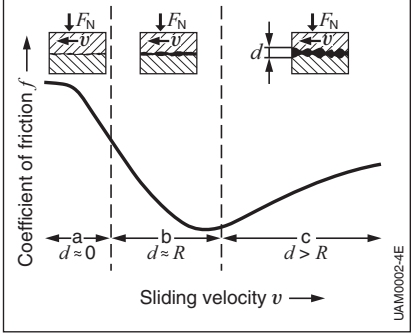

Table 2: Extract from SAE viscosity grades for transmission oils (SAE-J306 revision June 2005)

SAE viscosity grade	Maximum temperature [°C] for dynamic viscosity at 150,000 mPa·s (ASTM D 2983) [20])	Kinematic viscosity [mm²/s] at 100 °C (ASTM D 445 [21])	
		min.	max.
70 W	–55	4.1	–
75 W	–40	4.1	–
80 W	–26	7.0	–
85 W	–12	11.0	–
80	–	7.0	<11.0
85	–	11.0	<13.5
90	–	13.5	<18.5
110	–	18.5	<24.0
140	–	24.0	<32.5
190	–	32.5	<41.0
250	–	41.0	–

Engine oils

Engine oils are employed primarily to lubricate contiguous components in relative motion within the internal-combustion engine. The oil also removes heat generated by friction, carries abraded particles away from the friction surface, washes out contaminants, holds them in suspension, and protects metals against corrosion. The most common engine oils are mineral oils treated with additives (HD oils: Heavy Duty for high load, extreme operating conditions). Higher stress-resistance requirements combined with extended oil-change intervals have led to widespread application of fully and semi-synthetic oils (mixture of synthetic oil and mineral oil), e.g. hydro-crack oils. The quality of an engine oil is determined by its origin, the refining processes used on the mineral oil (except in the case of synthetic oils) and the additive composition.

Table 3: SAE viscosity grades for engine and transmission oils (SAE J300, January 2015)

SAE viscosity grade	Viscosity (ASTM D 5293 [22]) mPa·s max.	Limit pumping viscosity (ASTM D 4684 [23]) with no yield point mPa·s max.	Kinematic viscosity (ASTM D 445 [21]) mm²/s at 100 °C min.	max.	Viscosity under high shear[1] (ASTM D 4683 [24], CEC L-36-A-90 [25], ASTM D 4741 [26] or ASTM D 5481 [27]) mPa·s at 150 °C and $\dot{\gamma} = 10^6\ s^{-1}$ min.
0 W	6,200 at –35 °C	60,000 at –40 °C	3.8	–	–
5 W	6,600 at –30 °C	60,000 at –35 °C	3.8	–	–
10 W	7,000 at –25 °C	60,000 at –30 °C	4.1	–	–
15 W	7,000 at –20 °C	60,000 at –25 °C	5.6	–	–
20 W	9,500 at –15 °C	60,000 at –20 °C	5.6	–	–
25 W	13,000 at –10 °C	60,000 at –15 °C	9.3	–	–
8	–	–	4	<6.1	1.7
12	–	–	5	<7.1	2.0
16	–	–	6.1	<8.2	2.3
20	–	–	6.9	<9.3	2.6
30	–	–	9.3	<12.5	2.9
40	–	–	12.5	<16.3	3.5 (0W–40, 5W–40, 10W–40)
40	–	–	12.5	<16.3	3.7 (15W–40, 20W–40, 25W–40, 40 monogrado)
50	–	–	16.3	<21.9	3.7
60	–	–	21.9	<26.1	3.7

[1] Also called HTHS (High Temperature High Shear) viscosity.

Additives are classified according to their respective functions:
– Viscosity-index improvers
– Pour-point improvers
– Oxidation and corrosion inhibitors
– Detergent and dispersant additives
– Extreme-pressure (EP) additives
– Friction modifiers
– Anti-foaming agents

Oil is subjected to considerable thermal and mechanical stresses in the IC engine. The data on the physical properties of engine oils provide information on their application limits (SAE viscosity grades), but are not indicative of their other performance characteristics. Therefore, there are several different test procedures for evaluating engine oils:
– ACEA (Association des Constructeurs Européens de l'Automobile) standards, replaced the CCMC standards (Comité des Constructeurs d'Automobiles du Marché Commun) at the beginning of 1996
– API classification (American Petroleum Institute)
– MIL specifications (Military)
– Company specifications (e.g. ILSAC, International Lubricants Standardization and Approval Committee).

The approval criteria include the following:
– Sulfate-ash content
– Zinc content
– Engine type (diesel or spark-ignition engines, naturally aspirated or forced-induction engines)
– Load on power-transmission components and bearings
– Wear-protection properties
– Oil operating temperature (in oil pan)
– Combustion residue and chemical stress exerted on the oil by acidic combustion products
– The oil's detergent and residue-scavenging properties
– Its suitability for use with gasket and sealing materials.

ACEA (CCMC) Specifications

Engine oils for gasoline engines
– A1: Special high-lubricity oils with reduced viscosity at high temperatures and high shear for reducing viscous friction.
– A2: Conventional and high-lubricity engine oils without any restriction on viscosity grades. Higher requirements than CCMC G4 and API SH, withdrawn.
– A3: Oils of this category meet higher requirements than A2 and CCMC G4 and G5.
– A5: Improved "fuel economy" properties compared with A3 occasioned by lower viscosity including improved additive composition. Only for use in engines which have been specifically designed for this purpose.

Engine oils for passenger-car diesel engines
– B1: Corresponding to A1 for low friction losses and, consequently, reduced fuel consumption.
– B2: Conventional and high-lubricity engine oils compliant with the current minimum requirements (higher than those of CCMC PD2), withdrawn.
– B3: Exceeds B2.
– B4: Corresponds to B2, particularly suitable for VW TDI engines.
– B5: Oils surpass B3 and B4, improved "fuel economy" properties, also satisfies VW 50600 and 50601. Only for use in engines which have been specifically designed for this purpose.

Engine oils for passenger-car diesel engines with particulate filters
– C1: Since 2004, sulfate-ash content max. 0.5 %. Lowered HTHS (Ford).
– C2: Since 2004, sulfate-ash content max. 0.8 %. With HTHS ≥ 2.9 mPa · s (Peugeot).
– C3: Since 2004, sulfate-ash content max. 0.8 %. With HTHS ≥ 3.5 mPa · s (MB and BMW).
– C4: Since 2007, sulfate-ash content max. 0.5 %. With HTMS ≥ 3.5 mPa · s.

Engine oils for commercial-vehicle diesel engines
– E1: Oils for naturally aspirated and turbocharged engines with normal intervals between oil changes; withdrawn.
– E2: Derived from MB Specification Sheet 228.1. Primarily for engine designs predating the Euro II standard.
– E3: For Euro II engines, derived from MB Specification Sheet 228.3. In com-

parison with the predecessor category CCMC D5, these oils evince a significant improvement in soot dispersion capability and a much reduced tendency to thicken; withdrawn.
– E4: Diesel engines with Euro I to Euro III standards and high requirements, particularly for extended intervals between oil changes (according to manufacturer's specification). Based to a large extent on MB Specification Sheet 228.5.
– E5: For Euro III engines, reduced ash content (withdrawn).
– E6: For EGR engines (exhaust-gas recirculation) with/without diesel particulate filters and SCR-NO_x engines (Selective Catalytic Reduction, i.e. reduction of NO_x to N_2). Recommendation for engines with diesel particulate filters and operation with sulfur-free fuel, sulfate ash less than 1 % by mass.
– E7: For engines without diesel particulate filters of most EGR engines and of most SCR-NO_x engines, sulfate ash max. 2 % by mass.
– E9: For engines with/without particulate filters of most EGR and SCR-NO_x engines, sulfate ash max. 1 % by mass.

Example of a designation
According to the grade specification, a numerical code is usually supplemented.

Example: An A3/B3-04 is an engine oil for spark-ignition engines (Grade A) and diesel engines (Grade B) of quality category 3, tested accord to the ACEA classification grade issued in 2004.

API classification grades
– S Grades (Service) for gasoline engines.
– C Grades (Commercial) for diesel engines.
– SF: For engines produced in the 1980s; withdrawn.
– SG: Applicable since 1988, with more stringent sludge test, improved oxidation stability and wear protection.
– SH: Since mid-1993, corresponds to API SG quality level, but with more stringent process requirements for oil grade testing.
– SJ: Since October 1996, more tests than API SH.
– SL: Since 2001, lower oil consumption compared with SJ, lower volatility, improved engine cleanness, greater resistance to aging.
– SM: Since 2004, for gasoline and light diesel engines with improved wear protection, higher aging stability, improved pumpability, and also used oil.
– SN: Since October 2010, compared with SM improvements in piston cleanliness, sludging, and exhaust-gas treatment capability. Elastomer compatibility is also defined.
– CC: Engine oils for non-turbocharged diesel engines with low stress factors; withdrawn.
– CD: Engine oils for non-turbocharged and turbocharged diesel engines, replaced by API CF in 1994.
– CD-2: API CD requirements, plus additional requirements relevant to two-stroke diesel engines.
– CF-2: Oils with special two-stroke properties (since 1994).
– CE: Oils with CD performance characteristics, with supplementary test operation in US Mack and Cummins engines.
– CF: Replaced API CD in 1994. Specially for indirect injection, even if the sulfur content of the fuel is greater than 0.5 %.
– CF-4: As API CE, but with more stringent test procedure in single-cylinder Caterpillar turbo-diesel engines.
– CG-4: For diesel engines operating under very stringent conditions. Exceeds API CD and CE. Fuel sulfur content less than 0.5 %. Required for engines compliant with post-1994 emission-control legislation.
– CH4: Modern commercial-vehicle engine oil since 1998. Surpasses CG-4 in standards of wear, soot and viscosity. Longer oil-change intervals.
– CI-4: Since 2002 for high-speed four-stroke engines which can only still meet future exhaust-emission legislation with EGR. Suitable for sulfur content greater than 0.5 %.
– CI-4 plus: As CI-4, but with improved soot transport and higher requirements with regard to viscosity increase.
– CJ-4: Valid since 2006. For highway vehicles which must satisfy the USA

2007 emissions standards with diesel fuel (below 500 ppm sulfur content). Suitable for particulate-filter and NO_x reduction catalytic converters.
– CK-4: Improved protection for new diesel engines with among others increased aging stability, shear stability, piston cleanliness. Start 12/2016
– FA-4: For new diesel engines of the 2016/17 generation with low HTHS (2.9 to 3.2 mPa·s at 150 °C) among others to meet the required emission stipulations in the USA.

ILSAC
ILSAC (International Lubricants Standardization and Approval Committee) is a joint standard of General Motors, Daimler, the Japanese Automobile Manufacturers Association, and the American Engine Manufacturers Association.

ILSAC GF-3
In addition to API-SL, the standard requires a fuel-economy test.

ILSAC GF-4
Allocation to API-SM.

ILSAC GF-5
This standard has been in force since October 2010 with the aim of increased fuel reduction, elastomer compatibility, and improved protection of the exhaust-gas treatment systems (comparable with API-SN).

ILSAC GF-6
New specification with the aim of fuel economy for gasoline direct injection and turbocharged engines, expected around 2018. GF-6 A with conventional viscosities, GF-6B with viscosities ≤ SAE 0W16.

SAE viscosity grades
(SAE J300 [17], SAE J306 [18])
The SAE (Society of Automotive Engineers) grades are the internationally accepted standard for defining viscosity. It provides information on the temperature range in which the oils are used. The standard provides no information on the quality of the oil.

A distinction is drawn between single-grade and multigrade oils. Single-grade oils are designated for example by SAE 30. Low code numbers denote thin-bodies oils, higher code numbers denote more viscous oils.

Multigrade oils are the type in widespread use today. Two series are employed for the designation (see Table 2 and Table 3), where the letter "W" (Winter) is used to define specific cold-flow properties. These oils are also suitable for low temperatures. The viscosity grades including the letter "W" are rated according to maximum cold viscosity, maximum viscosity pumping temperature and the minimum viscosity at 100 °C.

Viscosity grades without the "W" are rated only according to viscosity at 100 °C.

Viscosity specifications at higher temperature (150 °C) and high shear stress (HTHS viscosity, see Table 3) are more practical. This value acquired particular significance with the introduction of oils with reduced high-temperature viscosity (below 3.5 mPa·s). These oils may only be used if manufacturer approvals exist.

A multigrade oil is designated for example by SAE 0W-30. This means that it has at –35 °C a viscosity of max. 6,200 mPa·s and satisfies the specification of an SAE 30 oil with a kinematic viscosity in the range of 9.3 to 12.5 mm^2/s at 100 °C and an HTHS viscosity of min. 2.9 mPa·s at 150 °C (Table 3, see also Figure 1).

Motorcycle oil
This essentially is no different from oil for automobiles. However, the stress for example with regard to shear load and specific surface pressure is if necessary higher and only the oils recommended by the manufacturer may be used.

Oil dilution
When vehicles are operated in short-distance service, unburned fuel can mix with engine oil (oil dilution, oil proliferation). This reduces the operating viscosity and increased wear can occur under mixed-friction conditions. In winter the presence of diesel fuel in engine oil can also cause paraffin-crystal precipitation, which compromises delivery (e.g. filter blockage) and can even cause deficient-lubrication conditions.

Transmission oils

Specifications for transmission oils are defined by the type of transmission and the stresses to which it is subjected throughout the entire range of operating conditions. The requirements (high pressure resistance, high viscosity stability relative to temperature, high resistance to aging, good anti-foaming properties, compatibility with gaskets and seals) can only be satisfied by lubricants treated with special additives. In contrast to engine oils, transmission oils contain no, or only minimal, detergent additives, considerably fewer basic constituents, and mostly no viscosity-index improvers. Most of them would be sheared and thus become inactive. The use of unsuitable and qualitatively inferior oils results typically in damage to bearings and gear-tooth flanks.

The viscosity must also suit the specific application. Viscosity grades for vehicular transmissions are defined in SAE J 306 [18] and SAE J300 [17] (Table 2 and Table 3). Transmission oils with roughly the same viscosity compared with engine oils are identified by higher code numbers so that they can be clearly distinguished from engine oils.

Synthesized oils are being increasingly used to meet special requirements (e.g. poly-α-olefins). Advantages over standard mineral oils include superior temperature-viscosity properties and increased aging resistance.

API classifications of transmission oils

- GL-1…GL-3: Outdated, no longer of practical significance.
- GL-4: Transmission lubricants for moderate-stressed hypoid-gear transmissions, and for transmissions which operate at extreme speeds and impact loads, high rotational speeds and low torques, or low rotational speeds and high torques.
- GL-5: Transmission lubricants for high-stressed hypoid-gear transmissions in passenger cars and in other vehicles where they are exposed to impact loads at high rotational speeds, and at high rotational speeds and low torques, or low rotational speeds and high torques.
- MT-1: For non-synchromesh manual transmissions in US trucks.

Many truck and component manufacturers have drawn up their own specifications and no longer rely on API classification grades.

Lubricants for automatic transmissions

Automatic transmissions differ from their manual-shifted counterparts in the way they transfer torque; non-positive mechanical and hydrodynamic force transfer is supplemented by friction coupling arrangements. Thus, the friction response of automatic transmission fluids (ATF) is extremely important. Applications are basically classified according to the friction characteristics.

General Motors

- Superseded grades: Type A, Suffix A, DEXRON, DEXRON B, DEXRON II C, DEXRON II D.
- DEXRON II E: Valid through 1994.
- DEXRON III F/G: Valid since 1994 and 1997. Features more stringent requirements for oxidation stability and consistency in frictional coefficient.
- DEXRON III H: Valid since 2005, but outdated since 2007.
- DEXRON VI: Valid since 2006.

Other manufacturers

(among others. Ford, MB, MAN, Mack, Scania, ZF): In accordance with fluids and lubricants specifications.

Lubricating oils

Lubricating oils comprise the components of basic oil and additive. The additives improve the properties of the basic oils, e.g. with regard to oxidation stability, corrosion protection, protection against scoring and seizure, or viscosity-temperature characteristics. In addition, system properties such as friction and wear are optimized in the desired direction.

There are a wide range of designations in the form of letters and numbers (see among others DIN 51502 [28]) for the most varied applications. For example, hydraulic fluids:

– HL: Mineral-oil-based hydraulic fluid with additives for improving corrosion protection and resistance to aging.
– HLP: As HL, but with extra additives against scoring and seizure.
– HVLP: As HLP, with extra viscosity-index improver.

Lubricating greases

Lubricating greases are thickened lubricating oils. A great advantage that greases enjoy over oil is that they do not drain from the friction surfaces. Complicated measures to seal them in place are therefore unnecessary (e.g. application in wheel bearings pumps, alternators, windshield-wiper motors, servo motors).

Composition

Table 4 provides a general overview of the components in a consistent lubricating grease as blended from three basic components – base oil, thickener, and additive.

Mineral oils are usually employed as the basic oil component, although full-synthetic oils have recently become more common as a replacement (e.g. due to more stringent requirements for aging stability, cold-flow properties, viscosity-temperature characteristics).

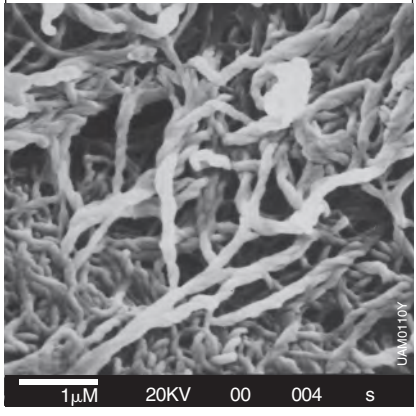
Thickeners are used as a binder for the base oil; metal soaps being generally employed (Figure 6). They bind the oil in a sponge-like soap structure (micelle) by means of inclusions and physical Van der Waals forces. The higher the proportion of thickener (depends on the type of thickener) in the grease, the less the penetration and the higher the NLGI grade

Table 4: Composition of lubricating greases

Whatever the friction pairing, the large number of lubricant components can be used to develop a high-performance lubricant.

Base oils	Thickeners	Additives
Mineral oils – paraffinic – naphthenic – aromatic Poly-α-olefins Alkyl aromatics Diester oils Polyhydric alcohol Silicones Phenyl ether oils Perfluoropolyethers	Metal soaps of metals Li, Na, Ca, Ba, Al Normal soaps (soaps with a carbonic acid, e.g. stearic acid) Hydroxy soaps (soaps with an additional hydroxide group, e.g. 12-hydroxystearic acid Complex soaps (e.g. Ca soaps with a short- and a long-chain carbonic acid) Polyureas PTFE PE Bentonites Silica gels	Oxidation inhibitors Fe, Cu ions, complexing agents Corrosion inhibitors High-pressure additives (EP additives) Wear-protection additives (anti-wear additives) Friction reducers (friction modifiers) Adhesion improvers Detergents, dispersants VI improvers Solid lubricants

(National Lubricating Grease Institute, US standard, see Table 5).



The additives serve to modify physical and chemical properties of the lubricating grease to achieve specific objectives (such as improvement of anti-oxidation properties, increased protection against scoring and seizure, and reduction of friction and wear).

Solid lubricants (e.g. MoS_2) are also added to lubricating greases (for instance for lubricating constant-velocity joints in motor vehicles).

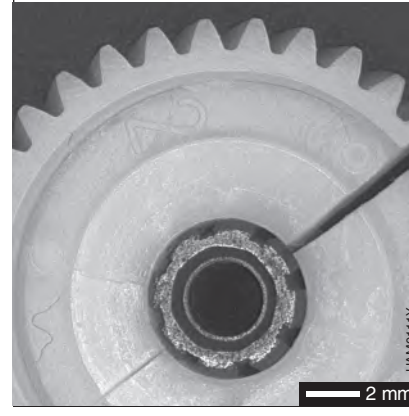
Table 5. Consistency grades for lubricating greases (DIN 51818 [29])

NLGI grade	Worked penetration acc. to DIN ISO 2137 [19] in units of 0.1 mm
000	445…475
00	400…430
0	355…385
1	310…340
2	265…295
3	220…250
4	175…205
5	130…160
6	85 to 150 (unworked penetration)

Figure 6: Photo of lithium soap taken by a scanning electron microscope
The oil is retained between the twisted soap fibrils.

Selection

Specific lubricating greases are selected with reference to their physical characteristics and their effects on the friction surface, and to minimize interaction between the grease and the contact materials. Mutually antagonistic effects with polymers are, for example: formation of stress cracks (Figure 7), consistency changes, polymer degradation, swelling, shrinkage, and brittleness.



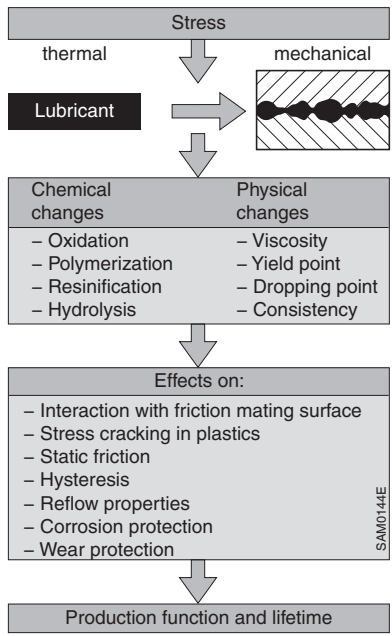
Thus, for example, mineral-oil greases and greases based on synthetic hydrocarbons should not come in contact with elastomers used together with brake fluid (polyglycol base) (e.g. substantial swelling of EPDM elastomers).

In addition, lubricating greases with varying compositions should not be mixed (changes in physical properties, grease liquefaction due to drop-point reduction).

Stress

Thermal and mechanical stresses result in chemical and/or physical changes which may have a detrimental effect on the function of the entire tribological system (Figure 8). Oxidation, for example, results in acidification, which can trigger corrosion on metal surfaces or stress cracking on some plastics. In the event of excessive thermal load, polymerization can cause the lubricant to solidify.

Figure 7: Stress cracks on a gearwheel made of polyoximethylene (POM), caused by poly-α-olefin (PAO)



Every chemical change automatically causes a change in physical properties. These include the rheological properties as well as changes in the viscosity-temperature characteristics or the dropping point. A marked lowering of the dropping point would result in the lubricant flowing away from the friction surface, even at moderate heat.

It is particularly important to remember that metals such as iron or copper (or metals containing copper such as bronze or brass) catalyze the oxidation of a lubricant, i.e. oxidation occurs much more quickly than without catalyst contact. Oxidation quickly renders the lubricity of grease insufficient. Often the soap structure decomposes, the grease then becomes oily, flows away from the friction surface, or hardens due to polymerization.

By correctly matching the lubricating grease and tribological system while taking into account the load and interaction, it is possible to enhance the performance potential of products substantially with sliding-contact opposed parts (e.g. transmission, friction or roller bearings, actuator and control systems) [30].

Figure 8: Stress exerted on lubricant and the resulting effects

Lubricants for high voltage requirements

Stronger electric alternating fields than previously occur with increasing operating voltage in alternators and electric motors. This can give rise for example in the ball bearings of motors or alternators to electric discharges between the rolling elements and the raceway. Sparks flash over and can cause tiny areas of the metal to melt. This is called electrical pitting and can cause premature bearing failure. The energy of these discharges will in future be potentially greater if power density and vehicle system voltage increase, e.g. 400 to 1000 V in electric and hybrid vehicles. Without suitable countermeasures there is a high risk of premature bearing damage, initially discernible from increased bearing noise. By reducing the specific resistance of the roller-bearing greases by magnitudes of around 5, for example with ionic liquids, it is possible to reduce dramatically the number and the energy of the discharges.

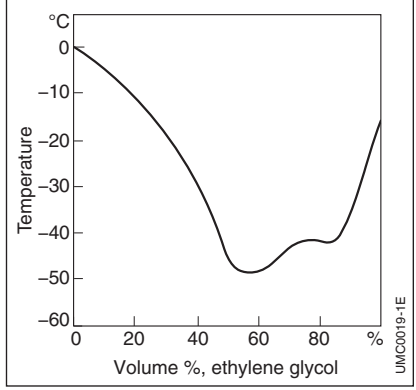
Coolants for internal-combustion engines

Requirements

When a fuel is combusted in the engine, the supplied energy is converted in the proportions of approx. 1/3 into kinetic energy and approx. 2/3 into heat. Roughly 50 % of this heat escapes via the exhaust system, the remainder is utilized or dissipated in the engine cooling circuit via the coolant. The coolant must for this purpose satisfy a series of important requirements:
– optimal heat-transfer properties,
– high heat capacity,
– low evaporative losses,
– good antifreeze properties,
– corrosion, erosion and cavitation protection of all the cooling-circuit materials,
– compatibility of elastomers, plastics, and coatings,
– avoidance of deposits ("fouling") which result in blockages,
– low maintenance requirement, long service life, and easy handling,
– environmental compatibility.

Table 1: Requirements regarding water from the main based on the radiator manufacturer's recommendation

Property	Requirement
Appearance	colorless, clear
Deposit	0 mg/*l*
pH value	6.5 to 8.0
Total hardness	≤ 4.5 mmol/*l*
Chloride	≤ 100 mmol/*l*
Sulfate	≤ 100 mmol/*l*
Hydrogen carbonate	≤ 100 mmol/*l*



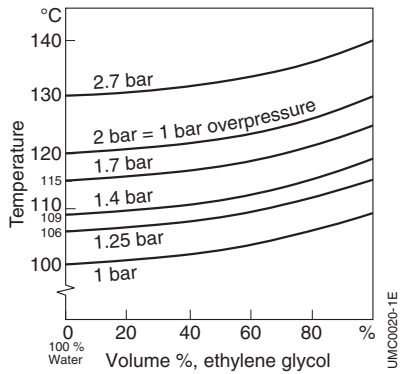
Composition of coolants

Customary coolants for engine cooling circuits consist of a mixture of water with a radiator protection agent approved by the automobile and engine manufacturers. The volume percentage of the radiator protection agent is for the most part between 40 % and 50 %.

Water
Owing to its high specific heat capacity and its correspondingly substantial thermal-absorption capacity, water is a very good coolant. Water from the main is usually used. Since the quality of such water can vary dramatically, the requirements with regard to the water used are specified by most automobile and engine manufacturers, and by radiator manufacturers (Table 1). A higher water ion content results in faster inhibitor consumption and possible after-effects such as, for example, flocculation (coagulation) of low-solubility reaction products, corrosion of circuit components, through to blockage of cooling ducts.

Radiator protection agents
The base material of radiator protection agents is for the most part 1,2-ethane-

Figure 1: Freezing point of coolant as a function of ethylene-glycol content



diol (ethylene glycol), or less commonly 1,2-propandeiol (propylene glycol). Both glycols have very good water-soluble properties. When mixed with water from the main, they lower the freezing point and raise the boiling point. The optimum level of these effects is achieved with a volume percentage of approximately 50 % (Figure 1). The boiling point is furthermore dependent on the operating pressure in the cooling system (Figure 2). The operating pressure of a passenger-car cooling circuit is in normal operation typically approximately 1.5 bar overpressure, under full load and in high-performance engines up to 2.5 bar and higher.

In the strict sense, with glycol-water mixtures there is not a defined freezing point, but an ice flaking point at which ice crystals begin to separate out in the fluid. At this temperature, the fluid medium can still be pumped through the cooling circuit.

The heat capacity of glycol-water mixtures is reduced compared with water from the main.

Since water/glycol mixtures demonstrate similar corrosivity to water from the main compared with metals, inhibitor systems are additionally admixed with the radiator protection agents.

Figure 2: Boiling-point curves of water/ethylene-glycol mixtures with different ethylene-glycol content as a function of pressure

Types of radiator protection agents

Radiator protection agents can essentially be classified into three groups, which differ with regard to the inhibitor systems used.

Conventional radiator protection agents containing silicate

Inhibitors and additives

These radiator protection agents contain primarily inorganic inhibitors such as, for example, silicate, nitrite, nitrate or molybdate. Organic inhibitors such as toluene or benzotriazole are also used.

To keep the pH value at the desired alkaline level over the entire period of use, buffer substances such as borate, phosphate, benzoate or imidazole are added to the radiator protection agent.

Radiator protection agents are completed by the addition of cleaning agents (e.g., sulfonates), antifoaming agents, and dyes.

Conventional radiator protection agents containing silicate have proved themselves in practice over decades. Particularly the proportion of silicate has counteracted the dangerous hot corrosion of aluminum engine through the formation of thin, protective coatings.

Service life

However, the drawback of this type of radiator protection agent is that it is not possible to select the concentrations of the inhibitor systems at any level owing to the low solubility of some additives. On the other hand, the inorganic inhibitors are reduced during driving operation; however, the necessary minimum concentrations of inhibitors may not be undershot here. Consequently, the service life of such a radiator protection agent is limited to around three years driving or 100,000 km (for passenger cars). This service life can be significantly reduced for example by the high thermal load of the cooling circuit in modern high-performance engines.

The limited service life of conventional radiator protection agents does not match the wishes of the automobile and engine manufacturers to extend the service intervals of vehicles. The manufacturers of

radiator protection agents are therefore responding with the development of "OAT products".

OAT radiator protection agents
OAT radiator protection agents (Organic Acid Technology) contain a combination of organic inhibitors instead of conventional inorganic inhibitors. Typical combinations are aliphatic mono- and dicarboxylic acids, azelaic acid and aromatic carboxylic acids, sebacic acid and benzotriazole. The combination of an inorganic inhibitor and carboxylic acid is also used. Pure OAT products, however, contain no silicate.

In contrast to conventional radiator protection agents containing silicate, the inhibitors in OAT radiator protection agents decrease must more slowly in driving operation. This enables to service life of the radiator protection agents to be increased and the maintenance requirement to be reduced.

Hybrid radiator protection agents
To combine the good long-term durability of OAT radiator protection agents with the good hot-corrosion protection of silicate inhibitors, hybrid radiator protection agents have been developed which contain a harmonized combination of both inhibitor types. In this way, local hot corrosion can be prevented by the rapid formation of silicate protective coatings, while good long-term corrosion protection, even after the consumption of silicate inhibitors, is provided by the more stable OAT inhibitors.

This on the one hand satisfies the demand for low-maintenance coolants, but on the other hand also takes into account the high thermal loads of modern engine technologies. Therefore these hybrid radiator protection agents, sometimes also called Si-OAT radiator protection agents, are today frequently used by major vehicle manufacturers for the initial fill.

Brake fluids

Requirements

Passenger cars and light commercial vehicles are equipped with hydraulic brake systems. A hydraulic medium transmits and converts the braking force from the brake pedal in the brake master cylinder into hydraulic pressure, which is routed via brake lines to the wheel brake and there converted back into braking force. Vehicle-dynamics control systems such as the antilock braking system or the electronic stability program can additionally modulate the hydraulic pressures at each wheel to prevent the wheels from locking through pressure reductions or to stabilize the handling through additional pressure build-ups. This medium is therefore subject to the following requirements.

Low compressibility
The basic requirement with regard to the hydraulic medium brake fluid for effective power transmission is very low compressibility. The liquid state of aggregation must be maintained in the entire operating range for this purpose.

Water-absorption capacity
During driving water can penetrate into the brake system at the wheels, particularly through the flexible brake hoses usually made from rubber material. If this water is not bound by the brake fluid, compressible water-vapor bubbles can form at temperatures above 100 °C. Consequently, no further pressure can be generated when the brake pedal is pressed because initially the compressible water vapor is compressed. This failure of the brakes is called “vapor lock”. Consequently, the market has seen the widespread acceptance of brake fluids which are completely mixable with water and exclude the presence of unbound, free water. Mineral-oil-based brake fluids also commonly used in the past have in practical terms been completely superseded by chemically glycol-based brake fluids (market share is approximately 99 %).

Standards for brake fluids
Brake fluids must comply with stringent requirements to ensure reliable brake-system operation. Their properties are defined in various standard requirements which are very similar in terms of content (SAE J1703 [1], SAE J1704 [2], FMVSS 116 [3], ISO 4925 [4], JIS K2233 [5]). Exclusively for the vehicle operating medium brake fluid the performance requirements of FMVSS 116 (Federal Motor Vehicle Safety Standard) became mandatory in the USA and often serve as a universal reference. In this standard the US Department of Transportation (DOT) – comparable with other standards – has defined specific ratings for salient properties (Table 1).

Table 1: Classification of brake fluids with different chemical bases

Chemical base / Classification	Glycol ether				Silicone	Mineral oil
Suggested color	Colorless to amber				Purple	Green
FMVSS 116	DOT 3	DOT 4		DOT 5.1	DOT 5	
ISO 4925 class	3	4	6	5-1		ISO 7308
SAE	J 1703	J1704 Standard	J1704 Low viscosity		J 1705	
JIS K2233 class	3	4	6	5		
Dry boiling point [°C] Wet boiling point [°C]	>205 >140	>230 >155	>250 >165	>260 >180	>260 >180	>235
Viscosity at –40 °C [mm²/s]	<1500	<1800 (DOT) <1500 (SAE, ISO, JIS)	<750	<900	<900	<2000

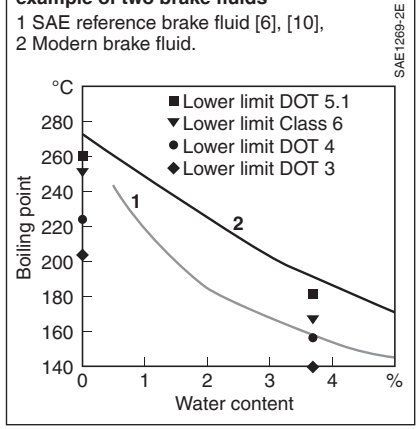
Characteristics

Boiling point
During braking the temperature at the wheel brake cylinders increases, in extreme cases (e.g., frequent braking on long downhill gradients) even into ranges around 200 °C. Vapor bubbles can form at temperatures above the operating medium's instantaneous boiling point. The brake fluid transforms at least partie into a vapor state that is too compressible for reliable braking operation. It is then no longer possible to operate the brakes as is the case with the presence of water-vapor bubbles; "vapor lock" brake failure occurs.

Dry boiling point
In their new state (e.g. in sealed containers) brake fluids typically contain no or very little water, i.e. the water content is typically < 0.2 %. Fluids, particularly in steel containers, sometimes reach values of < 0.03 %. The equilibrium boiling point in this new state is called the dry boiling point (ERBP: Equilibrium Reflux Boiling Point).

The boiling point of the hygroscopic glycol-based brake fluid decreases significantly as a result of water absorption. Consequently, the risk of a "vapor lock" increases accordingly at high wheel-brake temperatures.

Depending on operation and the climate region, typically a water-content increase of approximately 1 to 1.5 % per year is assumed.



Wet boiling point
The equilibrium boiling point of the brake fluid after a precisely specified procedure of water absorption is defined as the wet boiling point (wERBP: wet Equilibrium Reflux Boiling Point) and is intended to depict the boiling point of a brake fluid used for two to three years.

The brake fluid to be tested is removed after roughly one day from a very humid climatic chamber to measure the boiling point when a reference brake fluid has reached a 3.7 % water content. The boiling point of the operating medium continues to drop if further water is absorbed. Thus the brake-failure risk increases at high wheel-brake temperatures. This is the main reason why the brake fluid typically should be replaced every two years. Figure 1 shows by way of example the drops in boiling point that result from water absorption in two brake fluids.

A significant development trend on the part of the brake-fluid manufacturers in previous years was to increase the boiling point with increased water content.

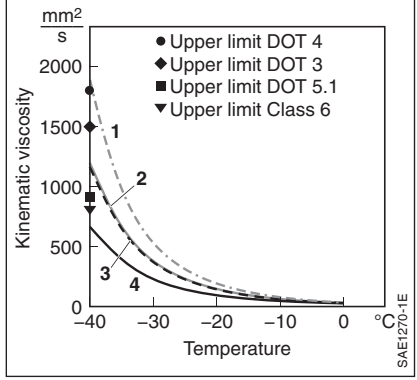
Viscosity
The viscosity describes the resistance to flow of the operating medium. As the viscosity increases, so too the pressure drops increase as the medium flows through lines and throttle points, e.g., in valves and pumps of the vehicle-dynamics control systems. This reduces, for example, the dynamics of the pressure build-up, which can reduce the effectiveness of the electronic stability program. Therefore, generally speaking, low cold viscosities and low dependence of viscosity on temperature are desirable. This is specified by upper limits for the viscosity at very low temperatures at –40 °C (cold viscosity). It should be as low as possible in order to facilitate high dynamics on the part of the pressure build-up. Reducing the viscosity at very low temperatures was a further development trend on the part of the brake-fluid manufacturers in past years. Figure 2 shows by way of

Figure 1: Reduction of the boiling point with increasing water content from the example of two brake fluids
1 SAE reference brake fluid [6], [10],
2 Modern brake fluid.

example the dependence of viscosity on temperature for two brake fluids. This has a clearly non-linear characteristic particularly at low temperature. As a general "rule of thumb": a 1 K reduction in temperature produces approximately a 10 % increase in viscosity. Likewise, approximately a 10 % increase in viscosity results at low temperature additionally from a 1 % increase in water content. This effect is another reason why the brake fluid should be changed.

Corrosion protection
FMVSS 116 (and also all the other standards) stipulates that brake fluids shall exercise no corrosive effect on those metals generally employed in brake systems. Appropriate additives guarantee the required corrosion protection, which is checked beyond required upper limits in high-temperature storage tests of metal plates in dry and in wet brake fluids.

Elastomer swelling
Elastomers are used as seals and gaskets in the brake system, for example in the brake master cylinder, in vehicle-dynamics control systems, and in hoses. Although a small amount of elastomer swelling is desirable and taken into account in the design of the sealing rings, it should not exceed 10 % under any circumstances; otherwise, it has a negative effect on the strength of these components.



Typically, EPDM is used as elastomer material for glycol-based (and also for rarely used silicone-oil-based) brake fluids. Mineral-oil-based brake fluids are not compatible with EPDM and required different elastomer materials (e.g., FKM).

Even minute levels of mineral-oil contamination (e.g., hydraulic fluids, mineral-oil-based brake fluid) of glycol-based brake fluid can destroy EPDM elastomers (e.g., sealing elements). This can ultimately lead to brake failure. To avoid such contamination, high standards of cleanliness must be maintained for the brake fluids used during service filling [10].

Chemical composition

Glycol-ether fluids
Most brake fluids are based on glycol-ether compounds. These generally consist of monoethers of low polyethylene glycols. The chemical formulation of the ISO and at the same time the SAE reference brake fluids is specified in detail in ISO 4926 [6]. Glycol components can be used to produce a brake fluid which conforms to DOT 3 requirements (Table 1), the downside is that their boiling point drops relatively quickly with water absorption. DOT 4 and DOT 5.1 brake fluids are characterized by the fact that glycol-ether borates are also used. This enables the water to be chemically bound. In this way, the boiling point drops much more slowly compared with DOT 3 fluids. The wet boiling point rises significantly (Figure 1). Thus, the risk of a "vapor lock" decreases significantly when the wheel brake is subject to increased water content and high temperatures.

Figure 2: Dependence of viscosity on temperature and water content from the example of two brake fluids
1 SAE reference brake fluid with 5 % water,
2 SAE reference brake fluid without water [6], [10],
3 Modern brake fluid with 5 % water,
4 Modern brake fluid without water.

Future development trends
ISO 4925 defines a further quality class, namely “Class 6”. This quality is better than that of DOT 4 and is characterized by its particularly low cold viscosity (Table 1). It constitutes the first combination of the two development trends of increased wet boiling point and reduced cold viscosity.

This trend towards higher wet boiling points and low cold viscosities will continue and combine. Increasingly “modern” brake fluids are being developed and offered.

In addition, the functionality of the vehicle-dynamics control systems – e.g., vehicle-speed controller including brake intervention as ACC (Adaptive Cruise Control) and AEB (Automated Emergency Braking) – is constantly increasing. The road towards (semi-)automated driving is clear. The frequency of use of the vehicle-dynamics control systems thereby increases. While a pump element in the ABS (antilock braking system) was only rarely active, its duration of use and hence also its operating load increase significantly by way of TCS (traction control system) and electronic stability program with comprehensive additional functions right up to automated driving.

This also renders necessary in future in the brake-fluid standards requirements, e.g., with regard to the lubricity of the brake fluid, in order to reduce wear. The same also applies to avoid noise when operating the brake master cylinder and clutch, which in the meantime is increasingly operated in manual transmissions with brake fluid. Working groups, particularly within the SAE and ISO, and the pfp TriNoWe (public funded project Tribology in Standards Worldwide; German: Tribologie in Normen Weltweit), are working on further developments of the standards.

Other types of brake fluids
Silicone-oil fluids (SAE J1705, [7])
Silicone-oil-based brake fluids are now only used in a few special applications, e.g. in motor sport, in which very short maintenance intervals are possible.

The disadvantage of these products is – aside from the high price – the higher compressibility. Furthermore, they are – like mineral oils – not hygroscopic and therefore not able to absorb water that penetrates into the brake system. For this reason, they are also called “Low Water Tolerant” brake fluids.

Mineral-oil fluids (ISO 7308, [8])
Additives for improving the fluid properties (e.g., lubrication) are known from mineral-oil technology. These were used previously for example in vehicles with central hydraulics, but are now no longer significant because they – like silicone-based fluids – cannot bind water.

Mineral-oil fluids should never be added to brake systems which are designed for glycol fluids (or vice versa), as this would destroy the elastomer seals. For this reason, the FMVSS suggests a color-coding system for the various brake fluids (see Table 1).

Fuels

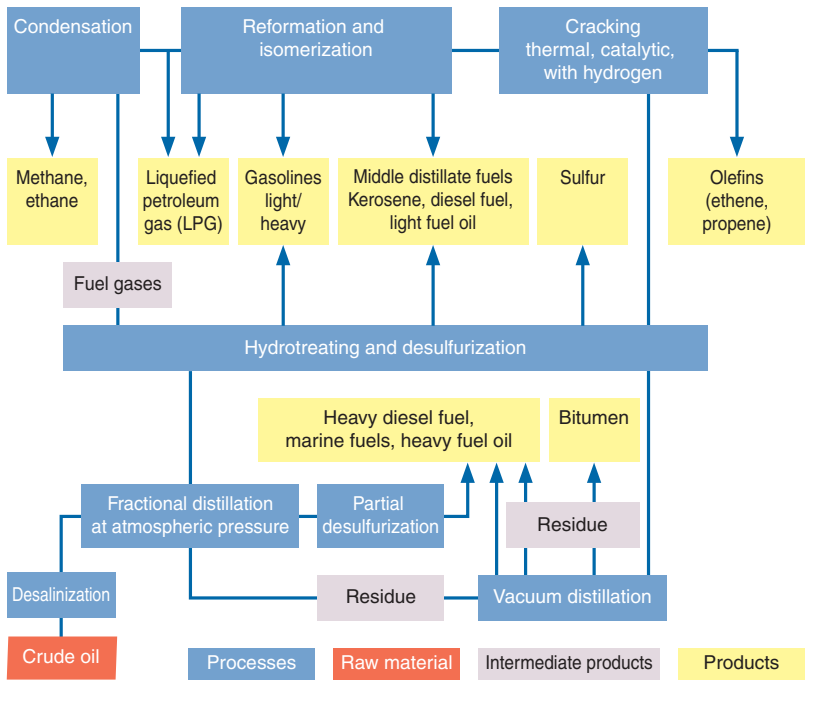
Overview

Composition

Fuels consist of a multitude of hydrocarbons, primarily of various paraffins and aromatic compounds.

Paraffins

Paraffins are linear, isoparaffins branched and cycloparaffins closed-chain hydrocarbons in which the atoms are linked to each other by single bonds. Molecules with single bonds are chemically less reactive.



Aliphatic compounds

Paraffins belong to the class of aliphatic compounds. Aliphatic compounds cover all linear, branched and closed-chain hydrocarbons whose molecules have one or more single bonds, one or more isolated multiple bonds or a combination of both types of bond. Molecules which exhibit an aromatic system are not classed as aliphatic compounds.

Aromatic compounds

Aromatic compounds are characterized by the property that the molecules have at least one ring, in which electrons are distributed around the entire ring. Benzene is a typical example. Aromatic compounds are likewise less active, because the elec-

Figure 1: Oil-refining processes in a refinery

trons are not located as a double bond between two carbon atoms.

Manufacture

Gasoline and diesel fuel are produced from crude oil. First the crude oil is desalted and distilled, where the hydrocarbons are separated, depending on the molecule size, into different fractions (Figure 1).

Distillation under atmospheric pressure

The process is begun with a distillation of the crude oil under atmospheric pressure, in which different substance streams of predominantly volatile components are produced. Depending on their composition, these substance streams form the basis for liquefied petroleum gas (propane and butane), gasoline, kerosene, and for the more volatile part of diesel fuel and fuel oil.

Distillation under vacuum

The remaining residue from the atmospheric distillation is further separated under vacuum. These fractions form the basis for the heavier components in diesel fuel and fuel oil and for light and heavy marine fuels. During vacuum distillation too a residue is left, which is processed into heavy fuel oil and bitumen.

Further processing

The ratio and the quality of the product fractions obtained by distillation do not yet meet market requirements such that further processing in complex chemical processes is required in the refinery.

Aside from the widely known desulfurization, larger molecules can be cracked purely thermally or in the presence of catalysts (thermal cracking, catalytic cracking). If this process is performed in the presence of hydrogen, it is known as hydrotreating or hydrocracking. Additional shorter-chain components can be produced from heavy oil for diesel fuel by hydrocracking.

The structure of molecules is modified in other refinery processes. During reforming aromatic compounds are produced from saturated aliphatic molecules, where hydrogen that is needed for hydrotreating or hydrocracking and desulfurization is created. Linear molecules can be converted into branched molecules by isomerization processes. These increase the octane number of gasoline and the low-temperature resistance of diesel fuel.

The interaction of the complex handling processes in a refinery are shown in greatly simplified schematic form in Figure 1.

Addition of biofuels and additives

Today proportions of biofuels are added to many fossil fuels worldwide. Certain properties of biofuels can be specifically used to satisfy the fuel-grade requirements. For example, bioethanol increases the octane number of gasoline and adding biodiesel to diesel fuel ensures sufficient lubricity. Additives are often also used to further improve product quality. Additives are active substances which are added to specifically adjust certain fuel properties.

Characteristics

Boiling range and ignition temperature
The boiling range of gasoline is between 30 °C and 210 °C, and that of diesel fuel between 160 °C and 370 °C. Diesel fuel ignites on average at approximately 350 °C (lower limit 220 °C), which is very early in comparison with gasoline (on average 500 °C).

Net calorific value
Normally, the net calorific value H_i (former term: lower calorific value) is specified for the energy content of fuels; it corresponds to the usable heat quantity released during full combustion.

The gross calorific value H_s (former term: upper calorific value), on the other hand, specifies the total reaction heat released and therefore comprises, as well as the mechanically usable heat, the latent heat created in the water vapor. However, this component is not used in the vehicle.

The net calorific value H_i of diesel fuels is in the range of 42.9 through 43.1 MJ/kg and is slightly higher than the calorific value of gasoline (40.1 through 41.9 MJ/kg).

Fuels or fuel constituents containing oxygen (oxygenates) such as alcohols (H_i of ethanol: 26.8 MJ/kg) and fatty acid methyl esters (H_i of biodiesel: 36.5 MJ/kg) have a lower calorific value than fuels which only contain hydrocarbons. The net calorific value is reduced because bonded oxygen does not contribute to the release of energy during combustion. Engine performance comparable with conventional fuels can therefore only be achieved with fuels containing oxygen by increased fuel consumption. Subsequently increasing the ethanol content in gasoline above 10 % (V/V) would in many existing vehicles result in a noticeable reduction of performance and in significantly higher fuel consumption.

Calorific value of air/fuel mixture
This is the calorific value of the combustible air/fuel mixture. It is dependent on the air/fuel ratio and determines the engine's power output. With a stoichiometric air/fuel ratio, this is roughly 3.5 - 3.7 MJ/m^3 for all liquid fuels and liquefied petroleum gases.

Sulfur content
In the interests of reducing sulfur-dioxide emissions (SO_2) and protecting the catalytic converters for exhaust-gas treatment, the sulfur content of gasolines and diesel fuels was limited for vehicle applications on a Europe-wide basis to 10 mg/kg as from 2009. Fuels which adhere to this limit value are known as "sulfur-free fuels". In this way, the final stage of the desulfurization of fuels is achieved.

Since 2017 in the US too the average sulfur content of gasoline which is supplied commercially to end consumers has been no more than 10 mg/kg, with individual exceptions being permitted, e.g., up to 80 mg/kg for refineries and up to 95 mg/kg in downstream areas. All sulfur-free diesel fuels (Ultra Low Sulfur Diesel, ULSD) for on- and off-road vehicles may not contain more than 15 mg/kg sulfur in the US.

In China the sulfur content of gasolines and diesel fuels may not exceed 10 mg/kg.

With the next stage of emissions legislation for on-road vehicles in India the fuels containing up to 50 mg/kg sulfur still available on the market have since 2020 been gradually replaced by sulfur-free products.

Generally, a marked increase in the desulfurization of fuels can be observed worldwide.

Gasoline

Fuel grades

Super fuels in Germany

In Germany two Super fuels with 95 octane are available; these differ in their ethanol content and may contain a maximum 5 % (V/V, % by volume) ethanol (Super) or 10 % (V/V) ethanol (Super E10). A Super Plus fuel with 98 octane is also available. Individual providers markets fuels with an octane number of at least 100 (V-Power Racing 100, Super 100plus, Ultimate 102), which in comparison with the Super fuels with 95 octane are changed in terms of basic quality and additives.

Fuels in the USA

Three different types of fuel are sold in the USA: Regular (92 octane), Premium (94 octane), and Premium Plus (98 octane). Fuels sold in the USA usually contain 10 % (V/V) ethanol. The addition of components containing oxygen increases the octane number and satisfies the requirements of modern, higher-compression engines with regard to improved knock resistance.

Reformulated gasoline is the term used to describe gasoline which, through its altered composition, generates fewer evaporative and exhaust emissions than conventional gasoline. The demands placed on reformulated gasoline are laid down in the USA in federal law (Clean Air Act). In comparison with standard quality, this legislation prescribes, for example, lower limits for vapor pressure, benzene and overall aromatic content, and final boiling point. It also prescribes the use of additives to keep the intake system free of contamination and deposits (detergents).

Fuel standards

European Standard EN 228 [1] defines the requirements for unleaded fuel for use in gasoline engines (Table 1). Further country-specific characteristics are set out in the national appendices to this standard. Leaded gasolines are no longer permitted in virtually all markets worldwide and by 2020 were only available in a few countries, e.g., Algeria and Iraq.

The US specifications defining fuels for gasoline engines are contained in ASTM D4814 (American Society for Testing and Materials) [2].

Most fuels for gasoline engines which are sold today contain components which in turn contain oxygen (oxygenates). Ethanol has gained in importance in Europe as well, since the “EU Biofuels Directive” stipulates minimum content figures for renewable fuels. But also those ethers

Table 1: DIN EN 228 (August 2017): Selected requirements of gasolines

Requirements	Unit	Characteristic	
Quality		Super E10	Super
Knock resistance: RON/MON for Super, min.	–	95/85[1]	
Density (at 15 °C), min./max.	kg/m^3	720/775	
Sulfur, max.	mg/kg	10	
Oxygen content, max.	% (m/m)	3.7	2.7
Ethanol content, max.	% (V/V)	10.0	5.0
Benzene, max.	% (V/V)	1	
Lead, max.	mg/*l*	5	
Volatility			
Vapor pressure, summer, min./max.	kPa	45/60

which can be produced from methanol or ethanol MTBE (methyl tertiary butyl ether) and ETBE (ethyl tertiary butyl ether) are used, of which, depending on the quality of the basic fuel, up to 22 % (V/V) may be added in Europe. A mixture of alcohols and ethers is also permitted. In Europe the overall quantity of oxygenates is limited by the stipulation of a maximum permitted oxygen content. Thus, E10 in Europe may exhibit a maximum oxygen content of 3.7 % (m/m, mass percent), which is already exhausted with the addition of 10 % (V/V) ethanol. When ether is added, the maximum permitted volume percentage of ethanol must be reduced accordingly. Worldwide many countries have defined minimum quotas for biogenic components in gasolines, which are achieved for the most part with bioethanol.

Adding alcohols increases the volatility at higher temperatures. Furthermore, alcohols can damage materials in the fuel system, lead for example to elastomer swelling, and trigger alcoholate corrosion on aluminum parts. Depending on the alcohol content and the temperature, demixing may result in response to only small amounts of water. During phase separation a new aqueous phase is formed with part of the alcohol from the fuel. The use of fuels containing alcohol therefore require additional measures on the vehicle and in the filling-station network.

The ethers do not encounter the problem of demixing. The ethers, which have a lower vapor pressure, a higher calorific value and a higher octane number than ethanol, are chemically stable components with good material compatibility. They therefore demonstrate advantages, both from an engine-engineering and a logistical standpoint. For reasons of sustainability, because of the CO_2 savings to be attained and due to the laying down of quotas for biogenic fuels, ETBE is used in the main.

The ethanol content in the European gasoline standard EN 228 was for a long time limited to 5 % (V/V) (E5). In 2013 EN 228 was in the first instance supplemented by a specification for 10 % (V/V) ethanol (E10). At present in the European market not all vehicles are yet equipped with materials to allow operation with E10. As the second quality, therefore, an exemption grade with a max. ethanol content of 5 % (V/V) is retained. E10 is conceived as the main grade in the gasoline market. E10 has failed to find favor with consumers in some of the European countries in which it has been introduced. E10 is primarily favored In Bulgaria, Romania, Slovakia, the Netherlands, Belgium, Luxembourg, and Finland, but in Germany is well below expectations with a market share of 13 % (as at April 2020).

In the USA most gasolines contain ethanol at 10 % (V/V) (E10), for which a vapor pressure higher by approximately 7 kPa is permitted according to the American standard ASTM D4814. If certain preconditions are satisfied, a vapor pressure that is up to 8 kPA higher is also according to EN 228, depending on the ethanol content.

In the USA the amount of ethanol that may be added to gasoline is limited by law to 10 % (V/V). Because there are increasing demands for this limitation to be dropped, the upper limit for ethanol has in ASTM D4814 been increased as a precaution to 15 % (V/V). The vapor-pressure increase of 7 kPa, which until now has been confined to E10, will also apply in future to E15.

Characteristics

Density

European standard EN 228 fixes the density of gasolines at 720 – 775 kg/m^3.

Octane number

The octane number defines the gasoline's antiknock quality (resistance to pre-ignition). The higher the octane number, the greater the resistance to engine knock. Iso-octane (trimethyl pentane), which is extremely knock-resistant, is assigned the octane number 100, while n-heptane, which is extremely knock-susceptible, is assigned the number 0.

The mixture of iso-octane and n-heptane, which exhibits the same knock resistance as the fuel to be tested, is determined in a standardized test engine. The proportion in % by volume of iso-octane in the mixture of iso-octane and n-heptane corresponds to the fuel's octane number.

Iso-octane has a high octane number, but there are components which are even more knock-resistant, for example toluene (RON = 124) or ethanol (RON = 130). The definition and verification of octane numbers above 100 is based on primary reference standards from iso-octane with different proportions of tetraethyl lead. To determine the amount of tetraethyl lead required for a specific octane number above 100, it was necessary to carry out comprehensive examinations of the knock characteristics of mixtures which consisted of benzene (RON = 99), varying proportions of iso-octane and heptane as well as tetraethyl lead.

Research and motor octane numbers
RON ((research octane number) is the octane number determined in testing using the Research Method [3]. It serves as the essential index of acceleration knock. The octane number determined in testing using the Motor Method [4] is the MON (motor octane number). The MON basically provides an indication of the tendency to knock at high speeds.

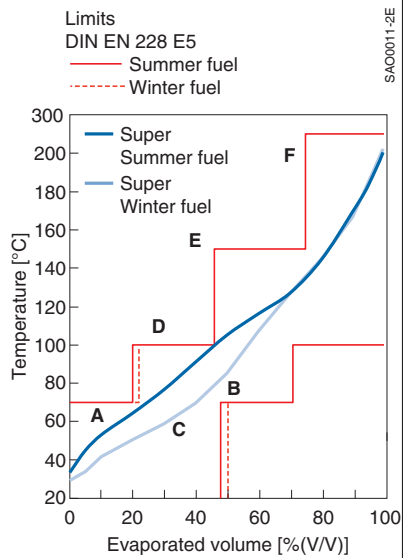
The Motor Method differs from the Research Method by using preheated mixtures, higher engine speeds and variable ignition timing. This places more stringent thermal demands on the fuel under examination. MON figures are lower than those for RON.

Increasing the antiknock quality
Normal (untreated) straight-run gasoline displays a low antiknock quality. Only by mixing such gasoline with different knock-resistant refinery components (reformed components, isomerisates) is it possible to produce fuels with high octane numbers which are suitable for modern, high-compression engines. Even components containing oxygen such as alcohols and ether increase the antiknock quality. They are therefore specifically added for this purpose.

Additives containing metal to increase the octane number, e.g., MMT (methylcyclopentadienyl manganese tricarbonyl), form ashes during combustion. The addition of MMT is therefore excluded in EN 228 by the fixing of a limit value for manganese in the trace range.

In view of the optimization of downsizing and turbocharging of direct-injection gasoline engines there are increasingly indications that high characteristic RON and MON values alone cannot guarantee actual sufficient knock resistance of fuels in the lower torque range. The pre-ignition behavior can also vary greatly for a similar RON such that an additional characteristic, the compression pre-ignition number (CPI), is suggested to characterize the tendency to pre-ignition [5].

Fuel volatility
The volatility of gasoline has both upper and lower limits. The lower limitation is chosen so that the fuel contains sufficiently volatile components to ensure a reliable cold start. However, the fuel's volatility may not be so high that at higher temperatures the fuel supply is interrupted by the formation of gas bubbles (vapor lock) and as a result difficulties when hot starting or problems when driving are encountered. Yet another factor is environmental protection, which demands that evaporative losses be kept low.



Fuel volatility is defined by different characteristic quantities. EN 228 defines for E5 and E10 ten different volatility classes distinguished by various levels of boiling curve, vapor pressure and VLI (vapor-lock index). To meet special requirements stemming from variations in climatic conditions, European countries can incorporate specific individual classes into their own national appendices in the standard. Different values are laid down for summer and winter.

A similar provision is included in the American gasoline standard ASTM D4814. Comprehensive tables describe the scope of application of the volatility classes, depending on the calender month and state.

Boiling curve
In order to assess the fuel in vehicle operation, it is necessary to view the individual areas of the boiling curve separately. EN 228 therefore contains limit values laid down for the volume of fuel that vaporizes at 70 °C, at 100 °C and at 150 °C. Up to 70 °C an minimum volume of fuel must be vaporized in order to ensure easy starting of the engine when cold (Figure 2, A). Suf-

ficient volatility in the lower temperature range is particularly important for vehicles in which the fuel preparation is still performed by means of a carburetor (Figure 2, B). However, the volume of fuel that vaporizes must not be too great either, otherwise vapor bubbles may be formed when the engine is hot and the evaporative emissions are too high (Figure 2, C). The volume of fuel that vaporizes at 100 °C determines, aside from the engine's warm-up characteristics, primarily the readiness for operation and accelerating performance of the engine at normal operating temperature, otherwise the non-volatile volume in the intake manifold condenses (Figure 2, D). The volume of fuel that vaporizes at up to 150 °C should be high enough to minimize dilution of the engine oil. In particular when the engine is cold, the non-volatile gasoline components find it difficult to vaporize and can pass from the combustion chamber via the cylinder walls into the engine oil (Figure 2, E). Too many non-volatile components in the uppermost range of the boiling curve can cause formation of residues, coking, and sooting (Figure 2, F).

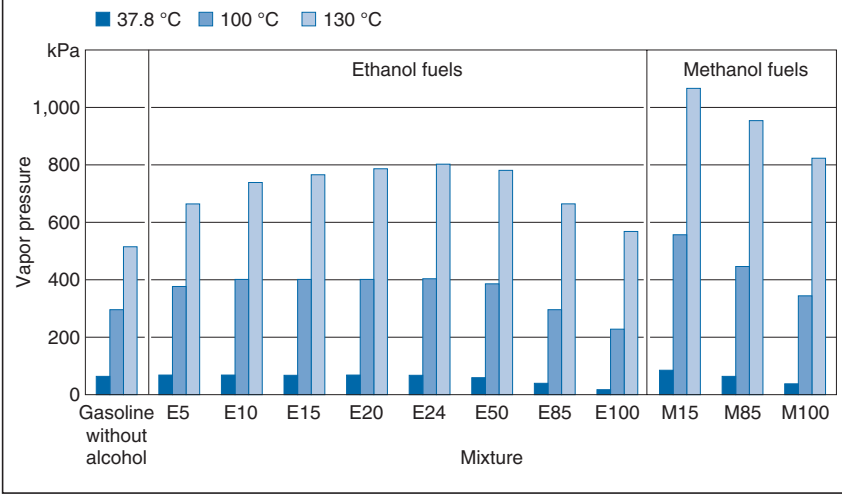
Figure 2: Boiling curve of gasoline according to ISO 3405 [6]
Explanations for A to F see text.

Vapor pressure

Fuel vapor pressure as measured at 37.8 °C (100 °F) in accordance with EN 13016-1 [7] is primarily a characteristic quantity with which the safety requirements in the vehicle's tank are established. Vapor pressure has upper and lower limits in all specifications. In Germany, for example, it is max. 60 kPa in summer and max. 90 kPa in winter.

In order to configure a fuel-injection system, it is also important to know the vapor pressure at higher temperatures (80...120 °C) because a rise in the vapor pressure due to the admixture of alcohol becomes apparent only at higher temperatures. When comparing the vapor-pressure curves of gasolines with different alcohol contents it becomes clear that the amount of alcohol at moderate temperatures (37.8 °C) barely affects the vapor pressure, while fuels with 10 % (V/V) ethanol at 130 °C exhibit a vapor pressure that is higher by more than 200 kPa (Figure 3). Fuels containing 20 to 30 % (V/V) ethanol achieve the highest vapor pressure (up to 800 kPa at 130 °C). Higher ethanol contents, however, lead to a reduction of the vapor pressure again because the intermolecular interactions increase under the polar ethanol molecules and these bind in a more pronounced manner. Methanol fuels develop at high temperatures even higher vapor pressures (vapor pressure at 130 °C of E15: 768 kPa; of M15: 1070 kPa).

If the fuel vapor pressure rises above the fuel-injection system pressure, for example during vehicle operation due to the effect of the engine temperature, this may result in malfunctions caused by vapor-bubble formation. Due to the increased volatility of alcohol fuels, especially for operation with M15, the validation range for system functions and vehicle applications must be checked and if necessary adapted.



Vapor/liquid ratio
The vapor/liquid ratio is a measure of a fuel's tendency to form bubbles. It refers to the volume of vapor generated by a specific quantity of fuel at a defined back pressure and a defined temperature. A drop in pressure (e.g., when driving over a mountain pass), or an increase in temperature, will raise the vapor/liquid ratio and with it the possibility of operating problems. ASTM D4814 lays down, for example for each volatility class, a temperature at which a vapor/liquid ratio of 20 must not be exceeded.

Vapor-lock index
The vapor-lock index (VLI) is the mathematically calculated sum total of ten times the vapor pressure (in kPa at 37.8 °C) and seven times the volume percentage of fuel that vaporizes at up to 70 °C. It is possible with this additional limit value to restrict the volatility of the fuel further with the result that the two maximum values for vapor pressure and boiling data cannot be achieved in the course of its production.

Additives
Additives can be added to improve fuel quality in order to counteract deteriorations in engine performance and in the exhaust-gas composition during vehicle operation. The packages generally used combine individual components with various attributes.

Care and precision are required both when testing additives and in determining their optimal compositions and concentrations. Undesirable side-effects must be avoided. Basic additives are added at the refinery to protect the plants and to ensure a minimum fuel quality. To further improve quality, brand-specific multifunction additives can be added at the refinery's filling stations when the road tankers are filled (end-point dosing).

Figure 3: Vapor pressure of gasoline as a function of temperature depending on the ethanol and methanol content (DIN EN 13016)

Detergents
The setting and preparation of the mixture composition of air and fuel in the combustion chamber is pivotal for trouble-free driving and minimization of pollutants in the exhaust gas. Keeping the entire intake system (fuel injectors, intake valves) clean is an important prerequisite for meeting the optimized conditions in the new state. Effective cleaning additives (detergents) help to keep surfaces clean and remove existing coatings.

Corrosion inhibitors
The ingress of water/moisture may lead to corrosion in fuel-system components. Corrosion can be effectively eliminated by the addition of corrosion inhibitors, which form a thin protective film on the metal surface.

Aging stabilizers
Oxidation inhibitors (antioxidants) are added to fuels to improve their stability during storage. They prevent rapid oxidation caused by oxygen in the air.

Blend components for fossil gasolines
Bioethanol
Production from sugar and starch
Bioethanol can be obtained from products containing sugar and starch and is the most widely produced biofuel worldwide. Plants containing sugar (sugar cane, sugar beet) are fermented with yeast, the sugar fermenting to form ethanol in the process.

When bioethanol is obtained from starch grains such as corn, wheat or rye are pretreated with enzymes in order to partially split the long-chain starch molecules. A split into dextrose molecules occurs during the subsequent likewise enzymatically performed saccharification. Bioethanol is created in a further process step by means of fermentation with yeast.

Production of lignocellulose
Enzymes can also be used to produce bioethanol from lignocellulose. Lignocellulose forms the structural framework of the plant cell wall and contains the chief constituents lignin, hemicellulose and cellulose. The advantage of this process is that the entire plant can be used and not just that part containing sugar or starch. Because of this new approach, this product is also referred to as 2nd-generation bioethanol. However, the enzymes can split cellulose, but not lignin. The enzymes developed to date are still highly sensitive with regard to the usable biomass such that this process is slow in acquiring economic significance.

Use of bioethanol
Bioethanol is, on the basis of its properties, highly suitable for admixing in gasolines, particularly in order to increase the octane number of pure gasoline. That is why virtually all gasoline standards permit the addition of ethanol as a blend component. Even the biofuel policy of the European Union leads one to expect that the market penetration and the proportion of bioethanol in gasolines will continue to rise if it is guaranteed that bioethanol is created on a sustained basis and not in competition with foods.

Bioethanol can also be used as a pure fuel in gasoline engines in flexible-fuel vehicles (FFVs). These vehicles can run both on gasoline and on pure ethanol as well as any mixture of gasoline and ethanol. A gasoline with 85 % (V/V) ethanol is offered in some European countries, for example Germany, France, and Sweden. On account of the cold-start problems at low temperatures, the maximum ethanol concentration is sometimes reduced depending on the local climate. Fuel samples exhibit typical ethanol contents of 75 to 85 % (E85) in summer and 65 to 85 % in winter. The quality of E85 is defined for Europe in the fuel specification EN 15293 [8] and in the USA in ASTM D5798 [9]. In Brazil gasolines are basically only sold as ethanol fuels, which are also called gasohol and contain 22 to 26 % (V/V) ethanol. Unblended ethanol, E100, is also available at many Brazilian filling stations, but this contains 7 % (m/m) water.

Methanol
Manufacture
Methanol is primarily produced not by regenerative means from fossil energy sources such as coal and natural gas, and therefore makes no contribution to reducing CO_2 emissions. Nevertheless, China for strategic reasons relies on methanol fuels because they enable part of its high fuel demand to be covered locally from coal. Here, M 15 appears to represent an upper limit for use in conventional gasoline engines. In China, an M85 analogous to E85 is additionally being discussed for flexible-fuel vehicles.

Use of methanol
With the same alcohol content, methanol fuels have a significantly greater corrosive effect on ferrous alloys than ethanol fuels. Even demixing occurs much more quickly when the fuel is fouled by water. Because of the negative experiences of methanol fuels in Germany during the oil crisis in 1973 and also due to its toxicity, the use of methanol as a blend component has again been abandoned in Germany. From a worldwide point of view, only occasional methanol admixtures are being conducted at present, and then for the most part – apart from China – with a content of well below 5 % (M5).

Diesel fuel

Diesel-fuel grades
As well as petroleum-based conventional diesel fuel, purely paraffinic fuels, particularly from renewable sources, and biodiesel have also become important.

Fuel standards
The standard that lays down the requirements for conventional diesel fuels in Europe is EN 590 [10]. The most important characteristics are set out in Table 2. Even the premium qualities additionally sold at some filling stations (e.g., Super diesel, Ultimate, V-Power diesel) satisfy this standard. Standard and premium diesel fuels differ in the basic quality, in the addition of paraffinic fuel components, and in the additives.

Up to 7 % (V/V) biodiesel (FAME) can be admixed with diesel fuel in accordance with EN 590, where the quality of the biodiesel is stipulated by standard EN 14214 [11]. The admixture of biodiesel improves lubricity, but also reduces oxidation stability. For the purpose of safeguarding sufficient oxidation stability, EN 590 was supplemented in 2009 to include the parameter induction time and a minimum requirement established. The induction time is a measure of the fuel's aging reserve.

The US standard for diesel fuels, ASTM D975 [12], specifies a smaller number of quality criteria and defines less stringent limits. It permits the admixture of max. 5 % (V/V) biodiesel, which must satisfy the requirements of standard ASTM D6751 [13].

Characteristics
Cetane number
The cetane number (CN) expresses the ignition quality of the diesel fuel [14]. The higher the cetane number, the greater the fuel's tendency to ignite. As the diesel engine dispenses with an externally supplied ignition spark, the fuel must ignite spontaneously (auto-ignition) and with minimum delay (i.e., ignition lag) when injected into the hot, compressed air in the combustion chamber. Cetane number 100 is assigned to n-hexadecane (cetane), which ignites very easily, while slow-igniting α-methyl naphthalene

is allocated cetane number 0. The cetane number of a diesel fuel is determined in a standardized CFR single-cylinder test engine with a variable compressor piston (CFR, Cooperative Fuel Research). The compression ratio of the fuel to be tested is measured at constant ignition lag. Reference fuels composed of cetane and heptamethylnonane, a component with the cetane number 15, are operated with the determined compression ratio. The proportion of cetane in the mixture is altered until the same ignition lag is obtained. The cetane proportion in percent specifies the cetane number.

The expenditure of an engine test to determine the cetane number can be avoided by determining in a constant-volume combustion chamber the ignition lag, i.e., the time interval between the start of injection and compression ignition. The derived cetane number (DCN) can be calculated from the ignition lag with the aid of empirically determined factors in accordance with the standard EN 15195 [15] or EN 16144 [16]. Alternatively, the DCN can also be determined in accordance with the standard EN 16715 [17] from the ignition lag and the combustion delay. The ignition lag is also measured in the standard EN 17155 [18]. The ignition lag of a primary reference material is used to assign the measured ignition lag to the cetane number. In this process this is referred to as the indicated cetane number (ICN).

Cetane numbers over 50 are desirable for optimum operation of modern engines, particularly under cold-starting conditions. High-quality diesel fuels contain a high proportion of paraffins with high cetane numbers. Aromatic compounds exhibit only a low ignition quality.

Cetane index

Yet another parameter of ignition quality is provided by the cetane index, which is calculated on the basis of fuel density and various points on the boiling curve. This purely mathematical parameter does not take into account the influence of cetane improvers on ignition quality. In order to limit the adjustment of the cetane number by means of cetane improvers, both the cetane number and the cetane index have been included in the list of requirements in the standard EN 590.

Boiling range

The boiling range of the fuel, i.e., the temperature range in which the fuel vaporizes and condenses again under standard conditions depends on its composition and is between 160 °C and 370 °C. Figure 4 shows boiling curves for different types of diesel fuel, the composition of which will be addressed in more detail later. A low initial boiling point is a prerequisite for a fuel suitable for use in cold weather, but also increases the risk of cavitation damage and results in greater system wear due to poorer lubrication properties.

Table 2: DIN EN 590 (October 2017): Selected requirements of diesel fuels

Requirements		Unit	Characteristic
Cetane number, min.		–	51
Cetane index, min.		–	46
Density (at 15 °C), min./max.		kg/m^3	820/845
Viscosity (at 40 °C), min./max.		mm^2/s	2.0/4.5
Sulfur content, max.		mg/kg	10
Lubricity, “wear scar diameter”, max.		µm	460
FAME content, max.		% (V/V)	7
Oxidation stability	Insoluble[3], max.	g/m^3	25
	Induction time (at 110 °C), min.	hours	20
Water content, max.		mg/kg	200
Total contamination, max.		mg/kg	24
CFPP[1] in six seasonal classes, max.[2]		°C	+5 to –20
Flash point		°C	>55

[1] Filterability limit. [2] Determined nationally, for Germany 0 to –20 °C.
[3] Sum total of insoluble substances after aging.

If, however, the end of boiling is at the high end of the temperature scale, this can result in higher soot emissions and nozzle coking. This refers to the formation of deposits as a result of the chemical decomposition of non-volatile fuel components in the spray hole and on the nozzle cone and the addition of combustion residues. The processes of carbon depositing are highly complex. Above all non-volatile fuel components from the refinery cracking processes contribute to coking.

The degree of coking, which is calculated from the measured hydraulic throughflow of the uncleaned and the cleaned nozzle, is for a specified nozzle geometry a measure of the tendency of a fuel to form deposits in the injection nozzles. Conversely, it is possible to assess with a reference fuel how the design of different nozzle configurations influences the formation of carbon deposits.

When the end of boiling is higher, the ingress of fuel over the cylinder walls into the engine oil is greater. For this reason, the percentage of non-volatile fuel components should not be too high.

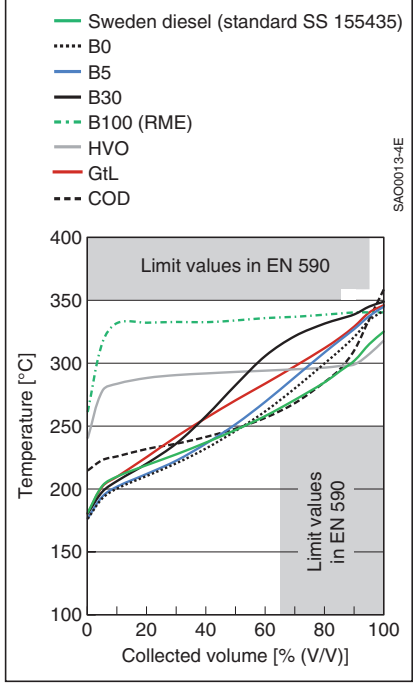


Figure 4 shows the boiling curves of different types of diesel fuels:

– Sweden diesel, fuel with reduced aromatic-compound content in accordance with the standard SS 155435 [19],
– B0, petroleum-based diesel fuel,
– B5, petroleum-based diesel fuel with 5 % biodiesel,
– B30, petroleum-based diesel fuel with 30 % biodiesel,
– B100, pure biodiesel, RME (Rapeseed Methyl Ester),
– HVO, paraffinic diesel fuel through hydrogenation of vegetable oils (Hydro-treated Vegetable Oil),
– GtL, paraffinic diesel fuel, synthetically produced from natural gas (Gas-to-Liquid),
– COD, diesel fuel from olefinic refinery components (Conversion-of-Olefins-to-Distillates).

The collected volume of condensate is plotted against the temperature in Figure 4. The high boiling range (320 to 360 °C) of biodiesel (B100) compared with petroleum-based conventional diesel fuel (B0) can be discerned. The admixture of 5 or 30 % biodiesel (B5 or B30) already impacts significantly on the higher content of the boiling range. The limitation of the admixture of biodiesel to max. 7 % (V/V) in EN 590 is not least due also to its non-volatility. Purely paraffinic fuels are more favorable than biodiesel with regard to the boiling range. Diesel fuel synthetically produced from natural gas (Gas-to-Liquid, GtL) exhibits similar boiling characteristics to conventional diesel fuel or Swedish diesel fuel reduced in aromatic-compound content in accordance with the standard

Figure 4: Boiling curves of different types of diesel fuels

B0, B5…B100 Admixtures of biodiesel,
RME Rapeseed methyl ester,
HVO Hydro-treated vegetable oil,
GtL Gas-to-Liquid,
COD Conversion-of-Olefins-to-Distillates.

SS 155435. In the boiling curve of paraffinic fuel created by the hydrogenation of vegetable oils (Hydro-treated Vegetable Oil, HVO) the relatively uniform composition in the middle boiling range becomes clear because the paraffins contained in the HVO have come from a narrowly limited fatty-acid spectrum.

Filterability limit
Precipitation of paraffin crystals at low temperatures can result in fuel-filter blockage, ultimately leading to an interruption of the fuel flow. In worst-case scenarios, paraffin particulates can start to form already at temperatures of 0 °C or even higher. The cold resistance of a fuel is assessed by means of the temperature at which the fuel filter becomes clogged under defined test conditions (CFPP, Cold Filter Plugging Point, filterability temperature limit). Standard EN 590 defines different limit values for the CFPP in various classes, and can be defined by individual member states depending on the prevailing geographical and climatic conditions.

Formerly, owners sometimes added regular gasoline to their vehicle fuel tanks to improve the cold response of diesel fuel. This practice is no longer necessary now that fuels conform to standards, and this may in any case cause damage particularly in today's widely used systems with high-pressure fuel injection.

Flash point
The flash point is defined as the temperature at which the quantities of vapor which a combustible fluid emits to the atmosphere are sufficient to allow a spark to ignite the air/vapor mixture above the fluid. For safety reasons (e.g., for transportation and storage), diesel fuel must comply with Hazard Class A III, i.e., its flash point must be above 55 °C. Less than 3 % gasoline in the diesel fuel is sufficient to lower the flash point to such an extent that ignition becomes possible at room temperature.

Density
The energy content per unit of volume increases in the case of purely fossil diesel fuel produced only from crude oil with density. Assuming constant activation of the injectors (i.e., constant injected fuel quantity), the use of fuels with widely different density causes variations in mixture ratios (change in the air/fuel ratio λ) due to fluctuations in calorific value. When an engine runs on fuel that has a high type-dependent density, engine performance and soot emissions increase; at low fuel density, these parameters drop. For this reason, the type-dependent density spread for diesel fuel is tightly limited.

When biodiesel is admixed with diesel fuel, the density of the mixture increases due to the higher density of biodiesel, but the energy content decreases due to the amount of oxygen contained.

Viscosity
Viscosity is a measure of a fuel's resistance to flow due to internal friction. Excessively low viscosity of the diesel fuel leads to increased return quantities in the injector, as a result of which the fuel-injection system is additionally heated up and in some cases the injected fuel quantity required for full load is no longer achieved. In addition, the risk of wear and cavitation erosion increases.

Much higher viscosity – for instance when pure biodiesel (FAME) is used – causes a higher peak injection pressure at high temperatures in non-pressure-regulated systems (e.g., unit injector systems) compared with petroleum diesel. The fuel-injection system may not therefore be applied with petroleum diesel to the permissible peak pressure. High viscosity also changes the spray pattern due to the formation of larger droplets. The droplet distribution in the combustion chamber is called the spray pattern. Since the fuel viscosity increases sharply in cold conditions, restrictions in fuel delivery may be experienced as a result of the reduction of the volumetric flow.

Lubricity
The hydrodynamic lubricity of diesel fuels is not as important as the lubricity in the mixed-friction range. The introduction of environment-compatible, hydrogenation-desulfurized fuels resulted in huge wear problems with distributor injection pumps in the field. Desulfurization also sees the removal of fuel components which are important to lubricity. Lubricity enhancers have to be added to many fuels to avoid these problems. The standard EN 590 prescribes a minimum lubricity, measured as wear of max. 460 µm in an oscillation wear test (High-Frequency Reciprocating Rig, HFRR [20]).

The minimum-lubricity requirement is also achieved when sufficient biodiesel, usually at least 4 % (V/V), is admixed with the diesel fuel.

Oxidation stability
The constituents of diesel fuels are subject to a more pronounced extent than gasoline to oxidation caused by oxygen in the air. This is the case particularly when biodiesel is admixed. Polymers and acids are produced during oxidation, which is also referred to as fuel aging. Aging polymers can directly give rise to the formation of coatings and to gumming in the fuel-injection system. Aging acids frequently react with metal ions to produce organic salts and soaps (carboxylates), which are insoluble in diesel fuel and therefore also form coatings.

It is important that the fuel, while it is in the vehicle, has a sufficient aging reserve. The aging reserve is measured as induction time under the test conditions defined in EN 15751 [21] at 110 °C. When diesel fuel at the filling-station pump exhibits an aging reserve of at least 20 hours according to this test standard, it is ensured that the fuel is stable enough for normal use. In the past, failures caused by fuel aging have only occurred in isolated cases when vehicles were subject to very long idle periods, in special agricultural applications, or also in the construction sector.

Total contamination
Total contamination refers to the sum total of undissolved foreign particulates in the fuel, such as sand, rust, and insoluble organic components, including aging polymers of the fuel. The standard EN 590 permits a maximum total contamination of 24 mg/kg. Very hard silicates which occur in mineral dust are specially damaging to high-pressure fuel-injection systems with narrow gap widths. Even a fraction of the permissible overall contamination level if the particulates were abrasive would cause erosive and abrasive wear.

Since 2014 there have in many regions of Europe been a large number of reports of damage to fuel-injection systems caused by abrasive particulates (e.g., to the seat of solenoid valves) [22]. Wear of this nature results in valve leakage, which lowers fuel-injection pressure and engine performance, and increases particulate emissions. Typical European diesel fuels contain about 2,500 particulates per 1 m*l*. Particulate sizes around 4 µm are particularly critical. High-performance fuel filters with high filtration efficiency are therefore necessary to prevent damage caused by particulates.

Water in diesel fuel
Up to approximately 100 mg/kg water dissolve in diesel fuel at room temperature. The solubility limit depends on the composition of the diesel fuel, particularly the aromatic-compound content, the additives, the proportion of biodiesel, and the ambient temperature. The standard EN 590 permits a maximum water content of 200 mg/kg. Although diesel fuels in storage tanks can contain much higher amounts of water, market surveys of fuels show that water content rarely exceeds 200 mg/kg. Samples often do not detect any water, or detection is incomplete, since water is deposited on walls in a separate phase in the form of undissolved, “free” water, or it settles at the bottom. Whereas dissolved water does not damage the fuel-injection system, even very small quantities of free water can cause wear or corrosion damage to fuel-injection components within a short period of time.

Additives
Additives, long a standard feature in gasolines, have attained increasing significance as quality improvers in diesel fuels. Additive packages, which are effective in a number of respects, are used for the most part. As the total concentration of the additives generally lies below 0.1 %, the fuel's physical characteristics – such as density, viscosity, and boiling curve – remain unchanged.

Lubricity enhancers
It is possible to improve the lubricity of diesel fuels with poor lubrication properties, caused, for example, by hydrogenation processes during desulfurization, by adding fatty acids or glycerides. Glycerides are partially cracked vegetable oils. Even biodiesel contains proportions of glycerides. In this case, if diesel fuel already contains biodiesel, no further lubricity enhancers are added.

Cetane improvers
Nitric-acid esters of alcohols, which shorten the duration until ignition (ignition lag), are frequently used as cetane improvers. They help, particularly during cold starting, to prevent an increase in combustion noise (engine noise) and extreme smoking.

Flow improvers
Flow improvers consist of polymer substances that lower the filterability temperature limit. They are generally added in winter to ensure trouble-free operation at low temperatures. Although flow improvers cannot prevent the precipitation of paraffin crystals from diesel fuel, it can severely limit their growth. The crystals produced are then so small that they do not clog the filter pores completely and allow the passage of fuel until they melt again as the engine heat begins to build up.

Detergents
Detergents are cleaning additives which are added to the fuel to keep nozzle holes free from deposits on the inside and at the outlet. The cleaning effect of detergents is based on their molecular structure of groups of different polarity: Long nonpolar hydrocarbon chains ensure good solubility in the fuel while coordination to the for the most part also polar coatings is facilitated by way of polar groups. Detergents function in this way as carriers with which existing deposits can be removed via the fuel. Furthermore, these additives can also prevent the build-up of new deposits by coordination of the polar groups to metal surfaces.

Corrosion inhibitors
Typical corrosion inhibitors are longer-chain organic monomeric and dimeric acids, amines or ammonium salts. These compounds are deposited with their polar end on the surfaces of metal parts and protect them against corrosion if water is entrained.

Antifoaming agents (defoamers)
Adding defoamers helps to avoid excessive foaming when the vehicle is refueled quickly. Antifoaming agents such as silicones reduce the surface tension, causing bubbles that are created to burst rapidly.

Blend components for fossil diesel fuels

Biodiesel

At present, biodiesel is the most important alternative fuel for diesel engines. The term biodiesel covers fatty acid esters which are created through transesterification of oils or greases with methanol. This creates fatty acid methyl esters (FAME). Fatty acid methyl esters are in their molecule size and thus also in their physical-chemical properties much more similar to diesel fuel than vegetable oils. Biodiesel and vegetable oils are therefore not the same. Nevertheless, biodiesel differs significantly from petroleum diesel, since the fatty acid esters are polar and chemically reactive. Conventional diesel fuel on the other hand is a nonpolar mixture of paraffins and aromatic compounds and therefore less active.

Manufacture

Vegetable oils or animal fats can be used as the starting material for biodiesel. In Europe primarily rape oil is used, in North and South America soybean oil, in Asia palm oil, and on the Indian subcontinent to an even smaller extent the oil from the purgier nut (jatropha). Used frying oil methyl esters (UFOME) are produced worldwide. Because of the global trade in biodiesel and its raw materials, fuels containing FAME as a rule contain mixtures from different sources.

Because transesterification of grease and oils is technically easier with methanol than with ethanol, the methyl esters are manufactured almost exclusively. Methanol is generally produced from coal. Therefore, fatty acid methyl esters cannot, strictly speaking, be seen as fully biogenic.

Properties

The properties of biodiesel are determined by various factors. The various vegetable oils differ in the composition of the fatty-acid blocks and demonstrate typical fatty-acid patterns. The type and quantity of unsaturated fatty acids have, for example, a decisive influence on the cold resistance and resistance to aging of biodiesel. The properties are also affected by the pretreatment of the vegetable oils and the production process of the biodiesel.

Standards

The quality of biodiesel is regulated in fuel standards. If technically tenable, limitations with regard to raw materials must be avoided. The quality requirements for biodiesel are therefore described not by way of the raw-material composition, but predominantly by the material properties. It is essential in particular to ensure suffi-

Table 3: DIN EN 14214 (May 2019): Selected requirements of FAME

Requirements	Unit	Characteristic
Density (at 15 °C), min./max.	kg/m^3	860/900

cient cold resistance, good resistance to aging (oxidation stability), and to eliminate contamination caused by the process.

The European standard EN 14214 is the most internationally comprehensive specification for biodiesel and describes the requirements relating to the use of biodiesel as a pure fuel and as a blend component for diesel fuel. This standard serves to ensure that the quality of biodiesel meets the requirements in both applications (Table 3).

The American biodiesel standard ASTM D6751 is less quality-oriented. For example, the minimum requirement for oxidation stability in this standard is less than half the aging reserve (induction time) specified in EN 14214. Thus, in the USA the risk of problems arising as a result of fuel aging, in particular under limit-value application and field conditions, is higher.

Other countries such as Brazil, India and Korea have geared themselves, to a large extent, towards the European B100 standard EN 14214.

Use in vehicles

Since the tax benefit was discontinued biodiesel has barely been used as a pure fuel (B100) in Germany. The introduction of diesel particulate filters and stringent requirements regarding the limitation of vehicle emissions under field conditions even over high mileages limit the use of B100 to a few special applications. Originally B100 was used predominantly in commercial vehicles, because the annual high mileage ensured fast consumption, which enabled problems with insufficient oxidation stability to be avoided.

From an engine-engineering viewpoint, it is more favorable to use biodiesel as a low-percentage mixture with petroleum diesel. The high proportion of petroleum diesel ensures sufficient stability and, at the same time, the biodiesel ensures an improved lubricating effect.

For practical purposes, it is important to specify not only the pure component B100, but also the diesel/biodiesel mixtures offered on the market. Here, the trend is towards admixtures up to max. 7 % biodiesel (B7 in Europe).

In closed fleets, higher proportions of biodiesel are also used (B30 in France, B20 in the USA). In the case of higher contents, the high boiling point of biodiesel can cause it to be heavily introduced into the engine oil after its has been injected into the combustion chamber via condensation on the cylinder walls. This affects, above all, vehicles which are fitted with diesel particulate filters, and in which filter regeneration occurs by way of a retarded secondary injection. Depending on the application, it is possible, particularly in slow part-load operation, to encounter an unacceptably high introduction of biodiesel, which necessitates shorter oil-replacement intervals. The higher boiling point of biodiesel can be taken into account by application in new developments of engines and vehicles.

An additional standard has been developed in Europe for B20/B30, EN 16709 [23], in which two grades with different biodiesel content are specified: B20 with 14 to 20 % and B30 with 24 to 30 % biodiesel. To avoid problems caused by fuel aging, the minimum oxidation-stability requirement from EN 590 (B7) has been adopted for both grades, i.e., the induction time must be at least 20 hours, irrespective of the biodiesel content. In this way, the new European standard EN 16709 differs fundamentally from the American standard ASTM D 7467 [24], in which merely an induction time of at least 6 hours was laid down for biodiesel contents of 6 to 20 %.

The standard EN 16734 [25] has also been adopted in Europe; this standard covers diesel fuels with biodiesel contents of 0 to 10 % and thus overlaps to a large extent with the standard EN 590 for standard diesel fuel (0 to 7 % biodiesel). Still the market demand for this additional quality is low. Furthermore, this fuel is not permitted to be placed on the market in all European countries.

Vegetable oils

Vegetable oils which have not been transesterified into biodiesel may not be admixed with diesel fuels due to their high density, high viscosity, and low volatility. Previously, vegetable oils, particularly rapeseed oil, were used with great success in older diesel engines subject to minimal emission requirements. Only few

modern diesel engines with high-pressure fuel injection can be run on vegetable oils, for example in tractors which have been approved for such operation.

Paraffinic diesel fuels
Further blend components for fossil diesel fuels are purely paraffinic fuels, which consist exclusively of saturated hydrocarbons. Since there are no aromatic components, the particulate, HC and CO emissions of purely paraffinic fuels are significantly reduced when compared with conventional fuels.

Manufacture
Paraffinic fuels can be created in three different ways:
– Fischer-Tropsch process [26]
– Hydrogenation of vegetable oils
– COD process (Conversion of Olefins to Distillates)

Fischer-Tropsch process
The starting product required is synthesis gas, which consists of hydrogen (H_2) and carbon monoxide (CO). It can be created from natural gas, coal or biomass. By converting synthesis gas, it is possible to build up on catalysts linear, straight-chain hydrocarbons (n-paraffins). The Fischer-Tropsch catalysts function quite non-specifically such that a wealth of different components is obtained, starting with gases through short-chain gasoline components, kerosene and diesel paraffins, right down to oils and waxes of high molecular weight. For reasons of economy, the production mixture is for the most part optimized to a maximum diesel yield. The frequently used designation synthetic diesel fuels makes clear that the hydrocarbons in the Fischer-Tropsch process are made from the building blocks H_2 and CO.

These fuels were originally also referred to as designer fuels, because the notion existed that the composition of synthetic diesel fuel could be geared exactly to the demands of diesel-engine technology. In view of the wide range of products obtained from Fischer-Tropsch synthesis, the notion of producing fuels of customized composition does not appear realistic.

For the designation of this type of synthetic fuels it is common practice to use the terms derived from the conversion process Gas-to-Liquid (GtL), Coal-to-Liquid (CtL), or Biomass-to-Liquid (BtL), depending on whether the paraffins have been created from natural gas, coal or biomass.

The production of CtL and GtL is economically significant. The production of GtL is only worthwhile with large natural-gas deposits where the natural gas cannot be attributed to any direct use. CtL and GtL are based on fossil energy sources such that no reduction in CO_2 emissions is achieved. In the case of BtL, there is no CO_2 advantage. However, industrial plants that produce BtL are not as yet in operation.

Biomass is utilized completely in the manufacture of BtL. The plants are first broken down into chemical building blocks from which fuels are then synthesized in a subsequent step. Fuels which are manufactured in this way are called second-generation fuels. This procedure differs fundamentally from the hitherto customary methods, which are used for the production of first-generation fuels and are based on the use of agricultural crops. Biodiesel can be created by transesterification and bioethanol by fermentation from the components contained therein such as fats, starches and sugars.

Hydrogenation of vegetable oils
Paraffinic diesel fuels can also be obtained by hydrogenating fats and oils. The term hydro-treated vegetable oil (HVO) is often used for these products. Unlike transesterification into biodiesel, conversion with hydrogen places fewer demands on the origin and quality of the starting materials. Hydrogenation results in a cracking of fats and oils, during which all the oxygen atoms and unsaturated bonds are also removed. Long-chain paraffins are obtained from the fatty acids, the glycerin content is converted into propane gas, and the oxygen is bound as water. Because paraffins are created from biomass in this way, they are referred to as bioparaffins. The production of bioparaffins can be implemented in separate plants or even integrated into existing refinery processes.

The hydrogenation of vegetable oils to HVO is developing increasingly into a significant alternative to the transesterification of biodiesel.

COD process
The third way of producing paraffins is to convert olefins in accordance with the COD process (Conversion of Olefins to Distillates), frequently only as a subsequent step to previous refinery processes. Olefinic product fractions are used for this purpose. Paraffins can be produced by oligomerization, a specifically controlled reaction between individual olefins, and hydrogenation.

Reprocessing
All three manufacturing processes described here are followed by an additional isomerization step in which linear molecules are converted into branched molecules. This is the only way to achieve the required cold resistance.

Properties
Regardless of the type of production, paraffinic hydrocarbon mixtures with very similar chemical compositions and excellent engine-engineering properties are created. The fuels are sulfur- and aromatic-free and have partly high cetane numbers. But because their density is below the lower limit value defined in EN 590, the new specification EN 15940 [27] was developed (Table 4). This standard describes the quality which is required to use the fuel as a pure component.

Use in vehicles
Paraffinic fuel in accordance with EN 15940 can be used in vehicles which have been approved for this fuel. Pure paraffinic fuels are used mostly in older vehicles with no diesel particulate filters and lend themselves to use above all in centers of population in order to reduce the particulate load on a local level. To reduce the CO_2 emissions of vehicle fleets, HVO has recently been increasingly used in the haulage industry.

Paraffinic hydrocarbons are ideal for marketing as blend components in premium diesel fuels. Furthermore, diesel fuels which fail to satisfy the requirements established in EN 590 can be improved by the addition of paraffinic components to such an extent that they conform to the standard.

Table 4: DIN EN 15940 (October 2019): Selected requirements of paraffinic diesel fuels

Requirements		Unit	Characteristic

Methane

Methane (CH_4) is the simplest aliphatic hydrocarbon. Gasoline and diesel engines can be run on methane.

Natural gas

Composition

Natural gas is fossil in nature. Natural gas is promoted worldwide and can be prepared with relatively little effort. The main constituent of natural gas is methane (CH_4) with a minimum content of 80 % (V/V). Further constituents are inert gases, such as carbon dioxide, nitrogen and short-chain hydrocarbons. Oxygen and hydrogen are also contained. Depending on its origin, however, its composition varies, which results in fluctuations when it comes to density, calorific value and knock resistance. The way in which natural gas is transported also impacts on its composition.

Unlike when it is transported as gas through pipelines, natural gas that is distributed by ships in liquid form as LNG (liquefied natural gas) contains hardly any CO_2, pentane, hexane, and hydrogen sulfide. The properties of natural gas as a fuel are set out in the European standard EN 16723-2 [30], in which standardized quality requirements with regard to natural gas, to pure biomethane and to blends of natural gas and biomethane are defined.

Table 5 provides an overview of the composition and properties of natural gas worldwide.

To be able to better describe the combustion behavior of gaseous fuels like natural gas, two additional product properties are defined.

Methane number

The methane number describes the knock properties and specifies the volume

percentage of methane in a methane/hydrogen mixture which exhibits in a test engine under standard conditions the same knock characteristics as the gaseous fuel to be tested. Pure methane is assigned the methane number 100, hydrogen the methane number 0. As with the definition of the octane number for gasolines, the following applies to gases and gas mixtures: the lower the methane number, the lower the knock resistance.

Wobbe index

The upper Wobbe index W_s specifies the gross calorific value H_s on a volumetric basis. For many applications it is important to know the energy content of the volumetric flow. Only with reference to the Wobbe index can the flow of gas be set to the desired amount of energy and the gas quality easily corrected in the event of changes. A consideration of the calorific value alone is not enough. The upper Wobbe index W_s is obtained by dividing the calorific value H_s by the square root of the relative density of the combustion gas. The relative density of the combustion gas is the quotient of the density of the combustion gas and the density of dry air, both determined under the same reference conditions (pressure and temperature). If, however, all that matters is the mechanically utilizable energy content in the volumetric flow, reference is made to the lower Wobbe index W_i, i.e., the net calorific value H_i on a volumetric basis.

Biomethane

Biomethane is treated biogas which is made from biogenic materials such as energy crops, liquid manure or waste containing biomass. The CO_2 savings from the use of biogenic basic material can be set off against the CO_2 emissions during combustion in such a way that the total CO_2 emissions for biomethane are clearly reduced compared with fossil natural gas. Production volumes of biomethane which exceed the local demand are frequently fed into the natural-gas network. In summer, when the demand for natural gas is too low for heating purposes, natural gas can contain significant amounts of biomethane.

A lot of CO_2 is produced in biogas plants as well as methane. Processes at plant scale in which CO_2 can be biologically converted by highly specialized microorganisms into methane are well advanced and are already being introduced occasionally.

Synthetic methane

In initial plants methane is also obtained from electricity whereby hydrogen (H_2) is generated by electrolysis from water. The conversion of H_2 with CO_2 to CH_4 is then performed chemically in the presence of catalysts in accordance with the Sabatier process.

Storage of natural gas

Natural gas is stored either in gas form (CNG, compressed natural gas) at a pressure of 200 bar or as a liquefied gas (LNG, liquefied natural gas) at –162 °C in a cold-resistant tank. LNG requires only one third of the storage volume of CNG, however the storage of LNG requires a high expenditure of energy for liquefying. Filling stations dispense natural gas almost exclusively in the form of CNG. LNG is as a rule only offered if the filling station can already be supplied with LNG.

CO_2 emissions

The hydrogen/carbon ratio of natural gas is roughly 4:1, that of gasoline on the other hand is 2,3:1. As a result of the lower amount of carbon in natural gas, it produces less CO_2 and more H_2O than gasoline when it is burned. A gasoline engine converted to natural gas creates, for a comparable power output without any further optimization, approximately 25 % fewer CO_2 emissions than when run on gasoline. However, if a small methane slip remains during combustion, the additional methane emissions must be taken into account in the climate-damaging-potential footprint since direct methane emissions have a 20-times greater impact than CO_2. Even escaping gaseous methane is relevant to the carbon footprint when for example an overpressure builds up in the LNG storage tanks and this is discharged to the atmosphere.

Use in vehicles

Natural gas is currently used primarily in passenger cars with gasoline engines which are of bivalent design, i.e., can be run separately on natural gas and gasoline. For buses and trucks there are gasoline gas engines which are of monovalent design for natural gas [31]. Also used in the diesel gas engine, in which natural gas in burned in mixed operation with diesel fuel. The natural gas is in this cased injected separately from the diesel fuel with the air into the engine [32].

Alternatively, natural gas can also be injected directly in a pilot-injection process together with the diesel fuels [33]. Whether the market for natural-gas vehicles will gain in importance depends primarily on the purchase and running costs for the vehicle owner, but also on the expansion of the filling-station infrastructure to CNG and LNG.

Liquefied petroleum gas

Liquefied petroleum gas (LPG), also called liquid gas, is obtained during the extraction of crude oil and during different refinery processes. LPG is a mixture of the main components of propane and butane. It can be liquefied at room temperature under comparatively low pressure. Because it has a lower carbon content than gasoline, approximately 10 % less CO_2 is produced during combustion. The octane number is approximately 100 – 110 RON. The demands placed on LPG for use in motor vehicles are laid down in the European standard EN 589 [34].

Passenger cars for liquefied petroleum gas are also for the most part bivalent and can therefore be run separately on gasoline and liquefied petroleum gas. However, liquefied petroleum gas can cause significant wear on the intake valves if valve or seat-insert materials have not been adapted to running on LPG.

Hydrogen

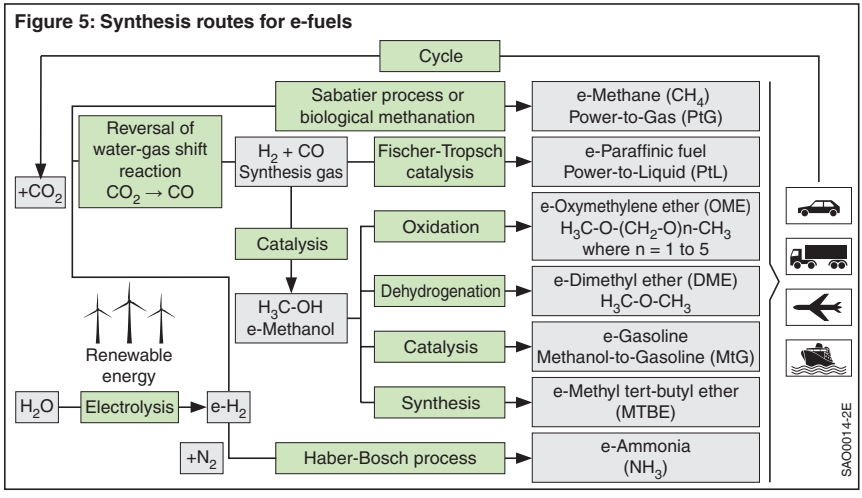
Manufacture

Hydrogen (H_2) can be produced from fossil or renewable sources. The classic production methods from fossil raw materials such as steam reforming of natural gas, gasification of coal in the presence of water or partial oxidation of mineral oil result in the release of considerable amounts of CO_2. Although no CO_2 emissions are produced locally during the engine combustion of hydrogen, the use of hydrogen of a fossil nature does not inevitably lead to a CO_2 advantage in direct comparison with natural gas, gasoline or diesel fuel.

Hydrogen can be regeneratively manufactured both by pyrolysis of biomass and by electrolysis or solar-thermal processes directly from water. CO_2 savings are obtained as a result of the production process and the overall expenditure of energy and are greater the more regeneratively produced energy is used in the process.

Because hydrogen today is primarily obtained industrially from natural gas, processes are also being developed with the aim of capturing the CO_2 created and injecting it into repositories (CCS, carbon capture and storage).

Storage



Hydrogen may have a very high mass-related energy density (approximately 120 MJ/kg and thus almost three times as high as that of gasoline), but its volume-related energy density is very low on account of the low specific density. When it comes to storage, this means that the hydrogen has to be compressed either under pressure (at 350 – 700 bar) or by liquefaction (cryogenic storage at –253 °C) in order to achieve an acceptable tank volume.

Another possibility is for the hydrogen to be stored as a hybrid. Certain metals and alloys form, with hydrogen, metal hydrides. The hydrogen that is embedded in the metal's atomic lattice can be released again by heating.

Use in vehicles

Hydrogen can be used both in fuel-cell drives and directly in internal-combustion engines. In the long term, emphasis is expected to be placed on use in fuel cells because this achieves better efficiency than in hydrogen internal-combustion engines.

Figure 5: Synthesis routes for e-fuels

Electricity-generated regenerative fuels

E-fuels refer to synthetic fuels which are manufactured with the aid of regeneratively produced electricity.

Manufacture
In the first step electrolysis is used to break down water into hydrogen (H_2) and oxygen (O_2). The created hydrogen, e-H_2, is the simplest e-fuel, which can be used directly, for example in a fuel cell.

Figure 5 shows how carbon-containing e-fuels can be constituted from e-H_2 in secondary reactions. Methane, e-cH_4, can be created by converting e-H_2 with CO_2. Gaseous e-fuels are called Power-to-Gas (PtG). It goes without saying that the CO_2 used must also be of a regenerative nature. Regenerative CO_2 can derive for example from biomass or be obtained from the ambient air. Due to the higher concentration of CO_2 industrial waste gases, for example from steel or cement works, suggest themselves as sources, but this CO_2 is not regeneratively produced.

To obtain in particular liquid e-fuels, accordingly named Power-to-Liquid (PtL), synthesis gas, a mixture of e-H_2 and carbon monoxide, is required. Carbon monoxide is available from CO_2 by a reversal of the water-gas shift reaction.
Starting out from synthesis gas, two basic reaction paths are possible. On the one hand, linear chains of hydrocarbons can be built up by means of Fischer-Tropsch synthesis. They are, depending on the chain length, typical constituents of gasoline, kerosene or diesel fuel.

Alternatively, e-methanol can also be produced from synthesis gas. Because limits are imposed on the direct use of methanol in gasoline engines, its further conversion to MTBE (methyl tertiary-butyl ether) or MtG gasoline (Methanol-to-Gasoline) suggests itself. Due to its high volatility and low cetane number of 5, methanol is not a fuel component for diesel engines Converting to dimethyl ether (DME) or to the higher oxymethylene ethers (OME) produces fuels with a cetane number > 70.

Also being discussed as a carbonless e-fuel aside from e-H_2 is ammonia (NH_3), which is easily available in the Haber-Bosch process from e-H_2 and nitrogen (N_2) and is possible both as a H_2 store and as a fuel.

Use in vehicles
All e-fuels which do not differ from the corresponding fossil or biogenous components or are very similar qualitatively to these are called drop-in fuels. e-H_2, e-CH_4, e-MTBE, MtG and Fischer-Tropsch gasoline and Fischer-Tropsch diesel fuel can either be used directly at 100 % in the overall vehicle population or else at least replace the conventional components in large if not equal proportions. This substitution potential, which would entail additional saving of significant quantities of CO_2 in the traffic sector, can from a technical standpoint be used directly and depends on the availability of e-fuels.

Other e-fuels such as e-DME or e-OME are, on account of their properties, not compatible with the vehicles in the on-the-road vehicle population. A new development of engines or at least their comprehensive adaptation is required to accommodate these fuels. The particulate emissions of these fuels are greatly reduced. In part, there can be technical advantages in the design of exhaust-gas treatment. Because of the necessary changes, however, these types of e-fuel are expected to find use in special applications and less so in the larger-scale vehicle population.

Prospects for e-fuels
Although the production of e-fuels requires an additional energy expenditure which is above its own energy content and the costs of their production, depending on the number of synthesis steps, far exceed the costs of the fossil components, e-fuels will be afforded opportunities in the future. Without e-fuels, for which a significant reduction of the production costs is forecast, the long-term CO_2 targets in the traffic sector cannot be achieved. Militating for the use of e-fuels is furthermore the fact that purely battery-electric drives can only gradually replace the internal-combustion engine in heavy goods vehicle traffic and long-distance transportation in the foreseeable future. For ships and in particular for aviation it is up to now

difficult to imagine that there could be a technical alternative to the replacement of fossil fuels with biofuels and e-fuels.

Research projects have hitherto failed to bring onto the market considerable quantities of e-fuels for the transport sector. Because the construction of large-scale plants for the production of e-fuels requires long lead times for planning, financing, design, and upscaling it is hardly expected by 2030 that significant proportions of fossil fuels can be replaced with e-fuels. All the more important then are short-term political moves that create a solid framework for investors so that e-fuels can make a contribution to meeting the CO_2 targets in traffic applications.

Results of research work into e-fuels and scenarios regarding their introduction are the subject of numerous publications. In the meantime, handbooks provide a good overview of this subject area [35].

Ethers

Dimethyl ether

Dimethyl ether (DME) with the structure $H_3C\text{-}O\text{-}CH_3$ has a boiling point of –25 °C and must therefore be kept under pressure at room temperature so that it can be injected in liquid form. The two methyl groups are separated by an oxygen atom in the DME. Molecules with carbon atoms isolated from each other generate little soot during combustion. DME also has a high cetane number, reducing combustion and lowering NO_x emissions. The high oxygen content of DME is however associated with a low calorific value H_u of 28.8 MJ/kg and thus a high volumetric increased consumption compared with diesel fuel (H_u of 43.0 MJ/kg).

Although DME from a combustion perspective is an ideal fuel for diesel engines, in reality only a few specially adapted vehicles use this fuel. DME liquefied under pressure is, due to its high vapor pressure and its low viscosity, not compatible with the existing injection components and engine designs developed for conventional diesel fuels.

The use of DME will, due to the necessary additional technical outlay on the vehicle, remain limited to just a few fleet vehicles in niche markets. Nevertheless, the possibility of using DME has been the subject of discussion again of late in connection with e-fuels. The manufacture of DME is performed by means of synthesis gas (H_2 and CO) is currently based mainly on carbon or natural gas, supplemented to a small extent by biomass or waste materials. If in future synthesis gas can be produced in larger quantities from hydrogen from electrolysis e-H_2 and regenerative CO_2, this could drive forward the use of DME in engine applications.

Oxymethylene ethers

Oxymethylene ethers (OME) too have carbon atoms isolated from each other by oxygen bridges and are therefore of interest due to their lower tendency to sooting.

It is clear from their chemical structure $H_3C\text{-}O\text{-}[CH_2\text{-}O]_n\text{-}CH_3$ that with OME ether molecules of different chain length are involved. The base component with $n=1$ (OME1) and a mixture of the longer

ethers with n = 3 to 5 (OME3-5) are being discussed as possible future fuels. OME too is an e-fuel when the synthesis gas from which OME is produced under other reaction conditions like DME consists of hydrogen from electrolysis and regenerative CO_2.

OME1

OME1 is technically easily available from synthesis gas. This oxymethylene ether, which is chemically more accurately called dimethoxymethane, is however not suitable either as a pure substance or as a blend component for existing diesel engines, although OME1 unlike DME is still liquid at room temperature.

With a low boiling point of 42 °C, low viscosity of 0.33 mm^2/s (at 20 °C) and a flash point of –18 °C, OME1 satisfies neither the hydraulic requirements with regard to high-pressure fuel injection nor the existing statutory safety provisions. Most research projects therefore focus on the synthesis possibilities and engine properties of the longer-chain ethers OME3-5.

OME3-5

Mixtures of the OME3-5 molecules have a boiling range that equates to a large extent to conventional diesel fuels. This opens up the prospect of being able to utilize the emission advantage of OME with fewer changes to the engine. Two properties of OME nevertheless prevent compatibility with the on-the-road vehicle population. The energy content of OME3-5 (H_i of OME3: 19.4 MJ/kg ; H_i of OME4: 18.7 MJ/kg; H_i of OME5: 18.1 MJ/kg) is less than half compared with diesel fuel (H_i of 43.0 MJ/kg), meaning that for the same engine power roughly 70 % higher volumetric injected fuel quantity is required. Furthermore, OME is not compatible with fluorocaoutchouc polymers, which are widely used as elastomer material in diesel fuel-injection equipment [36].

Engines with adapted materials and OME-specific calibration demonstrate significant advantages in untreated emissions, particularly low sooting. During combustion the formation of soot and NO_x is in reciprocal dependence of each other (trade-off). The application of high exhaust-gas recirculation rates permits a reduction of the NO_x emissions, which may be accompanied by a significant increase in soot particulates. This is not the case for OME because the formation of soot is greatly limited due to the carbon atoms isolated by oxygen bridges. Therefore both the concentration of NO_x and the number of soot particulates in the exhaust gas of OME can be greatly reduced [37]. The suitability of OME as a new fuel has also be verified in vehicle demonstrators [38].

To provide a basis for a future uniform quality for OME3-5, a tentative standard (DIN/TS 51699, [39]) is currently being developed in which the questions that are still open for example regarding thermo-oxidative stability, cold resistance, water content or limiting the content of OME2 and OME6 are addressed. Even a limit value for the total formaldehyde content must be introduced.

Unlike OME1, it is difficult to synthesize the higher oxymethylene ethers OME3-5. The equilibrium of starting materials, intermediates and end products arising from the reaction has a bearing on the chain length. During conversion the amount of formaldehyde that is formed must be controlled precisely, the water created removed, and released hydrogen recovered. For sustainability reasons the distillation outlay must also be kept as low as possible. The synthesis of OME3-5 is the subject of numerous research projects [40].

Urea/water solution

Application
A urea/water solution is used to reduce nitrogen oxides (NO_x) in the catalytic exhaust-gas treatment of diesel engines with the aid of SCR systems (see SCR system). To this end, this solution is not used as a fuel additive, but metered directly into the exhaust-system branch.

Designations
The solution used under the protected trade name AdBlue® consists of 32.5 % technically pure urea and 67.5 % demineralized water. The chemical total formula is: CH_4N_2O. Further designations are:
– carbamide in aqueous solution,
– Aqueous Urea Solution 32.5 % (AUS 32),
– NO_x reduction agent in acc. with DIN 70070 [1] or ISO 22241 [2] Part 1 to Part 4,
– urea/water solution,
– Diesel Exhaust Fluid (DEF),
– Agente Reductor Líquido de Óxido de Nitrogénio Automotivo (ARLA 32).

Properties
High temperatures and direct sunlight are to be avoided due to decomposition by heat. When AdBlue is heated above 25 °C, an ammonia solution is created as an aqueous solution or as an aerosol of ammonia as a hazard-determining substance.

AdBlue attacks base metals. Copper, alloys containing copper and unalloyed and galvanized steels, aluminum and glass are not suitable for contact with a urea/water solution.

AdBlue has a strong tendency to crystallization. White crystals form when the water that it contains evaporates. The growth of crystals is encouraged by increased air moisture. AdBlue has high penetration ability and a strong dispersion capacity. Lines/pipes can be blocked by crystallization. Blockages can be dissolved by warm water. It is essential to look out for the growth of crystals along electrical wiring/leads. Electric contacts can be jumpered by the high conductivity. Leads containing copper are corroded.

The product is not classified as hazardous and does not have to be specially labeled. The substance is not irritant, but after repeated or prolonged skin contact can cause degreasing of the skin and dermatitis. Experience in practice has shown reddened skin after a few minutes in contact with the medium.

With water hazard class 1, AdBlue is classified as slightly hazardous to water and may not be released into the environment.

At ambient temperatures below –10 °C containers, lines and equipment must be fitted with cold insulation and heating. Frozen AdBlue incurs no damage and can therefore be reused once it has thawed.

Storing AdBlue at temperatures below 0 °C is to be avoided due to the risk of freezing and the associated volumetric expansion. There is the danger of the container splitting. A leak may only become visible after thawing.

Table 1: Properties of AdBlue

Delivery form	Aqueous solution
Appearance	Clear and colorless
Odor	Odorless up to slight odor of ammonia
Solubility	Mixable with water in any ratio, poorly soluble in aliphatic hydrocarbons
Congealing point	–11.5 °C
Reaction	Weakly alkaline
Electric conductivity	Liquid and crystals good electric conductivity

Refrigerants for air-conditioning systems

The core component of the air-conditioning system in motor vehicles is as a rule a cold vapor-compression refrigerating system (see Passenger-compartment climate control). The underlying thermodynamic cyclic process – the Carnot cycle – is approximated with this system (see Thermodynamics). The two isentropic changes of state (according to Carnot) are approximated by a air compressor and a throttle element and the isotherms are approximated by evaporating and condensing refrigerant. Operating fluids for which the phase changes occur at tenable pressures are required especially for evaporation and condensation.

Table 1 shows the property values of the refrigerants R134a and R1234yf. The global warming potential (GWP) is a measure of the relative contribution of a greenhouse gas to the greenhouse effect. The reference forms the CO_2 with the global warming potential of one. The emission of 1 kg R134a would accordingly have a greenhouse effect comparable with the emission of 1300 kg CO_2.

Table 1: Property values of the refrigerants R134a and R1234yf

Property	R134a	R1234yf
Boiling point	–26 °C	–29 °C
Vapor pressure at 25 °C	6.56 bar	6.64 bar
Vapor pressure at 80 °C	25.97 bar	24.38 bar
Vapor density	32.4 kg/m³	37.6 kg/m³
GWP	approx. 1300	approx. 4

Development up to today

Refrigerant R12

Initially, combustible substances (e.g., methyl chloride CH_3Cl, sulfur dioxide SO_2 or diethyl ether $C_4H_{10}O$) were used in refrigerant systems. In around 1930 the American engineer Thomas Midgley developed chlorofluorocarbons (CFCs). The most important substance from this family for motor vehicles was R12 (CCl_2F_2). This substance accepted as non-poisonous and non-combustible was used in practically all passenger-car air-conditioning systems and was additionally available for a great many other applications.

In 1974 the chemists Molina and Rowland put forward the hypothesis that substances containing chlorine damage the ozone layer that protects us [1]. Subsequent observations of the ozone hole over Antarctica bore out this hypothesis. The evaluation of precise measurements finally provided certainty. This resulted on 16 September 1987 (in Montreal) in the signing of the Montreal Protocol, in which the resolution was passed to renounce chlorine chemistry.

Refrigerant R134a

From around 2000 onwards, the refrigerant R134a ($C_2H_2F_4$) was used as a substitute substance. But heightened sensitivity to all environmental impacts has also led to the limitation or restriction on the use of R134a. According to an EU Directive [2], air-conditioning systems designed to contain fluorinated greenhouse gases with a global warming potential of over 150 are to be prohibited in motor vehicles. R134a has a global warming potential of around 1300 and therefore falls below this Directive. Since January 2011 new vehicle types have no longer been permitted to be equipped with R134a and since January 2017 all new cars have been required to be equipped with a refrigerant that has a global warming potential of less than 150. Also applicable aside from this Directive is the EC Regulation [3], the main purpose of which is the avoidance or reduction of the emission of fluorinated greenhouse gases.

Refrigerant R1234yf
At the moment the only new refrigerant available that is produced in sufficient quantities is R1234yf ($C_3H_2F_4$) with a global warming potential of 4. Since 2017 it has, apart from a very few exceptions, been used by all manufacturers in all passenger-car air-conditioning systems. The very low global warming potential chiefly results from the fact that this substance has a very short service life in the atmosphere. R1234yf is however not undisputed. It is more easily flammable than R134a and in the event of a fire caustic and toxic reaction products are created. Therefore automobile manufacturers take additional safety precautions to ensure the customarily high safety of occupants.

Refrigerant CO_2
Air-conditioning systems with CO_2 as refrigerant are used in some upper-category passenger cars. CO_2 has by definition a global warming potential of 1 and is thus naturally predestined to be used. Unfortunately a CO_2 air-conditioning system cannot be operated with the same process and the same components. The process works on the high-pressure side in the supercritical range at very high pressures (100 to 150 bar). Therefore all the components must be newly developed and dimensioned for these unusually high pressures. Since such new developments affect not only development, production and sales but also to a significant extent service, a comprehensive market launch on 1st January 2017 could not be achieved.

An additional risk also arises in CO_2 systems. Because of the extremely high pressures a considerable amount of energy (pressure times volume) is stored in the system. This energy could for example in an accident be additionally released and cause further damage. Therefore enhanced safety precautions must also be taken for CO_2 air-conditioning systems.

Alternative possibilities

It is safe to assume that R1234yf will not be the last refrigerant used. One possibility is to build on the experiences with the CO_2 air-conditioning systems and expand this technology as a long-term solution. If this does not prove successful, natural substances which are really neutral in their impact on the environment can be considered. There have already been studies in this connection at the time of the discussions regarding renunciation of chlorine chemistry when scientists were locking for substitute substances for refrigerants containing chlorine [4]. The most natural substances would be water and air.

Water as refrigerant
In principle, water could be used in a cold vapor-compression refrigerating system, but evaporation and condensation would take place at extremely low pressures. In other words, the tiniest leaks would raise the pressure and the system function would no longer be guaranteed. The function has been verified in the laboratory. However, this would not be easily feasible at the current time.

Air as refrigerant
Air could be used in systems which operate according to the Joule process. Such systems are installed in virtually all commercial aircraft. However, the design of systems with much smaller output figures – i.e. for passenger-car applications – is more difficult and at the least entails diminished effectiveness. The process has been used with a certain degree of success for climate control in rail vehicles, for example in the ICE 1. The system output here is on a comparable scale to aircraft, but conventional R134a systems have a significantly better effectiveness.

At the moment the German Federal Environment Agency is supporting a research project in which systems with natural refrigerants are to be reassessed [5]. Since the Joule process is a pure gas process, it is inferior to the Carnot process in terms of effectiveness. It is used economically in aircraft due to the fact that some positive supplementary effects

are utilized. The air-conditioning system here has the additional task of pressurizing the cabin. The system weighs less than half as much as a comparable cold vapor-compression system and the drive can be effectively realized with compressed air from the engines.

Combustible substances as alternative refrigerants

Combustible substances could be further alternatives. In refrigerators R12 for example has been superseded by isobutane. In motor vehicles, however, the situation is a little more difficult in that as the result of a leak for example in the evaporator combustible substances would inevitably get into the passenger cell.

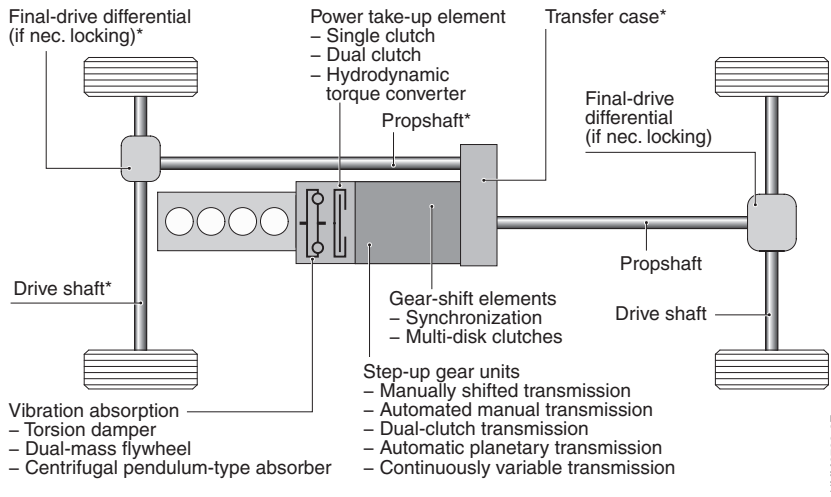
Drivetrain with internal-combustion engine

Drivetrain elements

The drivetrain is in automotive engineering assigned all the components which generate power for drive purposes and transmit that power to the road. The conventional drivetrain of a motor vehicle includes the internal-combustion engine, the transmission, the propeller shaft, the final-drive differential, and the drive shafts. The transmission contains a vibration damper, a power take-up element, and a step-up gear unit with gear-shift elements. Figure 1 shows the arrangement of these components for a standard drive (rear-wheel drive). It also shows the components for an all-wheel drive.



Hybrid drives feature an electric machine in addition to the internal-combustion engine. The components in the drivetrain that concern the internal-combustion engine are comparable with the conventional drive.

Functions of the drivetrain

The function of a drivetrain is to adapt the power outputs and torques made available by the engine to the respective driving situation and to the driver's commands. The transmission converts the torque into the tractive force for the wheels required to overcome the running resistances. For practical driving it must be possible to set different gear ratios in the step-up gear unit.

The internal-combustion engine converts the energy of the fuels supplied to it into mechanical energy, operates between a minimum and a maximum rotational speed in the process, and delivers a limited torque in this range. The rotational speed of internal-combustion engines is so high that their crankshafts are unable to drive the drive wheels directly. The step-up gear unit and the final-drive differential convert the engine speed to a range that produces wheel speeds suitable for driving. The overall gear ratio i_A (ratio of engine speed to wheel speed) is less than 1; the torque output to the wheels in relation to the engine

Figure 1: Drivetrain elements for a standard drive (rear-wheel drive)
Components marked * are optionally provided for an all-wheel drive.

torque is increased in the same ratio. The transmission acts as a torque converter.

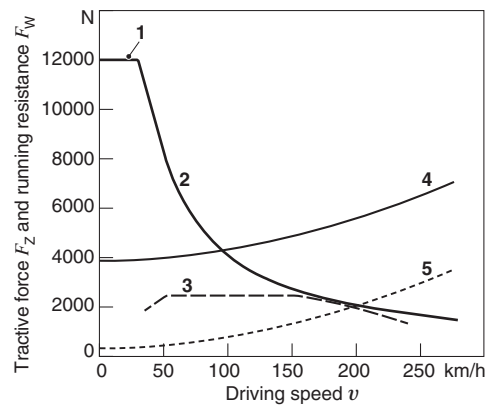
Unlike steam engines or electric machines, the internal-combustion engine cannot generate torque when it is at a standstill. Moreover, fuel consumption is very much dependent on the requested torque at the applied engine speed. Consequently, a drivetrain has further functions to fulfill:

– ensuring idle operation of the internal-combustion engine when the vehicle is at a standstill,
– facilitating driving off from a standstill,
– isolating the drivetrain from the rotational irregularities of the internal-combustion engine,
– reversing the direction of rotation of the drive wheels where necessary (reverse gear).

Tractive-force curves

Requirements

The requirements that a motor vehicle is to fulfill with regard to maximum climbing capability and acceleration on the one hand and top speed on the other hand define the necessary tractive force on the wheels and hence the demand on the transmission with regard to its spacing between the lowest and highest gears. The final-drive differential assumes some of the stepping-up duties so that the speed ratio in the step-up gear unit does not get too big for the different gears. The overall ratio i_A of the drivetrain is the product of the gear ratio i_n of the step-up gear unit in the selected gear and the constant gear ratio i_B of the final-drive differential.



Tractive-force hyperbola

The tractive-force hyperbola (Figure 2) shows as a function of the driving speed v and the drivetrain efficiency η_A the maximum available tractive force F_Z for the event that the internal-combustion engine could output its maximum power P_{max} over its entire speed range:

$$F_Z = \frac{P_{max}}{v}\,\eta_A.$$

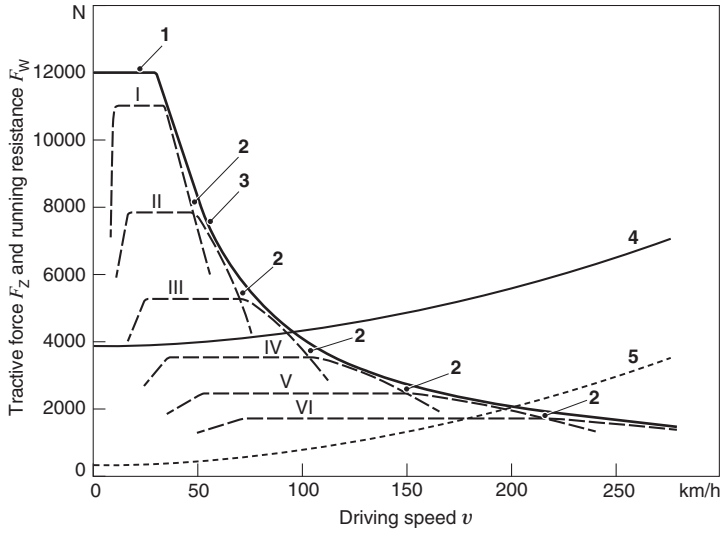
Figure 2: Tractive force as a function of speed for an internal-combustion engine without step-up gear unit (i.e., gear ratio of step-up gear unit equals 1)

1 Adhesion limit F_{Zmax},
2 Tractive-force hyperbola F_Z,
3 Tractive force F_Z for engine without step-up gear unit,
4 Characteristic running-resistance curve at gradient angle $\alpha = 10°$,
5 Characteristic running-resistance curve at gradient angle $\alpha = 0°$.

In the lower speed range the tractive force is limited not by the tractive-force hyperbola but by the adhesion limit F_{Zmax} between tire and road which is obtained from the product of the normal force F_N of the driven vehicle wheels and the coefficient of friction μ of the roadway:

$$F_{Zmax} = F_N \mu .$$

Influence of running resistances
The running resistance F_W of the vehicle without acceleration is made up of rolling resistance F_R, aerodynamic drag F_L, and climbing resistance F_S:



$$F_W = F_R + F_L + F_S .$$

The factors that influence the rolling resistance are the vehicle mass m, the gravitational acceleration g, the coefficient of friction μ, and the gradient angle α of the roadway. The aerodynamic drag contains the drag coefficient c_W, the frontal area of the vehicle A, the density ρ of the air, and the driving speed v. The factors that influence the climbing resistance are the vehicle mass m, the gravitational acceleration g, and the gradient angle α of the roadway. Consequently:

$$F_W = m g \mu \cos\alpha + 0.5 c_W A \rho v^2 + m g \sin\alpha .$$

In Figure 2 it becomes clear that an internal-combustion engine without a step-up gear unit would only operate in a very limited driving range. Here the tractive force F_Z of the engine only contains the transmission ratio of the differential so that the effect of torque conversion in the step-up gear unit can be clearly explained in the following.

Adaptation by step-up gear unit

Manual transmission

A manual transmission with defined gear ratios of the selectable gears (manually shifted transmission, dual-clutch transmission, automatic planetary transmission) effects an approximation of the maximum engine torque – which the internal-combustion engine develops between its minimum and maximum speeds – to the tractive-force hyperbola (Figure 3). The highest and the lowest gear ratios i defined the spacing φ_G of the transmission:

$$\varphi_G = \frac{i_{max}}{i_{min}} .$$

The tractive-force curves for the individual gears increase in the range above idle speed with increasing engine torque and drop off in the high speed range in response to decreasing engine torque.

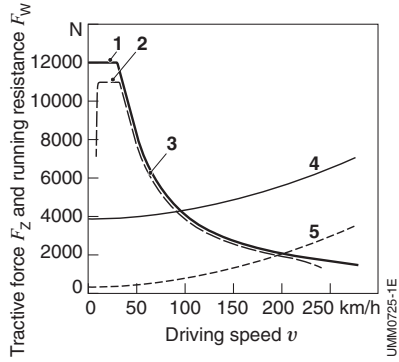
Table 1: Quantities and units

Quantity		Unit
c_W	Drag coefficient	–
g	Gravitational acceleration	m/s²
i_A	Overall ratio of drivetrain	–
i_n	Transmission ratio of a gear	–
i_B	Gear ratio of final-drive differential	–
m	Vehicle mass	kg
n	Engine speed	min^{-1}
v	Driving speed	m/s
A	Frontal area of vehicle	m²
F_Z	Tractive force at wheels	n
F_N	Normal force of vehicle	n
F_W	Running resistance	n
F_R	Rolling resistance	n
F_L	Aerodynamic drag	n
F_S	Climbing resistance	n
M	Torque	N m
P	Engine power	kW
α	Gradient angle of roadway	degree
φ	Gear step	–
φ_G	Transmission spacing	–
η	Efficiency	–
μ	Coefficient of friction of roadway	–
ρ	Density of the air	kg/m³

Both geometrical and progressive gear stepping can be implemented with the number of gears and the individual transmission ratios. The gear step φ between the gears is defined as the ratio of transmission i of two neighboring gears:

$$\varphi = \frac{i_{n-1}}{i_n} .$$

In the case of geometrical gear stepping the gear step is always the same. This is used in truck transmissions with high numbers of gears. A truck requires fine stepping in the entire driving range since its engine power is relatively low with regard to its high mass.



Progressive gear stepping is used in passenger-car transmissions. This means that the gear step becomes increasingly smaller to the higher gears. Consequently, the non-utilizable driving ranges (see Figure 3) are kept small in the car's main driving range although the number of gears is much smaller than in a truck. To achieve good driveability the tractive-force curves of the individual gears should intersect in each speed range (see Figure 3).

The point of intersection of the characteristic running-resistance curve at a 0° gradient angle with the tractive-force hyperbola defines the vehicle's top speed v_{max}. The ratio of the gear in which the top speed is to be reached should be selected in such a way that the engine outputs its maximum power at this point (fifth gear in Figure 3).

To reduce fuel consumption there are one or more gears with an overdrive ratio (sixth gear in Figure 3). In this gear the top speed cannot be reached (in Figure 3 a maximum speed of approximately 180 km/h on a 0° gradient is possible), but reducing the engine speed lowers the fuel consumption in a wide road-speed range.

Continuously variable transmission
A continuously variable transmission (CVT) can make any number of transmission ratios available. In this way, the maximum engine tractive force is introduced to the tractive-force hyperbola (Figure 4). On account of their design, continuously variable transmissions have a limited transmission spacing and a lower transmission efficiency. In Figure 4 the highest ratio corresponds roughly to the ratio of 5th gear of the multi-step transmission in Figure 3. Consequently, above all in the upper speed ranges, there is no possibility of reducing the engine speed and with it fuel consumption. This downturn in efficiency of the continuously variable transmission is however overcompensated for by higher overall-system efficiency (see Continuously variable transmissions).

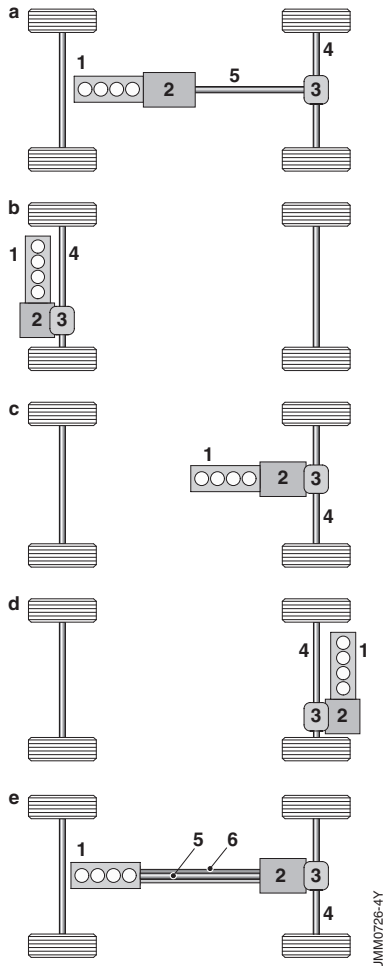
5 Characteristic running-resistance curve at $\alpha = 0°$.

Drive types

The arrangement of the engine and the step-up gear unit with vibration absorber and power take-up element depends very much on the vehicle category.

Standard drive
In a standard drive the engine with the step-up gear unit is arranged at the front in the front-axle area and the final-drive differential is arranged on the rear axle. The wheels on the rear axle are driven via the propeller shaft, the final-drive differential, and the drive shafts (rear-wheel drive, Figure 5a). The engine is longitudinally installed so that there are few limitations on engine length (e.g., 6-cylinder in-line engine) and thus on engine power output.



Until around 1930 this drive type was customary in virtually all vehicles; the designation standard drive dates back to that era. Since then, this drive type has featured almost exclusively in the upper mid-size and luxury categories.

Front-wheel drive
The front-wheel drive has in the meantime gained acceptance in vehicles ranging from the subcompact-size to the lower mid-size category and now features in more than 75 % of worldwide vehicle production. The engine and the step-up gear unit are generally arranged transversally to the direction of travel in the engine compartment (Figure 5b), but this entails limitations on engine size. Longitudinally installed engines are the exception. The steered front wheels are driven via the final-drive differential and the drive shafts. The final-drive differential is integrated in the step-up gear unit.

All-wheel drive
The all-wheel drive of many off-road vehicles is a variant of the standard drive with a transfer case situated in the direction of power flow after the step-up gear unit which transfers the transmission output torque to the front and rear axles (see Figure 1).

All-wheel drive is also possible in conjunction with a rear engine. All-wheel drive with a mid engine is difficult owing to the limited space available, therefore only a few vehicles feature this drive type. All-wheel drive with a front engine can be achieved

Figure 5: Arrangement of engine and transmission

5 Propeller shaft,
6 Tube.

with a transfer case mounted on the transmission.

Mid-engine drive
The engine is installed in front of the powered rear axle. There are vehicles with transversally mounted engines, but also some with longitudinally installed engines. The step-up gear unit and the final-drive differential are situated in the rear-axle area (Figure 5c).

Mid engines with rear-wheel drive are installed almost exclusively in sports vehicles.

Rear-engine drive
The engine, the step-up gear unit and the final-drive differential are situated in the area of the powered rear axle (Figure 5d). Rear engines with rear-wheel drive are in the meantime installed almost exclusively in sports vehicles.

The engine can be longitudinally or transversally installed at the rear.

Transaxle drive
In the case of the transaxle drive, the engine is installed at the front and the step-up gear unit and the final-drive differential are mounted on the rear axle (Figure 5e). The engine and the power take-up element with step-up gear unit are connected by a tube and together form a rigid drive unit. The tube contains the non-articulated drive shaft, via which the transmission is driven. The drive shaft rotates with the engine speed.

An advantage of this arrangement of transmission and engine is uniform axle-load distribution. This drive is used in sports cars.

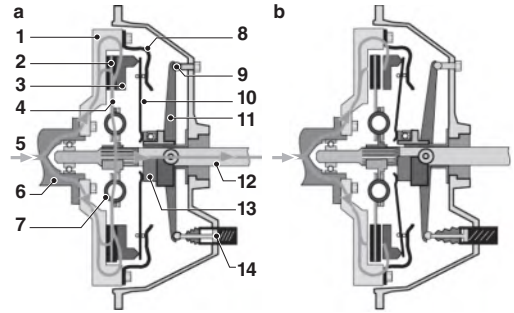
The inverted transaxle drive is also possible with a mid engine; the step-up gear unit and the final-drive differential are mounted here on the front axle.

Underfloor-engine drive
An underfloor layout is possible in commercial vehicles. The engine is situated between the axles; in a truck it is arranged on the frame. Uniform axle-load distribution results in good traction even when the vehicle is empty. But, because the engine is difficult to access, this concept has not caught on.

Power take-up elements and vibration isolation

The internal-combustion engine exhibits a minimum speed. To drive off from a vehicle standstill, the rotational-speed gap between the lowest engine operating speed and the stationary transmission input shaft must be closed by a speed converter [1]. In addition, during driving the gearshifts in manual transmissions cannot happen under load. The functions of this power take-up element are therefore:
– interrupting the power flow between the engine and the step-up gear unit,
– soft and smooth starting,
– transmitting the engine torque at different engine speeds to the step-up gear unit.

The vibration-isolation components reduce torsional vibrations at the crankshaft and thereby reduce noise and wear in the drivetrain.



Single clutch

The clutch is the link between the engine and the step-up gear unit, transmitting the engine torque through adherence by frictional forces to the input shaft of the step-up gear unit.

Single-disk clutch
The single-disk clutch installed in most manually shifted transmissions consists of the clutch disk fitted with a clutch lining (Figure 2), which in the engaged state is pressed by a pressure pate pretensioned by the disk spring (diaphragm spring) against the engine flywheel (Figure 1a). A frictional connection is established between the engine flywheel and the clutch disk. The clutch disk is connected with torsional strength via the hub to the transmission input shaft.

The clutch is actuated in a manually shifted transmission via the clutch pedal. Pedal-force transmission in passenger cars is increasingly being performed by hydraulic systems and increasingly less so via control cable. Without an external operating force the diaphragm-spring force keeps the clutch closed. To open the clutch, it is necessary to depress the clutch pedal. The hydraulically actuated

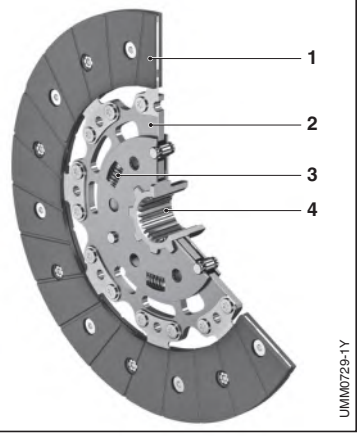
14 Slave cylinder.



slave cylinder presses the release fork forwards (Figure 1b); this in turn pushes the release bearing and with it the inner part of the diaphragm spring forwards in the direction of the clutch disk. The outer part of the diaphragm spring moves in the opposite direction and in so doing pulls the pressure plate away from the clutch disk. In this way, as the pressure on the clutch pedal increases, the transmitted torque decreases until the clutch is fully opened.

When during driving off the force is slowly withdrawn via the clutch pedal, the diaphragm spring relaxes and increasingly presses the pressure plate against the engine flywheel. The transmitted torque increases and the vehicle drives off. When speed synchronization between the engine and the transmission has taken place, the drive-off process is completed and the clutch is fully engaged.

Torsion-damped clutch disks with torsional-vibration springs on the inside (Figure 2) damp engine vibrations and protect the transmission. They also serve to ensure a smooth clutch response when driving off. Single-disk clutches are used in both passenger cars and commercial vehicles.

Figure 2: Clutch disk with clutch lining
1 Clutch lining,
2 Clutch-disk drive plate,
3 Torsional-vibration springs (torsion damper),
4 Hub, to transmission.

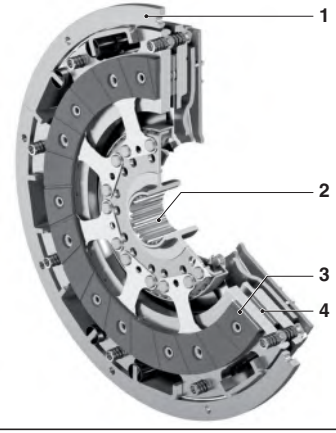
Double-disk clutch

In rare cases there are versions for higher torques with two clutch disks (Figure 3). This version would be chosen if the single-disk clutch were too large in diameter or the contact pressure were too great to transmit the required torque.

Both clutch disks act on only one transmission input shaft. For this reason, the double-disk clutch too belongs to the category of single clutches.

Design types

Single and dual clutches can take the form of both a dry clutch and an oil-cooled “wet” variant.



Dry clutch

Clutch linings for dry clutches consist for example of organic materials which are bound by resins. The materials used are similar to those of brake pads/linings. The aim is to achieve a high coefficient of friction for the clutches so as to keep the operating force and the diameter of the clutch small.

Wet clutch

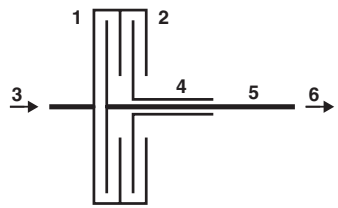
Multi-disk clutches with paper-like linings are used for wet clutches. These clutches are similar to the power-shift elements in

Figure 3: Double-disk clutch
1 From driving engine,
2 Hub, to transmission,
3 Clutch disk 1 with lining,
4 Clutch disk 2 with lining.

automatic transmissions (see Gear-shift elements). The function of the paper-like lining is obtained by oil wetting. More heat can be dissipated via an oil flow through grooves in the clutch disks from the clutch than is the case with dry linings, where cooling is effected by thermal masses (flywheel, pressure plate) and front there via air convection.

Control devices

Hydraulic clutch actuation



The master cylinder of the hydraulic control device is mechanically connected to the clutch pedal. The hydraulic fluid is withdrawn from the expansion tank for brake fluid. When the clutch pedal is pressed, pressure is built up in the clutch on the slave cylinder connected via a hose and the clutch opens as a result.

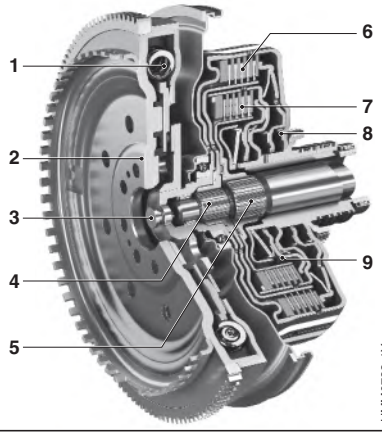
Clutch actuation for commercial vehicles

Large forces on the release bearing are required to actuate commercial-vehicle clutches. For light commercial vehicles compressed-air-boosted hydraulic systems are used to reduce the foot force on the clutch pedal. For heavy commercial vehicles electromechanical or electropneumatic systems are used [2].

Figure 4: Schematic diagram of a dual clutch

1 Clutch 1,
2 Clutch 2,
3 From vibration isolation, 4 Hollow shaft,
5 Solid shaft, 6 To transmission.

Dual clutch



The dual clutch (Figure 4 and Figure 5) is characterized by the fact that two independently controllable clutches transmit the engine power to two transmission input shafts (a solid shaft and a hollow shaft). In most cases the dual clutch is combined with a dual-clutch transmission (see Dual-clutch transmission).

Figure 5 shows a dual clutch with oil-cooled multi-disk clutches. These are very similar clutch elements as are used as power-shift elements in automatic planetary transmissions. Actuation is effected by co-rotating pistons, which generate an axial force by means of hydraulic pressure. When the disks are pressed together with increasing axial force, the torque that can be transmitted via the clutch increases (see Multi-disk clutch).

Alternatively, the disks can also be pressed together via release bearings.

Hydrodynamic torque converter

Design

The hydrodynamic torque converter (Figures 6 and 7) comprises the following components:

– impeller (connected to the internal-combustion engine),
– turbine (connected to the transmission input shaft),
– stator (connected via a one-way clutch to the transmission housing),
– lockup clutch, and
– integrated torsion damper.

Operating principle

The torque converter is filled with hydraulic oil. A gear pump delivers an oil pressure of 2 to 5 bar to prevent the oil from foaming and vapor pockets. The kinetic energy introduced by the engine is converted in the impeller into hydraulic energy. The faster the impeller driven by the engine rotates at speed n_P, the more oil is delivered by the impeller as the result of centrifugal force from the inside close to the rotational axis radially outwards. This oil flow strikes vanes

Figure 7: Structural design of hydrodynamic torque converter

in the neighboring turbine. The deflection of the oil flow to these vanes induces a torque which acts on the transmission input shaft. Because the conversion takes place using the hydrodynamic inertia of the oil, the hydrodynamic torque converter operates without wear.

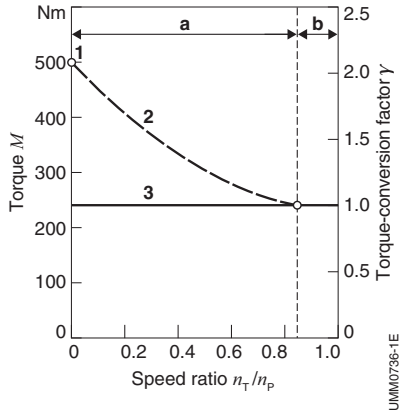
The torque at the impeller is called pump torque M_P, that at the turbine is called turbine torque M_T.

Converter increase

The oil flow is delivered in the turbine from the outside radially inwards, where it strikes the stator (Figure 6). The stator features vanes which have a curvature of 90° and are supported by means of a one-way clutch in one direction of rotation on the transmission housing. While the turbine (and hence the transmission inlet) is stationary or only rotates slowly at speed n_T, the stator vanes induce a retention of oil which results in a reaction-torque increase at the turbine. With the oil flow being supported by means of the stator with stator torque M_L on the transmission housing, it is possible that a higher torque is transmitted to the transmission input shaft than the internal-combustion engine delivers to the converter. This is referred to as a converter increase. The following torque equilibrium applies to the torque converter:

$$M_P + M_T + M_L = 0$$

With regard to the torque converter the pump torque is an input torque and hence the preceding sign is positive, while the turbine torque is an output torque and hence the preceding sign is negative.



The deflection of the oil flow in the stator is greatest when the speed difference between the impeller and the turbine is greatest – i.e., when driving off. This is then followed by the greatest torque increase. As the speed of the turbine (i.e. the transmission input shaft) increases, the angle of impact of the oil flow on the stator vanes changes. The oil retention and hence the torque supported on the transmission housing are reduced. The converter increase decreases. The characteristic can be seen in Figure 8 in the torque-conversion factor γ:

$$\gamma = -\frac{M_T}{M_P}.$$

At the stall point when the turbine is stationary $1.7 < \gamma < 2.4$ usually applies.

As long as $\gamma > 1$ applies the converter is in the so-called conversion range. The range where $\gamma = 1$ is designated the clutch range since no further torque conversion takes place here.

Figure 8: Torque-conversion factor in hydrodynamic torque converter

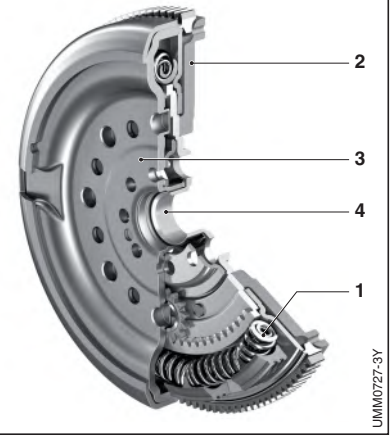
n_P Impeller speed.

When the torque-conversion factor γ has dropped to 1, the oil flow acts on the stator vanes against the previous torque direction. The one-way clutch, which constitutes the connection between the stator and the transmission housing, transmits no torque in this direction. The stator now also rotates without torque in the oil flow. The co-rotation of the stator prevents an unwanted deflection of the oil flow in the clutch range and consequently a deterioration of the converter efficiency.

Lockup clutch
Even in the clutch range the turbine never quite reaches the speed of the impeller; a speed difference of 2 to 3 % remains. Without this slip no torque could be transmitted. To keep the losses in the converter at $n_T \approx n_P$ as low as possible, hydrodynamic transmission is locked up by a multi-disk clutch. Here the turbine shaft – i.e., the transmission input shaft – is coupled for example with the converter housing. To maintain the high vibration comfort of hydrodynamic isolation, one or more torsion dampers are incorporated in the lockup clutch's power-transmission path.

Advantages of the hydrodynamic torque converter
Because of the converter increase when driving off, the hydrodynamic torque converter is highly suitable for vehicles that have to tow heavy trailers (e.g., caravans). Further advantages are derived from this power take-up element not being subject to wear and the excellent ride comfort attributable to hydrodynamic torque transmission.



Vibration isolation

A significant requirement imposed on the drivetrain is comfort. The requirements imposed on vibration isolation are increasing continuously since optimizations in the combustion process of engines, smaller engine displacements with turbocharging, lower engine speeds in all driving ranges, and reduced numbers of cylinders do indeed lower fuel consumption but, due to high crankshaft radial accelerations, cause a higher rotational irregularity of the combustion-engine torque.

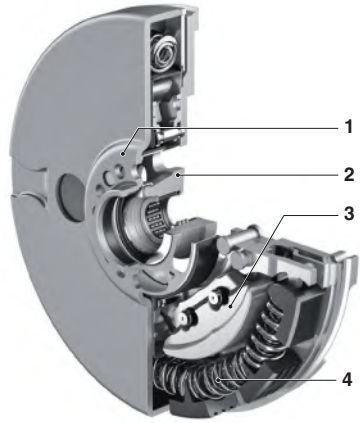
The purpose of vibration isolation is to reduce the torsional vibrations that occur as a result of the design of the internal-combustion engine. Vibration isolation can be effected by slip at the power take-up element, by damping the irregularity, by temporarily storing energy in a spring, by absorption, or by a combination of several methods.

In the case of vibration isolation by slip at the power take-up element, the mechanical energy of the vibration by friction is

Figure 9: Dual-mass flywheel with torsion damper (structural design)
1 Torsion damper (helical spring),
2 Primary flywheel with starter ring gear (from driving engine),
3 Secondary flywheel,
4 To power take-up element.

converted into heat. This energy is thus lost to the actual drive. Therefore this vibration-isolation option is now only used sporadically in critical vibration situations (e.g., low rotational speeds).

Torsion damper and dual-mass flywheel



The torsion damper consists of coil springs arranged in a circle between the engine and the power take-up element (Figure 9), which during the vibration temporarily store energy in the compression of the springs (by a limited torsion between crankshaft and transmission inlet) and output this energy again to the transmission inlet. It is possible by varying the spring stiffness and diameter to adapt the torsion damper to the respective combination of engine and drivetrain.

In the case of the dual-mass flywheel, the mass of the engine flywheel is split and the torsion damper is placed between the two flywheel masses (Figure 9), which are pivoted against each other via a separate thrust and radial bearing arrangement. The moment of inertia on the transmission side is increased by apportioning to the primary flywheel mass on the engine side and to the secondary flywheel mass on the transmission side. Low spring stiffness can bring about a specifically "soft" harmonization of the spring units which connect the two flywheel masses to each other. As a result, the resonant frequency of the dual-mass flywheel is shifted significantly below the idle speed of the engine and the exciting engine orders. A natural oscillation of the dual-mass flywheel is avoided in this way.

Dual-mass flywheels are used in vehicles from the compact class upwards.

Figure 10: Centrifugal pendulum-type absorber and torsion damper

1 From driving engine,
2 To power take-up element,
3 Centrifugal pendulum-type absorber mass,
4 Helical spring (torsion damper).

Centrifugal pendulum-type absorber

In the case of the centrifugal pendulum-type absorber the rotational irregularity is balanced by means of a counterforce by vibrating masses additionally mounted in the torsion damper (Figure 10). Thanks to suitable lever conditions the vibrating masses can be selected at a proportionally small level compared with the mass of the internal-combustion engine to be isolated. The centrifugal pendulum-type absorber is speed-adaptive since the centrifugal acceleration on the vibrating mass increases as the rotational speed increases.

Centrifugal pendulum-type absorbers are more expensive to manufacture, but have the advantage of lower weight compared with dual-mass flywheels. They are used in vehicles from the compact class upwards.

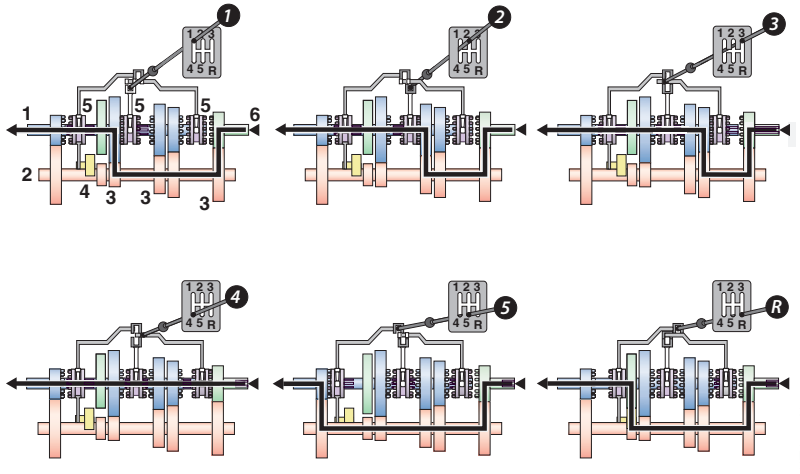
Step-up gear units

Different gear ratios are implemented in the manual transmission for the purpose of adapting the torque made available by the engine and the power to the respective driving situation and to the driver's requests. Each gear ratio is called a gear or speed. Together with the transmission ratio of the final-drive differential the high engine speed is converted to the wheel speeds required for driving.

Manually shifted transmissions are a combination of step-up gear units and gear-shift elements. The vibration-isolation and the power take-up elements are arranged between the engine and the transmission (see Drivetrain).

For further references on transmissions, see [1] and [2].

Components in manually shifted transmissions



Step-up gear units

Gears

The gear (or gear wheel) is a machine element which has uniformly distributed teeth around its circular circumference. Torque and rotary motion are transmitted by a positive engagement occurring in succession of the teeth of a gear with the teeth of other gears. Different numbers of teeth on the gears – and thus different gear diameters (Figure 1) – determine the gear ratio from one gear to another. Rotational speeds and torques are inversely proportionally converted with this gear ratio, with the power output apart from efficiency remaining the same. The advantages of a step-up gear train lie in its high power density through slip-free transmission.

The type of toothing most commonly used in step-up gear units is involute

Figure 1: Design of a 5-speed manually shifted transmission with spur-gear sets

toothing. Here the cross-section of a tooth flank depicts a part of an involute of a circle (Figure 2). This ensures that the engaging teeth touch each other along a straight line of action. The aim of involute toothing is to achieve a high amount of rolling and an accordingly low amount of sliding during the transmission of torque in order to minimize wear and heat generation in the toothing. Further advantages of involute toothing are the high tolerance in relation to wheelbase tolerances and relatively simple manufacturability. Figure 3 shows the parameters for a gear.

Straight and helical toothing

Helical gears are used for the most part in spur-gear drives. On these gears the teeth are arranged not parallel with the gear axes, but at an angle to them (Figure 4c). When the teeth of two gears mesh, the teeth do not bear on their full face width from the outset, as is the case with straight spur gears (Figure 4b). Instead, the bearing face width increases slowly as the gears continue to rotate until the teeth have contact over their full width. As the gears rotate out of the action zone the face width subjected to load also decreases slowly. In this way, the kinetic impulses when meshing are much smaller than on straight gears. Accordingly, fewer oscillations are excited, which provides for quieter running of the gears.

Acoustically, it is possible to discern the difference between straight and helical toothing in older manually shifted transmissions. In such transmissions the reverse gear is straight-toothed and "whines" when reversing, while the forward gears are acoustically inconspicuous when driving

Figure 4: Spur-gear set

b) Structural design of a straight spur-gear set,
c) Structural design of a helical spur-gear set.
1 Spur gear, 2 Axis.

forwards. Another advantage of helical gears is their higher load capability in that more teeth are simultaneously engaged than on straight gears.

Helical toothing generates axial forces which must be absorbed by means of a suitable bearing arrangement. Moreover, they are more complex to produce than straight spur gears.

Spur-gear set

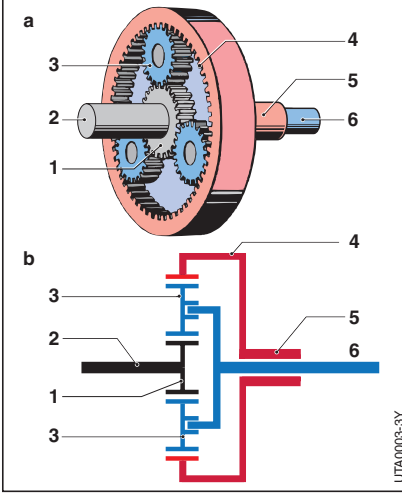
In spur-gear sets the gears are arranged on parallel axes (Figure 4). One of the gears is driven while the other is coupled to the output. The speed ratio from the drive gear to the output gear is obtained from the different numbers of teeth. In the vehicle transmission the gears can either be permanently coupled on shafts (fixed gear) or pivoted on them (movable gear).

Spur gears are easier to manufacture than internally toothed ring gears of a planetary-gear set. Moreover, the axial offset between input and output suggests itself for front-transverse drivetrains.

Spur-gear sets are used in manually shifted transmissions, automated manual transmissions, and dual-clutch transmissions.

Planetary-gear set

The planetary-gear set consists of a sun gear, an internally toothed ring gear, and several planetary gears. The planetary gears are interconnected by a carrier and mounted on this (Figure 5). The planetary-gear set, in contrast to the spur-gear set, has not only fixed axes. The axes of the planetary gears can circulate in an orbit around the axes of the sun and ring gears.



Basically, in each case one of the three elements (sun gear, ring gear, carrier) in the planetary-gear set can be used as the drive, while a second element is permanently joined to the transmission housing in order to provide output via a third element. With three drive options and three output options (with the third element stationary in each case) there are six different gear ratios which a planetary-gear set can offer when connected appropriately. Furthermore, by joining the three elements to each other, it is possible to achieve a circulation of the planetary-gear set as a block with the gear ratio one as the seventh ratio. However, the ratios of a planetary-gear set are not so staged that a planetary-gear set alone would be usable for the desired ratios of a passenger-car transmission.

Thanks to the symmetrical design and the distribution of torque to several planetary gears, the power density in the planetary-gear set is particularly high and accordingly the size in relation to the transmitted torque is small. Because of the coaxial position of the input and output shafts this type is particularly suitable for standard drivetrains. Several planetary-gear sets combined via shift elements are predominantly used in automatic planetary transmissions.

A planetary-gear set can also be used as a summation gearbox or transfer case. In this case, none of the planetary-gear set elements are joined to the housing. When it is used as a summation gearbox, two elements of the planetary-gear set are driven and output via the third element. When it is used as a transfer case, one of the planetary-gear set elements operates as the drive while the other two operate as the output.

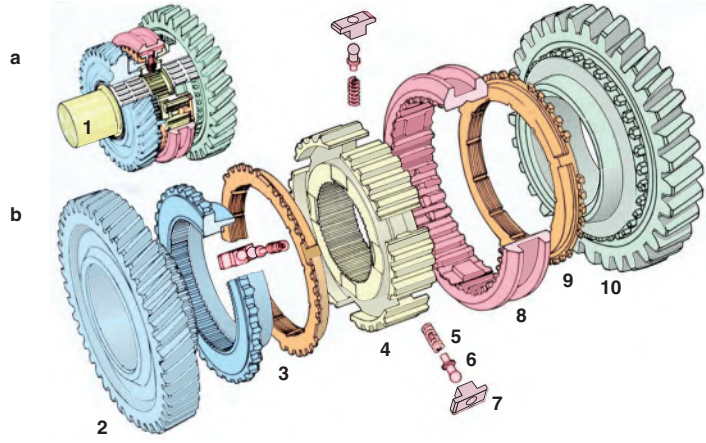
Gear-shift elements

Function of synchromesh

Manually shifted transmissions, automated manual transmissions, and dual-clutch transmissions as a rule have for each gear a spur-gear set whose teeth are permanently engaged (Figure 1). In each case one gear of the spur-gear set is permanently mounted on the shaft while the other is pivoted on it. In Figure 1 the gears with the exception of the first gear are pivoted on the main shaft (movable gears, control gears). The opposing gears in each case on the countershaft are permanently joined to the shaft and are thus not pivoted on it (fixed gears). The control gears are all permanently driven by the opposing fixed gear in each case. When a gear is not engaged, the control gears consequently rotate at a speed different from the shaft.

In the event of a gear change the corresponding control gear is sped up or slowed down to the shaft speed. When synchronism is in place a non-positive connection with the shaft is established. The device that brings about the equal rotational speeds is called a synchromesh.

Design



The synchronizer body is positively connected with the shaft (Figure 6). It carries the axially movable gearshift sleeve. The synchronizer body has recesses for three sliding blocks, which are pressed outwards by two compression springs against the gearshift sleeve. The gearshift sleeve features on the inside dog toothing which has recesses for the sliding blocks. In this way, it is possible to slide the gearshift sleeve with the sliding blocks to the right and left.

Synchronizing action

In the course of the synchronizing action the process of sliding the gearshift sleeve with the sliding blocks moves the synchronizer ring towards the conical friction surface on the control gear to be shifted (Figure 6). Recesses are worked into the synchronizer ring for the sliding blocks; the sliding blocks carry the synchronizer ring. The process of pressing the synchronizer ring with force F_S onto the conical friction surface of the control gear generates by way of sliding friction a torque M_S which would like to match the control gear to the speed of the shaft. Lockout toothing on the

UMM0739-2Y

synchronizer ring prevents the dog toothing of the gearshift sleeve from meshing with the shift toothing before the control gear and shaft are synchronized (Figure 7). In this process the dog toothing of the gearshift sleeve contacts the tooth angles of the lockout toothing on the synchronizer ring and the friction torque of the synchronizer ring counteracts any evasion of the lockout toothing. Further rotation of the synchronizer ring relative to the gearshift sleeve is prevented by axially movable sliding blocks.

The recesses for the sliding blocks in the synchronizer body are exactly the same width as the sliding blocks, while the recesses in the synchronizer ring are slightly wider. In this way, the synchronizer ring can, as pictured in Figure 7, move relatively through a small angle. The sliding blocks transmit the torque from the synchronizer body to the synchronizer ring. The external teeth on the synchronizer body, synchronizer ring and shift toothing are dimensioned in such a way that they can establish positive locking with the dog toothing of the gearshift sleeve.

c) Establish positive locking.
1 Dog toothing on gearshift sleeve,
2 Lockout toothing on synchronizer ring,
3 Shift toothing on control gear,
4 Synchronizer ring,
5 Control gear,
6 Relative motion of synchronizer ring in relation to gearshift sleeve.

Once the synchronization of the control gear and the shaft is achieved, the synchronizing torque and consequently also the torque acting on the lockout toothing are zero. The applied shift force F_S now induces, via the tooth angles of the synchronizer-ring lockout toothing, the synchronizer ring to rotate relative to the gearshift sleeve so that the shift-sleeve dog toothing can be slid over the synchronizer-ring lockout toothing into the control-gear shift toothing. This establishes positive locking between the shaft and the control gear.

Increased shift force can reduce the synchronizing time, but in the long term this will cause increased wear of the friction lining on the synchronizer ring. Also, the lockout toothing can be turned back by increased shift force already before synchronization and the shift-sleeve dog toothing advanced up to the control-gear shift toothing. When the shift-sleeve dog teeth and the shift toothing on the control gear engage at different speeds, this results in “gear-shift rasping”.

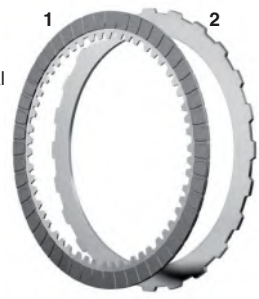
Multi-cone synchromesh

Synchromeshes with two or three conical friction surfaces arranged on top of each other are used to synchronize components with high mass inertia. These are referred to as double-cone or triple-cone synchromesh.

Often two and sometimes even three characteristic forms of synchromesh are fitted in transmissions. For the most part the control gears of first gear and reverse gear are equipped with triple-cone synchromesh because here the differences in speed between the gearshift sleeve and the loose running control gear are greater than in higher gears. The control gears of second and third gears are equipped with double-cone synchromesh, and the other gears with single-cone synchromesh. The advantage of this arrangement in manually shifted transmissions is that the shift forces are similarly high for all the gears.

Multi-disk clutch

A multi-disk clutch usually consists of a number of inner and outer disks. The inner disks have on their inside diameter synchronization toothing for example for joining the clutch to components in the transmission, while the outer disks have the synchronization toothing on their outside diameter (Figure 8). A disk is glued in each friction contact with a paper-like lining; as a rule this is the disk with the internal toothing. The other disk has a smooth steel surface.



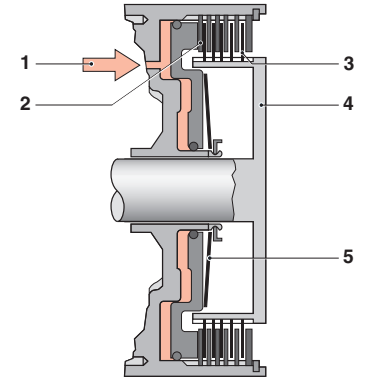
The disks are axially movable thanks to the connection via the toothing. They can be pressed together by means of a hydraulic mechanism (Figure 8) so as to create non-positive connection.

A higher torque can be transmitted for the same operating force by the use of a number of alternately stacked inner and outer disks and the greater lining surface area thereby obtained. To ensure that the multi-disk clutch is efficiently cooled, the paper lining has grooves for a constant throughflow of cooling oil.

The oil-cooled starting clutch and the dual clutch are distinct types of the multi-disk clutch. Multi-disk clutches are of fundamental importance to the function of automatic planetary transmissions, in which the gear to be shifted is introduced into the energy flow with frictional engagement and without interruption of tractive force.

Figure 8: Multi-disk clutch

1 Inner disk with internal toothing,
2 Outer disk with external toothing.



Multi-disk brake

The multi-disk brake is a special type of multi-disk clutch. The multi-disk brake differs in that for example the outer disks are connected to a non-rotating component such as the transmission housing and the clutch disks are stationary in the closed state while the elements of a multi-disk clutch rotate in the closed state. The multi-disk brake can be used for example to support a planetary-gear set element against the transmission housing in order to effect a transmission ratio.

Manually shifted transmissions

Design

Manually shifted transmissions (MTs) are usually designed as spur-gear drives in which the gear shift and the drive-off process are performed manually by the driver. Normally a dry single clutch is used as the power take-up element for passenger-car applications, double-disk clutches are also used for heavy commercial vehicles. In manually shifted transmissions each gear – except for transmissions with direct gear, in which the input shaft is directly connected to the output shaft – is rendered by a spur-gear pair (Figure 10). The different ratios of the numbers of teeth per spur-gear pair produce the different gear ratios.

In a double-shaft transmission the gears are seated on the main shaft or the countershaft. All the gears are permanently mounted on these shafts and as a result all the spur-gear pairs are engaged. Each spur-gear pair of a gear has a fixed gear, which is permanently connected to a shaft, and a movable gear (control gear), which is pivoted on the other shaft. The control gears can be seated on the main shaft, but also on the countershaft. For each gear the associated control gear is non-rotationally connected to the shaft by gear-shift elements. The individual control gears are coupled via synchromeshes (see Figure 6). The gearshift sleeves are moved into the position appropriate for the gear to be selected via gearshift forks and gearshift rods depending on the gearshift lever (Figure 11).

12 Idler gear for reverse gear.
I…VI First through sixth gear, R Reverse gear.

Manually shifted transmissions for the most part have five to six forward gears and one reverse gear. The spacing (ratio of the gear ratios from the lowest to the highest gear) of the transmissions is roughly four to eight.

Manually shifted transmissions belong to the category of tractive-force-interrupted transmissions. To change a transmission step the power flow must be disconnected by the clutch.

Transmissions for standard drive

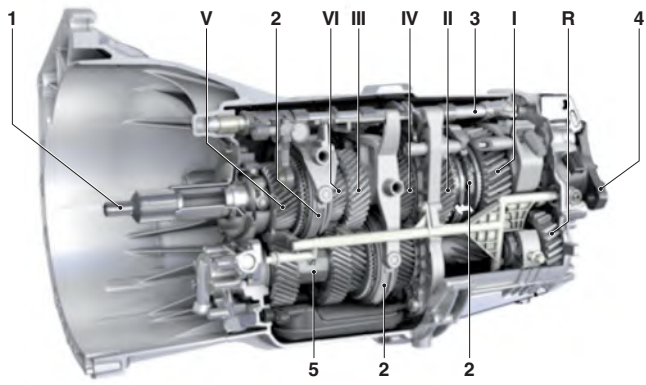
The designs for a standard drive (Figure 10 and Figure 12) have a coaxial input and output and a countershaft. In other words, the input shaft (transmission input shaft) and output shaft (main shaft) lie in the same plane (transmission with in-plane shafts). The direction of the power flow is not altered. The direction of rotation of the output shaft is the same – apart from for the reverse gear – as the direction of rotation of the input shaft because the power flow is provided via spur-gear pairs or in direct gear without transmission ratio by gears.

A constant transmission ratio transmits the engine power from the transmission input shaft to the countershaft. The control gears of the different transmission ratios are coupled by means of synchromeshes to the main shaft or countershaft so that the power flow can be delivered via the spur-gear pair in question to the transmission output.

The direction of rotation is reversed for the reverse gear by an idler gear.

Transmissions for front-wheel drive

Types with one countershaft (double-shaft transmission, see Figure 13) or two countershafts parallel to the drive (triple-shaft transmission) have established themselves in front-wheel drives. In a front-wheel drive the final-drive unit with differential is integrated in the transmission.



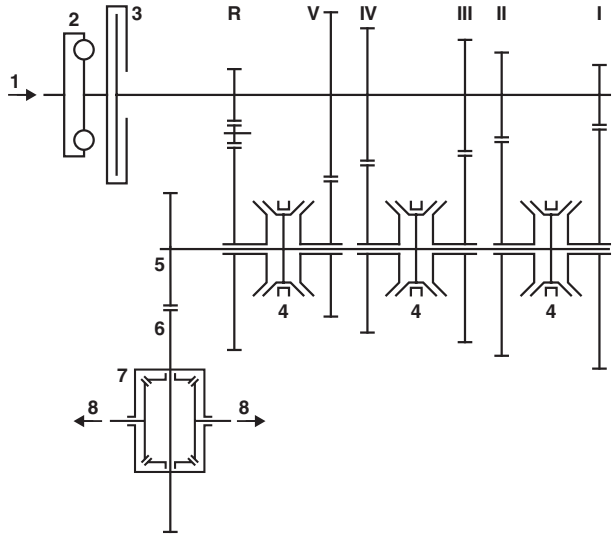
Double-shaft transmissions

In the double-shaft transmission in Figure 13 the fixed gears are seated on the input shaft and the control gears are non-rotationally connected to the countershaft according to the selected gear. This is a transmission without out-of-plane shafts because the input and output shafts do not lie in the same plane. This is because only one spur-gear pair is used to establish a transmission ratio.

The final-drive unit is driven in the double-shaft transmission by a constant transmission ratio of the countershaft.

Figure 12: Structural design of a 6-speed manually shifted transmission for a standard drive

1 Transmission input shaft, 2 Synchromeshes, 3 Gearshift linkage,
4 To final-drive unit, 5 Countershaft.
I…VI First through sixth gear,
R Reverse gear.



Triple-shaft transmissions
Splitting the transmission steps between two parallel countershafts enables the transmission to be short in its construction. The gears of the transmission input shaft drive the gears on the two countershafts (transmission output shafts). Seated on these shafts are the synchromeshes, which couple the gear responsible for the selected gear to the corresponding countershaft. In each case one gear on the countershafts meshes with the spur gear of the differential.

Depending on the gear selected, one gear or the other is non-rotationally coupled with the corresponding countershaft and drives the spur gear of the differential. The space required for components is reduced thanks to the control gears and the synchromeshes being split between two countershafts.

The overall length can be further optimized for a triple-shaft transmission by the double use of fixed gears on the drive shaft. Here one fixed gear meshes with two control gears (e.g., for the third and fifth gears) on the different countershafts.

Application
Manually shifted transmissions are still popular in Europe even in new vehicles. In the USA and Asia the demand for manually shifted transmissions is declining, apart from in certain sports cars.

Automated manual transmissions

Design

Automated manual transmissions (AMTs) have a mechanical design comparable to a manually shifted transmission (Figure 13).

Operation

The clutch is operated by electromotive or electrohydraulic actuators (Figure 14) which are actuated by a transmission control unit. Figure 15 shows the basic design of an electromechanical system. As is the case for operating the clutch, servomotors are used to operate the synchromeshes and thereby change gear. This helps to provide the operating comfort of a fully automatic transmission. The driver can choose between fully automatic control and manual input of the gear. There is, however, no clutch pedal.

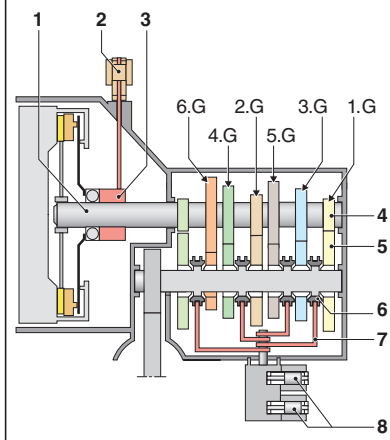
With the electrohydraulic control system, actuation is essentially performed via an electrically driven hydraulic pump, a pressure accumulator, and a hydraulic actuation unit with the actuators for selecting the gears.

Figure 14: Structural design of an actuator for an automated manual transmission for front-transverse drive

1 Clutch,
2 Clutch actuator.

Advantages and disadvantages

Like the manually shifted transmission, the automated manual transmission is a tractive-force-interrupted transmission, which gives rise to disadvantages in shifting comfort compared with other automatic-transmission construction types. However, the interruption of tractive force is generally shorter than in a manually shifted transmission.



Efficiency is higher when compared with an automatic planetary transmission, resulting in lower fuel consumption.

Application

Automated manual transmissions are used as standard in the commercial-vehicle sector, but have not been able to make the breakthrough in the passenger-car sector. The reason for this is the poor comfort due to the interruption of tractive force during the gearshift.

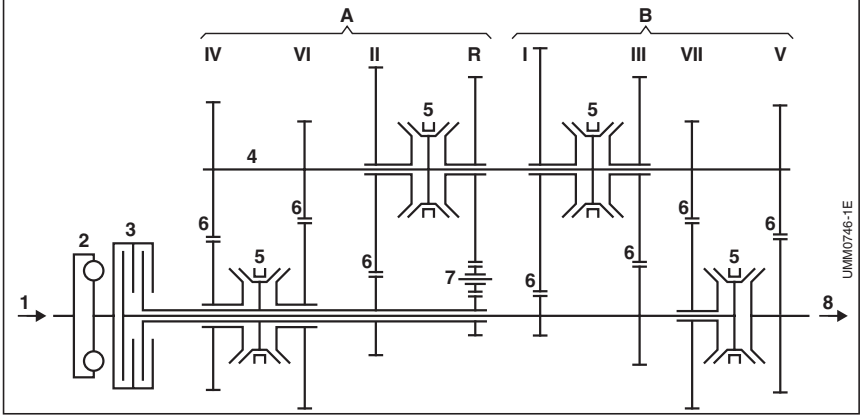
Dual-clutch transmissions

Design

Dual-clutch transmissions (DCTs), also known as direct-shift transmissions (DSTs), consist of two separate spur-gear sub-transmissions which can be connected in each case via a clutch (see Double clutch) to the internal-combustion engine.

The two clutches in the double clutch can be operated independently of each other. They can be designed as dry-running or wet-running systems (see Double clutch). The wet-running clutch is used if high torques are to be transmitted. A hollow shaft leads from the inner clutch to the transmission; the solid shaft driven by the outer clutch runs inside the hollow shaft. The gear wheels for the individual gears are seated as fixed gears or as control (movable) gears on these two shafts (Figure 16, Figure 17).



The gears are usually lubricated by direct splash oil. The oil is supplied by a mechanically driven oil pump or an electric oil pump. The oil cooler optionally mounted on the transmission is integrated in the cooling circuit.

Operation

By splitting the even gears (two, four, six) and odd gears (one, three, five, seven) between the two sub-transmissions (Figure 16) it is possible to change the gear ratios by means of power-shifting. When sub-transmission A is engaged via the inner clutch, in sub-transmission B the next gear higher or the next gear lower is pre-assigned via the corresponding synchromesh. The electronic transmission control uses among others the accelerator-pedal position, the engine load, and the engine speed to decide which gear is pre-assigned. For example, a fully depressed accelerator pedal and a low engine speed indicates that the next gear lower must be selected (kickdown). When the inner clutch is released and at the same time the outer clutch closes (or vice versa), the gearshift to the pre-assigned gear is initiated. The clutches are actuated by clutch valves. The gearshift sleeves are controlled by hydraulically actuated gearshift forks.

The overlap of closing and opening of the clutches results in a nearly tractive-force-interruption-free gear change. A dual-clutch transmission therefore offers the comfort

Figure 16: Schematic diagram of a 7-speed dual-clutch transmission for a standard drive

A Sub-transmission with even gears,
B Sub-transmission with odd gears.

of an automatic transmission. But only one gear on the other sub-transmission can ever be preselected. However, multiple upshifts or multiple downshifts can be achieved sequentially or by means of so-called support shifts via an intermediate gear (power transmission by slipping clutch during the gearshift).

The reverse gear can be assigned to either the even or the odd sub-transmission. In Figure 16 the reverse gear is assigned to the even sub-transmission. The direction of rotation is reversed by an idler gear.

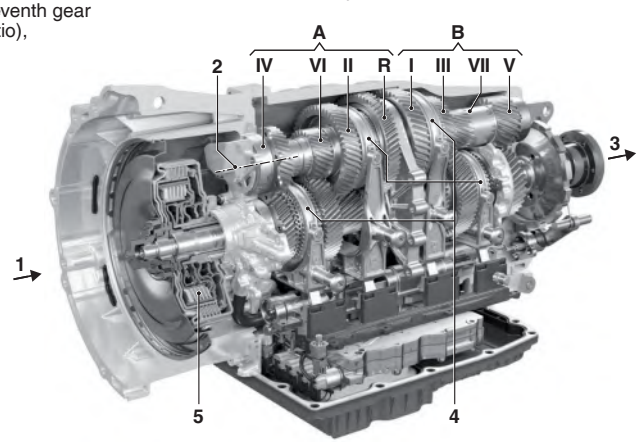
All the synchromeshes are moved into the center position once Neutral has been selected with the gearshift lever. As a result no gear is engaged. When the engine is stopped the two clutches are open. The transmission therefore needs a parking lock. A parking-lock gear engages the spur gear of the final-drive unit. A locking pawl blocks the parking-lock gear when the gearshift lever is moved into the P position. In the Park position the mechanical parking lock stops the vehicle from rolling away.

The clutches are used both for load sharing during shifting and for the drive-off process.

Advantages and disadvantages

The advantage of dual-clutch transmissions is that, unlike automatic planetary transmissions, they are suitable for engine speeds in excess of 7,000 rpm. Dual-clutch transmissions are therefore used in among others sports cars.

The spur-gear construction in dual-clutch transmissions facilitates advantageous gear-set versions especially in front-transverse transmissions with their axial offset between transmission input and transmission output shafts. In these gear sets the final-drive differential, unlike an automatic planetary transmission, is driven directly by the countershafts, providing for less meshing and consequently greater transmission efficiency in front-transverse transmissions.



In contrast to a transmission with a hydrodynamic torque converter there is no torque multiplication in a dual-clutch transmission when driving off. Therefore a greater transmission ratio and thus a greater transmission spacing are required in first gear.

Application

Thanks to the dual-clutch transmission the automatic transmission has also found its way into the lower vehicle classes with smaller engines and front-wheel drive.

Automatic planetary transmissions

Design

Automatic planetary transmissions (ATs) realize their transmission steps through a series of planetary-gear sets arranged in succession which are connected to each other in different ways by shift elements (multi-disk clutches and mullti-disk brakes (Figure 18). The number and arrangement of planetary-gear sets and clutches are dependent on the number of gears implemented in the transmission.

A hydrodynamic torque converter usually serves as the power take-up element for an automatic planetary transmission.

Operation

Depending on the shift system, different transmission ratios can be set with a single planetary-gear set; however, not all these ratios can be used for driving (see Planetary-gear set). Therefore a number of planetary-gear sets are required. An 8-speed transmission can for example be achieved with four planetary-gear sets and five shift elements (Figure 18). By means of different combinations of several simultaneously closed or opened shift elements the transmission schematic shown (Table 1) can realize eight forward gears and one reverse gear.

Planetary-gear sets are often used in which parts of the individual single planetary-gear sets are structurally brought together. Two types of planetary transmissions have gained acceptance. In the Ravigneaux gear set two different planetary-gear sets and sun gears operate in a common ring gear (Figure 19); in the Simpson gear set two planetary-gear sets and ring gears operate around a common sun gear. These designs reduce structural complexity and costs.

In automatic planetary transmissions eight to nine gears have proven to be the optimum with regard to reduced fuel consumption and good driveability. For a smaller number of gears the combustion-engine program map is not yet opti-

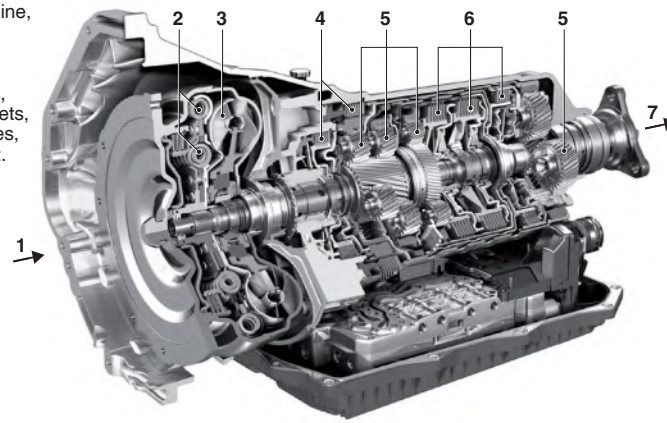
mally developed to drive constantly in the internal-combustion engine's optimum consumption and performance range. For a larger number of gears additional shift elements or planetary-gear sets are required which diminish the efficiency of the transmission and hence the drivetrain in most driving situations. The energy that is required for the greater number of gear shifts can no longer be compensated by better utilization of the combustion-engine program map.

Figure 19: Ravigneaux gear set (diagram).
1 Ring gear, 2 Planetary-gear set 1,
3 Sun gear 1, 4 Planetary-gear set 2,
5 Sun gear 2.



Advantages and disadvantages
The planetary-gear sets have coaxial input and output. This results in advantageous transmission construction types particularly for the standard drive, where the engine crankshaft and the axle-differential drive are on the same axis (Figure 20).

Since the transmitted power is shared in the planetary-gear sets between a number of planetary gears spread over the circumference, automatic planetary transmissions are characterized by a high power density. The comfort of a power-shift transmission is achieved by targeted overlapping shifts of the clutches.

The hydrodynamic torque converter provides for high driveaway and maneuvering comfort. The torque multiplication in the converter has a positive effect on the vehicle's driveaway performance. The slip in the converter is eliminated with a converter lockup clutch. This reduces the losses in this transmission and makes it efficient, even in comparison with manual transmissions.

Application
Automatic planetary transmissions, owing to their type of construction, are used in vehicles with longitudinally installed engines, i.e., in mid-range vehicles and upwards, but also in buses.

Continuously variable transmissions

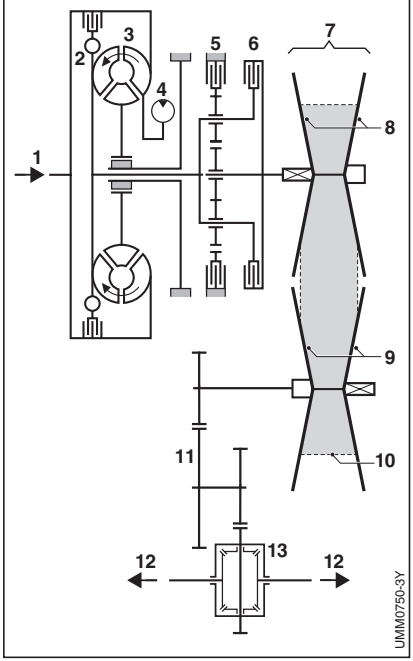
Power and torque transmission via variator

In continuously variable transmissions (CVTs) power is transmitted with a variable gear ratio via a wrap belt (pushbelt) or a wrap chain which runs in a groove from a first to a second V-pulley set (Figure 21). The combination of two V-pulley sets and a wrap belt or a wrap chain is called a variator. Each V-pulley set consists of two tapered pulleys which facing each other. One of these pulleys is axially movable ("loose"). This axial displacement changes the spacing between the pulleys and with it the radius on which the pushbelt or the chain runs. The combination of different, infinitely variable running radii on the two V-pulley sets products the variator's gear ratio.

The transmission of torque from one V-pulley set to the other is based on friction. The required frictional force is achieved by hydraulically pressing together the pulleys of each V-pulley set. Each loose pulley contains one or two hydraulic pistons to which oil pressure is applied by the control system. The amount of pressure must be determined for each V-pulley set. The force that must be exerted on the pushbelt or the chain depends on the instantaneous torque, the gear ratio, and the desired gear ratio. The pressure is then calculated taking account of the required force, the surface of the piston (or pistons), and the actual rotational speed of the V-pulley set. The centrifugal-force effect also generates a pressure which must be taken into account.

Design of a CVT

Figure 21 shows the typical mechanical design of a CVT. On the input side a power take-up element is used, usually a torque converter (as pictured in Figure 21), or less commonly a wet multi-disk clutch. A planetary-gear set is typically used to shift between forward gear, neutral, and reverse gear. A final-drive unit (usually in the form of two transmission steps) and a differential are arranged after the variator. Figure 21 does not show the control system and the parking mechanism.



Because of the relatively large center distance between the variator input and output, CVTs are best suited for use in a front transverse drive (Figure 22). However, they are also used in combination with longitudinally installed engines.

Open-loop control

Actuation, cooling and lubrication of the CVT is performed by an electronically controlled hydraulic system. The electronic control system uses a number of sensors and actuators in the transmission and information from other systems in the vehicle which is normally transmitted via a CAN bus.

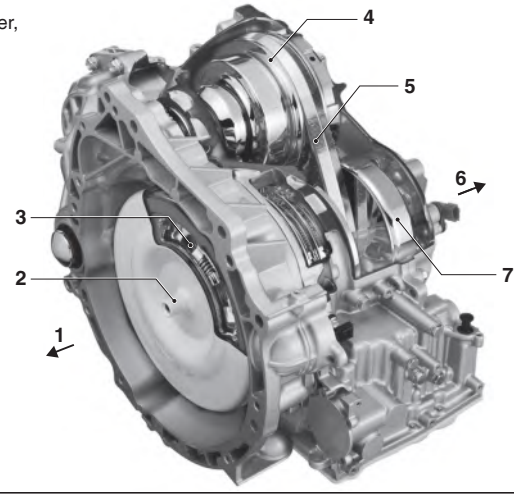
12 To the wheels, 13 Differential.

The hydraulic unit contains values that control the oil pressure or the flow to a number of components in the CVT. The oil is supplied by an engine-driven pump, usually a gear pump or a vane pump. In the last few years more and more CVTs are being equipped with an additional (small) electric oil pump which keeps the hydraulic system filled when the engine is shut down by a start/stop system. The oils used in CVTs are special oils similar to ATF which are optimized in terms of their friction properties.

CVT features

Because the gear changes take place with continuous variability, the CVT offers a high level of ride comfort without tractive-force interruption. Unusual driveability as experienced by some drivers can be avoided by using under certain circumstances programmed “fixed” gear ratios.



A transmission spacing with a factor of up to 7.3 enables the engine to be operated in a wide speed and load range, which is beneficial in terms of both power output and fuel consumption. This benefit outweighs the naturally higher losses of a friction-based transmission. With regard to mechanical efficiency, the wrap chain fares slightly better than the pushbelt. However, the pushbelt is better when it comes to NVH (Noise Vibration Harshness).

Applications

CVTs are used in passenger cars with both internal-combustion engines and hybrid drives. CVTs for electric vehicles are being developed. CVTs for vehicles with lower power output such as mopeds, snowmobiles and side-by-side vehicles (SSVs) frequently use a dry rubber-belt variator and a mechanical control system.

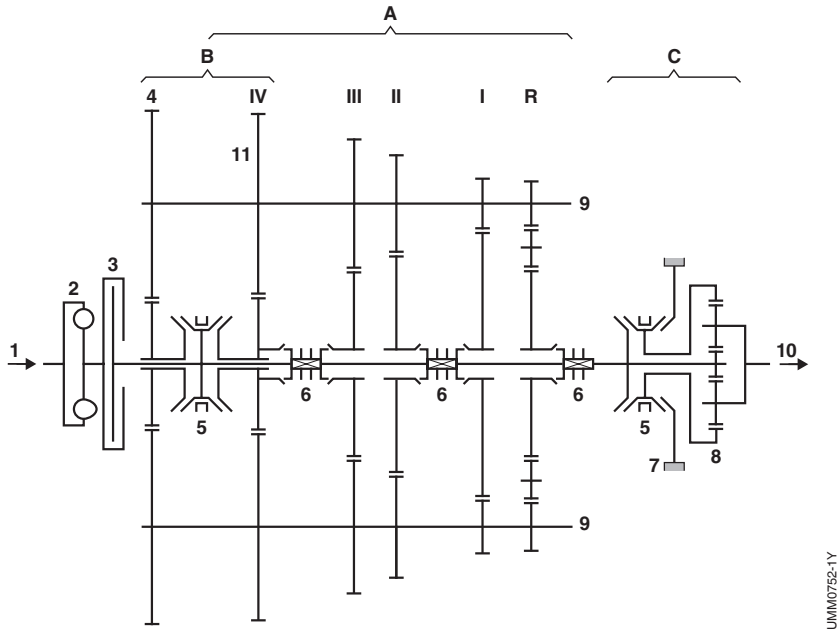
Commercial-vehicle transmissions

Commercial-vehicle transmissions differ significantly in their dimensions from passenger-car transmissions. The reasons for this are not only higher engine torques and engine power output, but also above all the much higher mileage demands of sometimes over one million kilometers. The commercial-vehicle sector features predominantly manually shifted transmissions, automated manual transmissions, and automatic planetary transmissions.

Manually shifted transmissions and automated manual transmissions



The standard construction has gained acceptance as the drivetrain concept in trucks with a gross weight rating of over 3.5 tons. The high loads on the rear powered axle(s) and the associated potential high drive force of the drive wheels are the reason for this drivetrain concept.

Sub-transmissions

Primarily manually shifted transmissions and automated manual transmissions have become prevalent in the truck sector. Up to 16 gears are obtained in manually shifted transmissions and automated manual transmissions. To minimize construction expense, two to three sub-transmissions (splitter box, main box, range-change box) are arranged in succession (Figure 23). In a truck transmission with 16 gears the main box has for example four forward gears and one reverse gear. Mounted upstream of this main box is a splitter box with two gears. The splitter box allows intermediate ratios

I…IV First through fourth gear in main box.
R Reverse gear.
A Main box, B Splitter box, C Range-change box.

of the four gears of the main box. Often the splitter box is used with a full payload since only small gear steps are possible for the very high vehicle weights in relation to the drive power. When the truck is unladen, the ratio of engine power to vehicle weight is much more favorable such that the greater gear steps of the main box can be shifted without using the splitter box.

Splitter and main boxes transmit the torque in the transmission variant shown in Figure 23 to two countershafts. This enables narrower gear widths despite the very high torques in the truck and a smaller center distance between the shafts to be chosen.

Mounted downstream of the main box is a range-change box. The transmission step between the two gears of the range-change box corresponds to the ratio spacing of the main box from first to fourth gear. This means that when shifting the range-change box gear from slow to fast gear at the same time the main box is shifted from fourth to first gear and vice versa. In this way, the spacing of the main box is utilized twice.

In this way, multiplying two splitter gears by four gears of the main box and two gears of the range-change box produces the maximum number of gears for these transmissions of 16 possible forward gears.

Synchromesh

During the gear change in the main box the movable gears are coupled with the shaft gears via shift dogs. The rotational speeds of the gears must be matched in the process. This task is performed by the synchromesh in manual transmissions for passenger cars. In a truck transmission the components of the synchromesh mechanism are not in the main box for weight reasons. In a manually shifted transmission it is therefore necessary to double-declutch when downshifting and double-clutch when upshifting. In this way the rotational speed of the transmission is adapted to the gear to be selected.

Accordingly, gearshifts for a manually shifted transmission on the one hand are uncomfortable and on the other hand need time for the driving speed to decrease again. For this reason automated manual transmissions have become prevalent in the truck sector. The rotational speed for the gearshift is adapted by means of the electronic transmission control.

Automatic planetary transmissions

The longitudinally or transversally mounted rear engine has gained acceptance in buses in order to guarantee maximum transport space for passengers and luggage.

The automatic planetary transmissions used predominantly in buses as a rule have six gears. These transmissions have essentially the same design as those in a passenger car, but their dimensions are adapted to the higher torque and mileage demands.

Differentials

A differential has one input and two outputs. Differentials are most commonly used as final-drive differentials. Their purpose is to distribute uniformly the torque to the two drive wheels when driving straight ahead and when cornering. In all-wheel drive vehicles differentials are used as transfer cases to distribute torque between the vehicle axles.

Figure 1: Schematic diagram of a bevel-gear differential

B Output, drive shaft, left,
C Output, drive shaft, right.
1 Bevel-gear pinion,
2 Bevel crown wheel,
3 Differential bevel gears,
4 Drive-shaft gears,
5 Differential case.

Final-drive differentials

The final-drive differential distributes the torque coming from the manual transmission uniformly to the two drive shafts of a vehicle axle. Since when cornering the inner cornering wheel describes a smaller circle and thus turns more slowly than the outer cornering wheel, the final-drive differential must be able to compensate differential speeds between the drive wheels on an axle.

Bevel-gear differential
On a standard drive the input and output of the bevel-gear differential are offset by 90°. The bevel-gear differential drive transmits the torque from the bevel-gear pinion to the bevel crown wheel (Figure 1 and Figure 2). The bevel crown wheel (differential drive gear) transmits the torque via the differential case to the axle shafts of the differential bevel gears. The differential bevel gears distributes the torque to the two drive-shaft gears.

When the vehicle is driving straight ahead the two drive-shaft gears rotate at the same speed. The differential bevel gears circulate at the speed of the bevel crown wheel without rotating about their own axle shaft. They act as drivers and distribute the torque uniformly to the two drive shafts.

When cornering the differential bevel gears compensate the difference in speed of the drive shafts by rolling off on the drive-shaft gears rotating at different speeds. In this process the differential bevel gears rotate on their axle shafts, which are mounted in the differential case.

In most final-drive units the bevel-gear pinion meshes outside the axis center of the bevel crown wheel (Figure 3). This is called a hypoid drive. The advantages of a hypoid drive are:
– Smoother running since a greater number of gears mesh with each other.
– Higher torque transmittability since the bevel-gear pinion has a larger effective diameter due to the axial offset.

The drawback of this arrangement is the increase in sliding as opposed to rolling-off

between the bevel-gear pinion and the bevel crown wheel. However, this can be successfully countered with particularly pressure- and shear-resistant hypoid gear oils.

In front-transverse transmissions the bevel-gear pinion and the bevel crown wheel are replaced by two spur gears acting as pinion and differential drive gear (see Automated manual transmissions). Since the differential gears are designed as bevel gears, this design type is still classed as a bevel-gear differential.

Spur-gear differential

In a spur-gear differential the differential gears are designed as spur gears. There are various design types which utilize the different connection forms of planetary transmissions. In the differential pictured in Figure 4 the torque is routed via the differential drive gear directly into the planetary-gear carrier. The planetary-gear carrier distributes the torque to the planetary gears arranged in pairs on both sides. The planetary gears of a pair mesh with each other in each case with half the face width. The outer halves of the planetary gears mesh with the sun gears. The sun gears direct the torque in each case to the drive shafts [1]. Unlike a standard planetary transmission, there is no ring gear here. The differential case is the planetary-gear carrier for both planetary-gear sets. Sun gear 1 is at the same time drive-shaft gear 1, sun gear 2 is drive-shaft gear 2. Planetary gears 2 in Figure 4 are drawn with dashed lines because they are offset to the rear in the leaf plane and interlocked with planetary gears 1 with half the face width.

When the vehicle is driving straight ahead the two drive shafts rotate at the

same speed. The planetary gears circulate at the speed of the differential drive gear without rotating about their own axle shaft. They act as drivers and distribute the torque uniformly to the two drive-shaft gears.

When cornering the planetary gears compensate the difference in speed of the drive shafts by rolling off on the sun gears rotating at different speeds. In this process the planetary gears rotate on their axle shafts in the planetary-gear carrier.

Locking differential

A differential can transmit torque only as long as both vehicle wheels can transmit this torque to the roadway. As soon as the adhesion at a wheel breaks down (e.g. due to black ice), the wheel begins to spin. Since rotational speed but not torque is transmitted on the drive shaft of this wheel, the differential gears cannot be supported on the drive-shaft gear of the spinning wheel and torque is transmitted to the other drive-shaft gear. Consequently, the other wheel stops and transmits no drive torque, although adhesion with the roadway would be possible at this wheel in some cases.

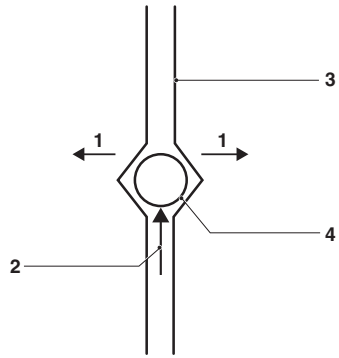
Figure 5: Schematic diagram of a multi-disk self-locking differential
1 Bevel-gear pinion, 2 Bevel crown wheel,
3 Axle shaft, differential bevel gear,
4 Drive-shaft gear, 5 Differential case,
6 Multi-disk clutch,
7 Thrust rings, 8 Differential bevel gear,
9 Edge, thrust ring.
A Input, propeller shaft,
B Output, drive shaft, left,
C Output, drive shaft, right.

The purpose of the locking differential is to transmit drive torque to the two drive shafts, even if a wheel of a driver shaft has reduced adhesion with the roadway.

The locking differential has, in addition to the components described above, multi-disk clutches installed between the differential case and the driver shafts (Figure 5). One thrust ring per multi-disk clutch is installed in the differential case. The thrust rings are non-rotationally connected to the differential case but can move axially to be able to press against the multi-disk clutches. The axle shafts of the differential gears are mounted in recesses between the thrust rings (Figure 6). The axial forces that are produced during power transmission with bevel gears press the thrust rings onto the multi-disk clutches, and this is done more intensely the more torque is transmitted in the bevel-gear drive. The higher the transmitted torque, the higher the locking torque of the multi-disk clutch can be.

With equally good adhesion at both wheels, the majority of the torque is transmitted via the thrust rings to the differential gears, which distribute the torque – since they function as drivers – uniformly to the two drive shafts (Figure 5).

If, due to the loss of adhesion at a wheel, a difference in speed arises between the two drive shafts and thus also between the differential case and the drive shafts, torque is transmitted by the pressed multi-disk clutch to the drive shaft that is rotating at the slower speed.



The level of torque and hence the degree of differential locking are dependent on the number of disks and their coefficient of friction, which can be varied by way of different friction linings.

Beyond this design variant there are further solutions approaches for locking differentials, e.g. an actively activatable multi-disk clutch between the drive shafts.

2 Application of force from differential case,
3 Edge, thrust rings,
4 Axle shaft, differential bevel gear (top view).

Brake intervention with locking-differential effect

Since the introduction of antilock braking systems and driving-dynamics control (Electronic Stability Program) it has been possible to activate brakes of individual wheels. This opportunity is used to brake the faster wheel starting from a specific difference in speed between two drive shafts. Here, torque from the drive shaft rotating at the faster speed in relation to the body is supported via the brake. This enables the differential gears to transmit torque to the drive shaft rotating at the slower speed even without a lock in the differential.

Electronic transmission control

Functions and requirements

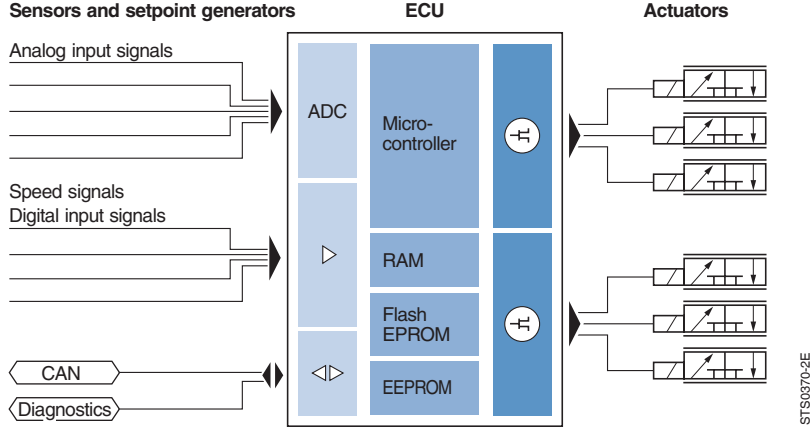
Hydraulics

Predominantly electronically actuated hydraulic systems are now used to control automated and automatic transmissions. Clutch actuators actuate dry clutches and gear selectors shift the gears in automated manually shifted transmissions and in dual-clutch transmissions. Shift elements activate the multi-disk clutches and multi-disk brakes in wet clutches and in automatic planetary transmissions.

The actuators, in this case the electrohydraulic actuators, serve as the connecting element between the electronics and the hydraulics. Actuators convert an electrical actuating signal output by the electronic control unit into an actuating force. Pressure-control valves ensure precise control of pressure levels at the shift elements (clutches and friction elements). As well as controlling, boosting, and distributing the hydraulic pressures and volumetric flows for the shift elements, this mechatronic system also supplies the torque converter, provides the lubricating pressure, and cools the automatic transmission.

Electromechanics

As an alternative to the hydraulic systems there are automated manually shifted transmissions and some dual-clutch transmissions with electromechanical control in which electric motors take on the role of the hydraulic system (actuate clutch, engage and select gear). These are designed for dynamic and wear reasons as BLDC (Brushless Direct Current) motors.



Electronics

Hydraulic actuation is retained for the clutches, while the electronics assume responsibility for gear selection, for gearshifting, and for adapting the pressures in accordance with the torque flow. The advantages are:

– a number of gearshift programs including adaptive drive functions,
– improved, constant gearshift comfort over the full service life,
– adaptability to different types of vehicle,
– simplified hydraulic control.

To guarantee these processes safely, comfortably and to suit the situation the control system requires various operating data which are acquired by sensors [1] (Figure 1):

Figure 1: Electronic transmission control

– transmission output-shaft speed,
– transmission input-shaft speed,
– pressure at the clutches,
– selector-lever position,
– positions of the program-selector and kick-down switches.

Further information such as engine speed, driver command, and engine torque is acquired by the engine ECU and transmitted via the CAN bus to the transmission control. The transmission control unit processes this information according to a predefined program and uses the results in determining the control variables to be output to the electrohydraulic actuators.

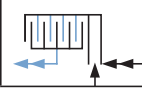
The transmission control must satisfy different requirements depending on transmission types and thus also varies greatly in its circuit complexity. Furthermore, the ambient conditions of different installation locations differ greatly in terms of temperature range, vibration, and tightness requirements. Implementations range from the simple remote-mounted ECU (the ECU is separated from the transmission) through an add-on ECU (e.g., for a dual-clutch transmission or a continuously variable transmission) to the complex electronic module for a dual-clutch transmission or automatic transmission which is installed inside the transmission housing (Table 2).

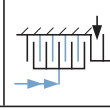
Transmission-control components

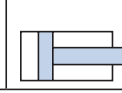
Components on the transmission

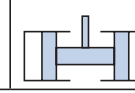
The transmission control comprises the following components:
– pressure-control and flow valves,
– hydraulic components (e.g., restrictors, dampers, slides, filters),
– control block (generally acts as the base carrier for the control unit),
– electronic transmission control unit.

The electrohydraulic control is accommodated in the transmission housing. The control is subject to further requirements with regard to temperature, change of temperature, contamination, and vibrations; it must also exhibit a high degree of media resistance to transmission oil [2].









The conceptual distinction between actuator and shift element is shown in Table 1.

Table 1: Definition of actuator and shift element

Designation	Actuator	Shift element			
Installation location	Transmission control	Transmission			
Example	Electrohydraulic actuator (e.g., solenoid valve) 	Clutch 	Brake 	Clutch actuator 	Gear selector 

Option of intervention by the driver
Selector lever
The classic selector lever in the center console with the positions P, R, N and D and a cable to the transmission is replaced in today's shift-by-wire system by simple rotary or rocker switches which permit more freedom in the vehicle's passenger-compartment design. However, the main functions have been retained and are the same for all automated transmissions:
– P "Park"; the parking lock is activated in the transmission, preventing the vehicle from rolling,
– R "Reverse" engages the reverse gear,
– N "Neutral" or idle; i.e., there is no power transmission between the engine and transmission,
– D "Drive"; forward driving is activated.

Many systems still have a so-called M gutter which allows the gear to be manually selected.

Program selector
The driver can select the following programs by pushbutton or switch:
– E "Economy", results in economical driving in as high a gear as possible (Economy mode),
– S "Sport program", performance-oriented gear selection (Sport mode),
– M "Manual selection" of gear.

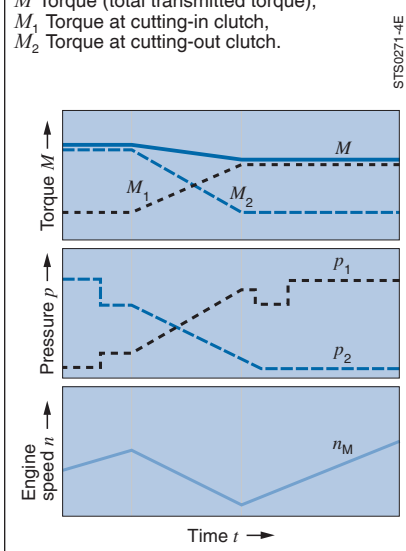
The Economy mode or Sport mode can also be selected by intelligent control in the software depending on the driver's driving performance.

Shift-point control

Drive programs
In selecting the gear to be engaged, the system refers to the rotating speed of the transmission output shaft and the driver command before triggering the appropriate solenoid valves or pressure regulators. The driver chooses between different drive programs (e.g., for optimum consumption- or performance-based driving) via the selector lever or an adaptive drive program is implemented which selects the optimum gear from the driving situation and driver type. In addition, the selector lever allows manual input from the driver.

Gearshift sequence from the example of an upshift in a multi-speed transmission
Power upshifts take place in an automatic transmission, unlike a manual transmission, without interruption of tractive force as overlap control. While clutch 1 opens for gear x, clutch 2 must close for gear y (Figure 2).

Figure 2: Overlap control
p_1 Pressure at cutting-in clutch,
p_2 Pressure at cutting-out clutch,
n_M Engine speed,
M Torque (total transmitted torque),
M_1 Torque at cutting-in clutch,
M_2 Torque at cutting-out clutch.



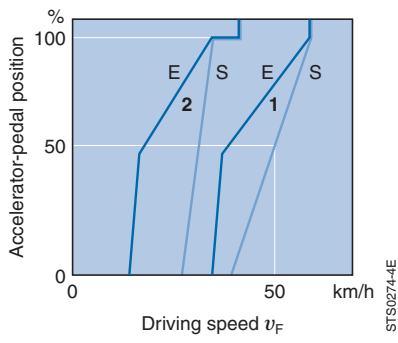


Figure 3 shows the upshift curve for shifting from first to second gear in Economy and in Sport modes, i.e., the accelerator-pedal position and speed at which the gear shift takes place. The same applies to downshifting. There must be a gap between the upshift and downshift curves (hysteresis) to avoid gear hunting.

Driving-situation detection
Variables such as linear and lateral acceleration are used for driving-situation detection, resulting in the detection of hills or corners. For this purpose progressive systems additionally incorporate the information from the navigation system in order to prepare future driving situations. The speed with which the accelerator pedal is pressed and the number of kick-down operations in a defined period of time or the frequency of brake-pedal operation serve to identify the type of driver (from very economy- to very performance-minded). A complex control program selects the appropriate gear for the current operating conditions and driving style. In other words, it suppresses trailing-throttle upshifts on the approach to and during corners, or automatically responds to slow throttle openings by activating a drive program for low engine-speed upshifts.

Concepts which combine the high level of convenience of such "intelligent" gearshift programs with facilities for active adaptation to individual driver preferences have become very widespread. The selector levers of these systems have a second parallel gutter (M gutter), in which simply touching the selector lever initiates an immediate gear shift (provided no engine-speed limits are exceeded). Alternative solutions come in the form of paddles or ± buttons on the steering wheel.

Figure 3: Upshift curve from first to second gear and downshift curve from second to first gear in Economy and Sport modes
1 Upshift curves,
2 Downshift curves.
E Economy mode,
S Sport mode,
Range above 100 % is triggered by kick-down switch.

Converter lockup
A converter lockup can be used in both multi-speed and continuously variable transmissions. A mechanical lockup clutch can be employed to improve the efficiency of the transmission unit by eliminating torque-converter slip. The variables employed to determine when conditions are suitable for activation of the converter lockup mechanism are engine load, transmission output-shaft speed, and state of the transmission.

Control of shift quality
The accuracy with which the pressure at the friction elements of the clutches is adjusted to the level of torque being transmitted (determined with reference to engine load and speed) has a decisive influence on shift quality; this pressure is regulated by a pressure regulator. Shifting comfort can be further enhanced by briefly reducing engine torque (via an engine intervention) for the duration of the shift (e.g., in a gasoline engine by retarding the ignition timing, reducing the injected fuel quantity, or cylinder cutout); this also reduces friction loss at the clutches and extends their service life.

Adaptive pressure control
Crucial parameters such as clutch fill time and slip time are permanently monitored to ensure a constant gearshift quality throughout the transmission's service life. In the event of deviations from specified limits, pressure corrections are made in the system in order to maintain an optimum time characteristic during the next gearshift and thus optimum shift quality.

Safety strategy
Special monitoring circuits and functions prevent transmission damage stemming from operator error, while the system responds to malfunctions in the electrical system by reverting to a backup mode. It is important to ensure at all times that vehicle instability does not arise.

Software-development requirements
Software development for automated transmissions must satisfy the following requirements:
– Compliance with functional safety (ASIL D, Automotive Safety Integrity Level, [3]),
– ASPICE (Automotive Software Performance Improvement and Capability Determination) as the development process in the international development network [4],
– AUTOSAR as the interface standard (Automotive Open Systems Architecture, [5]), and
– Software sharing between ECU manufacturers, transmission manufacturers, and vehicle manufacturers.

Hydraulic control

Functions
The main purpose of hydraulic control is to regulate, boost and distribute hydraulic pressures and volumetric flows. This includes generating the clutch pressures, supplying the torque converter, and providing the lubricating pressure. The hydraulic-control housings (hydraulic control plate) are made of diecast aluminum and contain a number of finish-machined slide valves and electrohydraulic actuators.

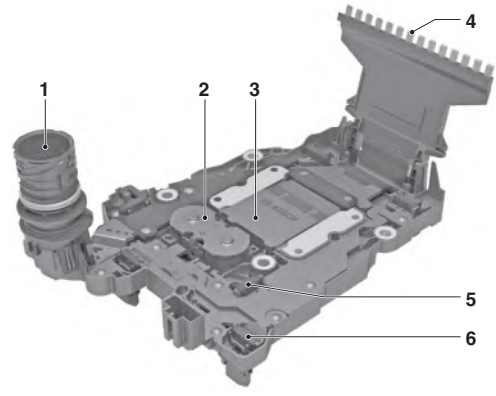
Figure 4 shows the electronic module with the sensors of electronic transmission control for a hydraulically actuated dual-clutch transmission. The electronic module is screwed to the hydraulic control plate and is seated inside the transmission wholly or partly in the transmission oil pan. The module is subject to high tightness and heat-resistance requirements in order to protect the electronics.

Electrically driven auxiliary oil pumps are increasingly used to generate the hydraulic pressure in line with demand, increase efficiency, and maintain the hydraulic pressure when the internal-combustion engine is stopped (e.g. in start/stop or hybrid systems). The activation and power electronics for the BLDC motor (Brushless Direct Current) are implemented either on the pump itself or as part of the electronic module.

Electrohydraulic actuators

Electrohydraulic actuators (electrohydraulic converter elements such as solenoid valves and pressure regulators) form the interface between the electronics with electrical signal processing and the hydraulics. They convert the low-power actuating signals into an actuating force with the increased power required for the process. The actuators monitor the oil flow and the pressure characteristics in the hydraulic control plate for this purpose. Actuators are consequently essential final control elements and form the basis of electrohydraulic transmission control. A solenoid and a hydraulic valve together form an electrohydraulic actuator.

General actuator requirements
Because they are installed directly in the transmission, electrohydraulic actuators are subject to the following specific requirements:
– endurance strength up to 5,000 hours or 300,000 km,
– vibration resistance up to 5,000 hours or 300,000 km,
– resistance to heat and insensitivity to change of temperature in the range of –40 to 160 °C,
– small size (saving on installation space and costs),
– media resistance to automatic transmission fluid with additives and water content,
– vibration insensitivity up to 30 g,
– generation of low hydraulic vibrations,
– operating time (100 %).



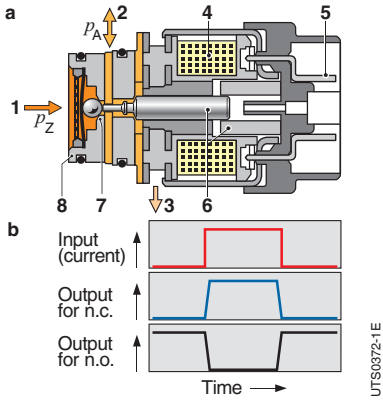
There are further specific requirements with regard to regulable pressure and throughflow as well as hysteresis and leakage.

Actuator design variants
There are different actuators, depending on function and design:
– switching valves (on-off solenoid valves, On/Off),
– pulse-width-modulated solenoid valves (PWM),
– flat-seat pressure-control valves (DR-F),
– spool pressure-control valves (DR-S),
– proportional solenoids (PM).

Solenoid valves
The on-off or PWM solenoid valves produce two different methods of converting an input signal (current or voltage) into an output signal (pressure).

Switching valve
The logic with the states 0 and 1 is sufficient for a simple switching valve and is generally controlled via the current (Fig-

Figure 4: Electronic module of a transmission control
1 Transmission connector (to wiring harness),
2 Pressure sensors,
3 ECU integrated in the electronic module,
4 Connectors for contacting the hydraulic valves,
5 Sensor domes of position sensors (rear side),
6 Sensor domes of speed sensors (rear side).



ure 5). This design is called on-off solenoid valve, the associated hydraulic circuit is fashioned as either a normally closed (n.c.) contact (closed at zero current) or a normally open (n.o.) contact (open at zero current).

The supply pressure p_Z generated by the transmission oil pump is applied ahead of the flange and closes the ball seat when the valve is closed at zero current. Because there is no pressure applied in the operating-pressure channel at zero current, the valve is "closed at zero current". In this state the operating pressure that supplies the consumers (e.g., a clutch) is connected directly to the return to the transmission-oil tank (oil pan) so that an applied pressure can decrease there or a contained oil volume can drain.

When a current is applied to the switching-valve winding the magnetic force draws the armature with the plunger connected to it towards the ball and opens the ball seat. The oil flows to the consumer and builds up the pump pressure there. At the same time the return to the transmission-oil tank closes.

These solenoid valves are characterized by low costs, low leakages, simple activation electronics, and low susceptibility to dirt. However, they are used increasingly less owing to the rising complexity and comfort requirements of transmissions [6].

PWM valves

Essentially, PWM valves are designed in exactly the same way as on-off solenoid valves. There are however designed for a higher switching speed and higher mechanical loads. To adjust pressures infinitely, they are used as so-called proportional valves. With the pulse-width-modulated input signal a volumetric flow proportional (rising) or inversely proportional (falling) to the pulse duty factor is generated which in turn generates the

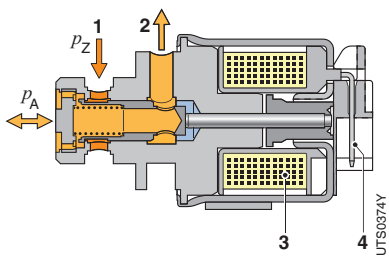
output pressure via the pressure drop at a preliminary restrictor (Figure 6).

PWM valves are characterized by properties such as low costs, low susceptibility to dirt, simple activation electronics, and a small hysteresis. However, PWM valves are used increasingly less because they generate undesirable noises.



For important characteristic data, please refer to Table 3 [6].

PWM valve with high throughflow

The PWM valve with high throughflow (Figure 7) essentially has a similar design to the previously described standard PWM valve, but provides larger opening cross-sections with a larger diameter and longer opening lift of the closing element. This design requires a larger copper winding with a higher magnetic force.

Pressure-control valve, flat-seat and spool designs

Two different pressure-control principles are used for analog valves: flat-seat and spool pressure-control valves [7]. Both principles involve complete closed-loop control circuits because the controlled pressure intervenes directly in the equilibrium of forces.

Flat-seat pressure-control valve

A flat-seat pressure-control valve (DR-F) is a proportional valve with a variable helix and a fixed helix (Figure 8). The DR-F op-

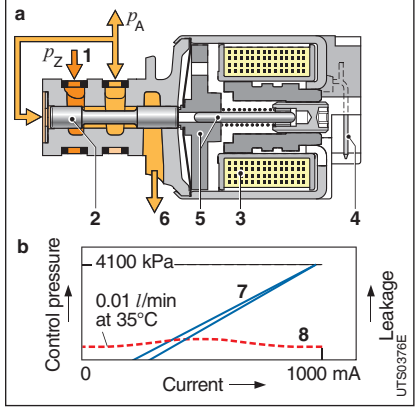
Table 3: Important characteristic data of on-off and PWM solenoid valves

Criterion	On-off valve	PWM valve	
Type		Falling curve	with high throughflow
Supply pressure [kPa]	400…600	300…600	400…1 200
Throughflow at 550 kPa [*l*/min]	>2.5	>1.5	>3.9
Clock frequency [Hz]	20	40…50	40…50
Coil resistance [Ω]	12.5	10	10

erates with an upstream restrictor (fixed helix) which is integrated either in the external hydraulic control or in the pressure regulator. The restrictor has a significant influence of the pressure-regulator characteristic, the precise matching of which is made possible by the integration of the restrictor in the pressure regulator. The ratio of the hydraulic resistances of the two restrictors cannot be arbitrarily small; a DR-F therefore has a residual pressure. This is why the effective control range cannot decrease to 0 kPa. This also results in a permanent pressure-regulator leakage. Energy losses are generated by this permanent oil flow into the transmission-oil tank. To compensate for this, transmission oil pumps with a higher volumetric flow are required, which is detrimental to the overall energy efficiency of a transmission and also results in higher fuel consumption.



In a DR-F the hydraulic pressure (p_H), the magnetic force (F_M), and the spring force (F_F) influence the equilibrium of forces. The hydraulic pressure acts on the sensing surface of the piston. The magnetic force is proportional to the current that flows through the coil and a defined initial state is achieved with the aid of the spring force. When the flat seat (variable helix) opens oil flows back to the transmission-oil tank, bringing about a pressure reduction at the restrictor (fixed helix) and enabling the control pressure (p_A) to be adjusted. In the case of a flat-seat pressure-control valve with falling characteristic curve the magnetic force acts in the direction of the hydraulic pressure force (F_H) against the spring force. As a result the pressure in the control space decreases as current increases. In the case of a flat-seat pressure-control valve with rising characteristic curve the hydraulic pressure force and the spring force are in opposition to the magnetic force. Accordingly, the pressure in the control loop increases as current increases (Figure 8). A flat-seat pressure-control valve is accordingly an adjustable pressure-relief valve with hydraulic control function whose advantages disadvantages are set out in Table 4.

Spool pressure-control valve

A spool pressure-control valve (DR-S) operates with two helices and is also called a dual-helix pressure regulator or spool. The controlled pressure (p_A) is tapped between the inlet helix and the outlet helix (Figure 9). This results from the opening ratio at the inlet and outlet helices. Maximum pressure is obtained when the outlet helix is closed and zero pressure obtained when the inlet helix is closed. As in the flat-seat pressure-control valve the magnetic force, which is proportional to the current, the spring force, and the hydraulic pressure force, acts on the equilibrium of forces. The return of the controlled pressure to the sensing surface, e.g., the end face of the spool, via an internal channel closes the control loop. The control loop can also be closed via oil channels in the control plate. A spool pressure-control valve can like a flat-seat pressure-control valve be designed with a rising or falling characteristic curve.

The advantages and disadvantages of a spool pressure-control valve are set out in Table 5.

Proportional solenoid
Inserting a separating plane is between the hydraulic spool and the solenoid section of the spool pressure-control valve produces a proportional (linear-force) solenoid (PM) and a spool. The advantage of this separation is the use of standardized proportional solenoids and functional adaptation by individual spools. Otherwise they are functionally identical to spool pressure-control valves.

Table 4: Advantages and disadvantages of a flat-seat pressure-control valve (DR-F)

Advantages	Disadvantages
High accuracy	High leakage
Low cost	Residual pressure
Not susceptible to dirt	Costly electronics
Insensitive to disturbances	Difficult damping
	Seat rebound

Table 5: Advantages and disadvantages of a spool pressure-control valve (DR-S)

Advantages	Disadvantages
High accuracy	High susceptibility to dirt
Insensitive to disturbances	Costly manufacture of precision parts
Low temperature sensitivity	Costly electronics
Low leakage	
No stops	
Dampable	
Zero pressure achievable	

Characteristic values
Typical characteristic values of flat-seat and spool pressure-control valves are set out in Table 6.

Use of different actuators
Table 7 shows the respective links between the individual transmission functions and the actuator types that can be used in a multi-speed transmission and in a continuously variable transmission (CVT). The decision whether a PWM valve, on-off valve, DR-F, DR-S or PM is used also depends on among others the following system factors [7]:
– installation location,
– dynamic properties of the system,
– leakage,
– accuracy,
– costs,
– dirt concentration and dirt composition.

Not to be underestimated either are the experiences of the customer with the respective actuator types (e.g., risk, confidence level) or even the effort to be applied in switching existing control concepts to other actuators.

Table 6: Typical characteristic values for flat-seat (DR-F) and spool pressure-control valves

Criterion	DR-SI	DR-F	
Type	DR-S	D26 falling curve	D20 rising curve
Supply pressure [kPa]	700…2500	500…600	500…800
Controlled typical pressure [kPa]	0…2500	40…600	40…800
Typical current range [mA]	0…1200	150…770	150…1000
Dither frequency [Hz]	<200	<200	<200
Chopper frequency [kHz]	3	1	1
Diameter [mm]	28	26	23

Methods for controlling shift elements
There are two different pressure-control variations to initiate the actuating process of a shift element (clutch, brake or gear selector): direct control and pilot control [8].

Pilot control
A large volumetric flow is required to enable a shift element (e.g., a clutch) to be quickly filled. To control large volumetric flows the actuators must likewise be of such a very large size to be able to deliver the necessary forces. To avoid this, pilot control operates with two control circuits, the pilot control circuit (0 to 6 bar) and the main control circuit (approx. 20 bar). The electrohydraulic actuator is situated in the pilot control circuit. A lower pressure is applied at this actuator (pilot control valve) than at the check and booster valves, which are located in the main control circuit. The pilot control valve controls these spool valves by making hydraulic fluid available at the respective control surfaces (Figure 10).

Table 7: Linking of transmission functions and actuator types

Multi-speed transmission					
Function	PWM (old)	On/Off	DR-F	DR-S	PM
Control main pressure	×		×	×	×
Trigger gear change			×	×	×
Modulate shifting pressure			×	×	×
Control converter lockup clutch	×		×	×	×
Reverse-gear interlock		×			×
Safety functions (fail-safe)		×	×		×

Continuously variable transmission (CVT)

Adjust gear ratio			×	×	×
Control belt tension			×	×	×
Control starting clutch			×	×	×
Reverse-gear interlock		×			×

Direct control
In the case of direct control the electrohydraulic actuator is integrated directly in the main control circuit. As a result, there is no need for the supply, check, and booster valves used in pilot control. The volume provided by the pump and the pressure made available to actuate the shift element are thus controlled directly by the electrohydraulic actuator (Figure 11).

Internal-combustion engines

Thermal engines

Operating principles and concept

Internal-combustion engines are classified as thermal engines. The essential feature of a thermal engine is cycle direction, which is characterized by the output of work.

Contrasting with thermal engines are heat pumps, also called refrigerating machines, which are characterized by cycle direction in the opposite direction and require drive power in order to operate.

The operating principle of thermal engines is always the same. A working medium is compressed, whereupon energy is supplied while the medium is compressed with a corresponding further increase in pressure. This is followed by an expansion with power output. In open cycles the working medium which has performed the work is discharged. In closed cycles the initial state must be re-established by cooling the working medium before compression is restarted in open and closed cycles.

Table 1: Characteristics and functioning principles of important thermal engines

Thermal engine	Steam circuit	Stirling	Steam engine	Gas turbine	Jet engine	Reciprocating piston engine	Wankel rotary engine

Many thermal engines are characterized by an energy input resulting from a combustion process (Table 1). During combustion the energy chemically bound in the fuel is supplied as reaction heat to the cycle. Here compounds containing carbon and hydrogen oxidize with oxygen, which is why typically ambient air with approximately 21 % volume of oxygen makes up a significant part of the working medium.

Cycle direction

The factor that is crucial to cycle direction is the energy input. Here, a distinction is initially made between stationary (or continuous) energy input and non-stationary (or cyclical) energy input. What all piston engines including the Stirling engine have in common is a non-stationary energy input which only ever occurs close to compression dead center with minimum cylinder volume.

A particular feature of all open cycles is an internal energy input which is achieved by the addition and combustion of fuel. In contrast, closed cycles require an energy input via heat exchangers. Here there is no direct contact between the working medium and combustion processes, with the exception of heat conduction. Unique in this context is the steam engine, which vaporizes the working medium by means of a heat flow from an external source and then supplies it to the piston engine.

Another particular feature of the various thermal engines is the different energy sources which are used. Three different energy sources can be used: solids, liquids and gases. The main advantage of thermal engines which operate with an open cycle and an internal energy input is that they do not require any heat exchangers for cycle direction and are therefore compact in design. This advantage can be amplified by using liquid fuels with a high energy density. Gas engines, for example when deployed in passenger cars and commercial vehicles, are also becoming more attractive (running costs, good fuel consumption). The internal-combustion engine can thus be derived from a selection of thermal engines.

Efficiency

The internal-combustion engine is characterized by open cycle direction with internal combustion. Non-stationary operation facilitates the intake and compression of the working medium at mass-averaged peak temperatures above 2,500 K and averaged peak pressures above 200 bar with a very good maximum efficiency above 40 %.

Stationary cycles, being limited by the properties of the materials, do not achieve mass-averaged peak pressures and temperatures of this magnitude, but instead achieve maximum local peak temperatures around 2,500 K. Gas turbines therefore operate at a lower level of efficiency. The closed cycle of the steam circuit achieves a higher level of efficiency than gas turbines with a likewise moderate pressure of around 50 bar. This is achieved by a significant lowering of the low-pressure level. The other thermal engines are much lower in terms of their maximum efficiency.

Reciprocating-piston engine

The internal-combustion engine, in its reciprocating-piston-engine variation, is the primary thermal engines used for mobile applications. A wide range of fuels is conceivable in principle, but diesel and gasoline are still the main energy sources used.

Real cycles

A cycle is a thermodynamic process which has identical initial and final states (see Thermodynamics). The cycle usually passes through several changes of state in such a way that with a thermal engine work is drawn from the cycle. Here the working medium of the cycle undergoes thermodynamic changes of state.

Ideal reference cycles are suitable for demonstrating basic correlations. In the case of new, as yet unknown engines, they help to provide an overview of their method of operation and efficiencies. However, a real cycle calculation is required for detailed analyses.

Real cycles are set in proportion to the ideal cycles. This means that the heat capacities are considered for example depending on temperature or pressure.

The chemically altered composition of the smoke gases is also approximated in the substance variables in order to take into consideration the changed physical properties based on combustion. In particular, what is assumed is not an adiabatic change of state, but rather at least one polytropic curve with an exponent adapted to the heat loss, or even the heat loss to the wall is used, e.g. with the Woschni approach from the Reynolds similarity theory [1].

The charge cycle is calculated with its dissipation losses (flow losses, real flow cross-sections, see Fluid mechanics) and thus the residual exhaust gas is also taken into account. Furthermore, empirical approaches are normally used for friction and the fuel calorific value is calculated depending on the air ratio. Ultimately, in particular the heat addition (combustion process, heating process) and the heat dissipation (heat transfer) are modeled in detail.

One way to quickly assess real cycles is to describe them using an efficiency chain. Here the real cycles are successively depicted by taking individual characteristic quantities into account.

Overall efficiency
The overall efficiency or effective efficiency η_{eff} sets the effectively available power P_{eff} in proportion to the energy flow $\dot{Q}_{\text{add}} = \dot{m}_{\text{B}} H_{\text{u}}$ which was added by the fuel mass flow $\dot{m}_{\text{B}}$ and its lower calorific value H_{u}:

$$\eta_{\text{eff}} = \frac{P_{\text{eff}}}{\dot{Q}_{\text{add}}} .$$

Diesel engines have at higher loads an effective efficiency of approx. 45 %, large slow-running diesel engines have a much higher effective efficiency. Gasoline engines have, depending on the combustion process, an effective efficiency at their best point of approx. 42 %.

Mechanical efficiency
The mechanical efficiency sets the effectively measured power P_{eff} in proportion to the pressure-indicated cycle power P_{ind}. The indicated power is determined from the work W – this is the area of the real pressure characteristic against volume $\int pdV$ – and the time t per working cycle according to the following relationship:

$$P_{\text{ind}} = \frac{dW}{dt} \approx \frac{\Delta W}{\Delta t} .$$

The effective power differs from the indicated power essentially in the frictional losses (piston, bearings), the power-transmission losses from control elements (camshaft, valves), and the power of the accessories (oil and water pumps, fuel-injection pump, alternator). For the mechanical efficiency:

$$\eta_{\text{m}} = \frac{P_{\text{eff}}}{P_{\text{ind}}} .$$

Normal mechanical efficiencies are load-dependent and at full load come in at just under 90 %, while at low part load (10 % load) values around 70 % are registered.

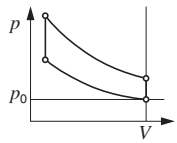
Efficiency-of-cycle factor
The efficiency-of-cycle factor describes the efficiency with which the real cycle can be approximated by the chosen reference cycle. It therefore contains losses resulting in particular from dissipation losses. For a detailed loss analysis it is recommended to split the efficiency-of-cycle factor between the high-pressure loop and the charge-cycle loop (Table 2).

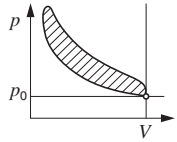
Normally, for calculation purposes, an ideal gas with temperature-dependent heat capacities is assumed and the cycle is used with geometrically identical dimensions, the same air ratio, without residual exhaust gas, complete combustion, and thermally isolated walls. An engine described in this way is also called a “perfect engine”. The efficiency-of-cycle factor at full load is in the range of approximately 80 to 90 %.

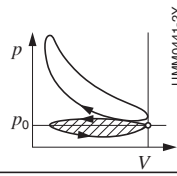
If an ideal gas with constant heat capacity is still to be used, it is possible to introduce the “efficiency of the perfect engine”, which sets the power of the “perfect engine” in proportion to the power of the “ideal cycle”.

Fuel-conversion factor
In particular, gasoline engines with rich-mixture combustion (air/fuel ratio $\lambda < 1$) are subject to high HC and CO emissions, which usually cannot be taken into account in the approach of added heat via the fuel calorific value H_{uB}. However, the exothermy of these gases H_u is considerable, which is usually also reflected in higher exhaust-gas temperatures after the oxidation-type catalytic converter. It is taken into account in the fuel-conversion factor:

$$\eta_B = \frac{(H_{uB} - H_u)}{H_{uB}} .$$







$\eta_B = 1$ is usually set for diesel engines. In gasoline engines the figure can drop to 0.95, and with very rich air ratios $\lambda < 1$ even further below that.

Efficiency chain
The entire efficiency chain can be described as follows (Table 2):

$$\eta_{eff} = \eta_i \, \eta_m = \eta_{th} \, \eta_g \, \eta_m .$$

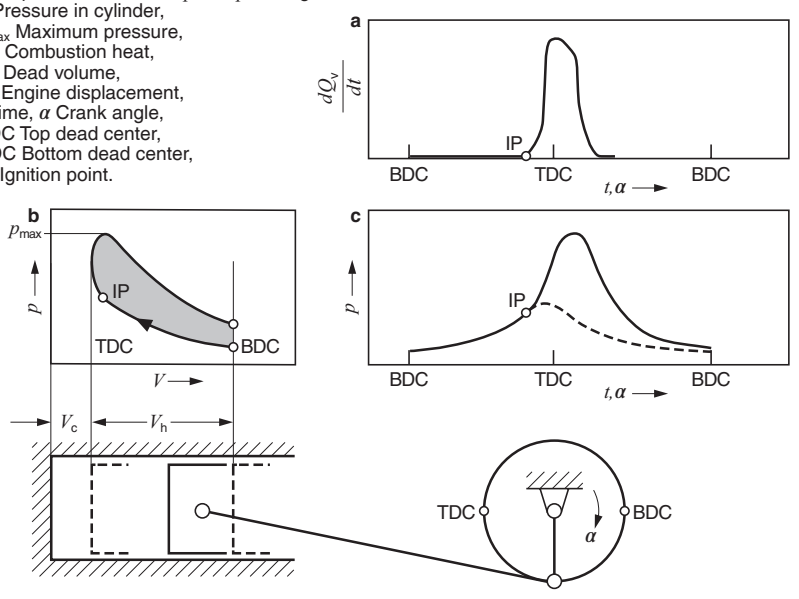
Mixture formation, combustion, emissions

All internal-combustion engines share the common feature of combustion occurring after induction of the fresh mixture or air and after subsequent compression. In reciprocating-piston engines with internal combustion this takes place close to top dead center (TDC). The result is a pressure increase, which is transmitted via the piston and the connecting rod to the crankshaft in the form of a crankshaft torque (Figure 1).

The sequence of compression and subsequent combustion on the one hand has a significant impact on the pressure characteristic and thus on the efficiency and the torque output. On the other hand, this sequence defines the creation of emissions inside the engine. In this respect, gasoline and diesel engines differ in their process control.



Gasoline engine

The characteristic feature of a gasoline engine is that it uses an external ignition source, normally an electrode spark plug. Ideally a suitable homogeneous air/fuel mixture is created to provide the required flammability. This is achieved by means of external mixture formation (intake-manifold injection) or internal mixture formation (gasoline direct injection).

Mixture formation

For the most part, a homogeneous mixture preparation is effected in a gasoline engine, i.e. the intake air is fully mixed with the vaporized or atomized fuel during the induction and compression strokes. The excellent vaporization qualities of gasoline enable it to be injected into the intake manifold. Modern stratified-charge combustion processes are, on the other hand,

Figure 1: The engine power cycle

characterized by partially heterogeneous mixture formation (see Stratified-charge operation).

Mixture formation is decisively influenced by the vaporization conditions, the injection pressure, the cylinder-charge movement, and the time available with the aim of homogenization. Essentially, mixture formation involves the interaction of two processes: droplet vaporization caused by the temperature difference (Figure 2) and droplet disintegration by aerodynamic forces (Figure 3). Intake-manifold injection and direct injection differ here (Table 1).

Intake-manifold injection

In the case of intake-manifold injection, a film of mixture is created on the intake-manifold wall ahead of the intake valve whose fuel mass is reduced more intensively as the air velocity increases. This air velocity changes along broadly linear lines with the engine speed. On

account of the low temperature and incomplete vaporization in the intake manifold with the resulting formation of film, intake-manifold injection occurs at a very low injection-pressure level below 10 bar.

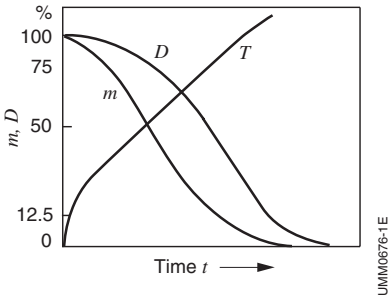
The dynamics of the wall-applied fuel film and the mechanisms involved during vaporization are one of the main causes of inaccurate fuel metering, above all during transient engine operation. Only the smaller droplets entrained with the intake flow reach the inside of the cylinder (Figure 3). Typically, their characteristic diameter is already less than 30 µm. Here, droplet acceleration is proportional to the ratio of relative velocity to the air and to the droplet diameter.

The very high turbulence intensity and the high flow velocities in the valve gap result in very good mixture formation.

Figure 3: Droplet formation

a) Characteristic flow situation in valve gap,
b) Interaction between droplet diameter and relative velocity of droplets with regard to air flow.
1 0 %,
2 50 %,
3 Over 90 %.

As process control progresses the remaining small fuel droplets assume the temperature of the mixture and vaporize (Figure 4). This enables the vaporized fuel to distribute more effectively in the combustion chamber, resulting in homogenization. An optimum combustion-chamber design prevents intensive contact of fuel with the wall, since this always involves the risk of fuel condensation.



Gasoline direct injection

Gasoline direct injection does not utilize the mechanisms of mixture formation in the valve gap. A higher injection pressure of 50 to 350 bar is therefore required. Injection is completed by no later than the gas-flow bottom dead center – i.e. at the end of the induction stroke – to allow sufficient time for homogenization during the compression stroke. Multiple injections are also carried out in the induction and compression strokes in order to achieve better homogenization. This increases the charge movement, which in turn encourages mixing. In heterogeneous combustion processes injection occurs only at the end of the compression stroke (see Stratified-charge operation).

The mixture included in the combustion chamber is now compressed, depending first and foremost on the throttle-valve position and the compression ratio, to

Figure 4: Droplet vaporization

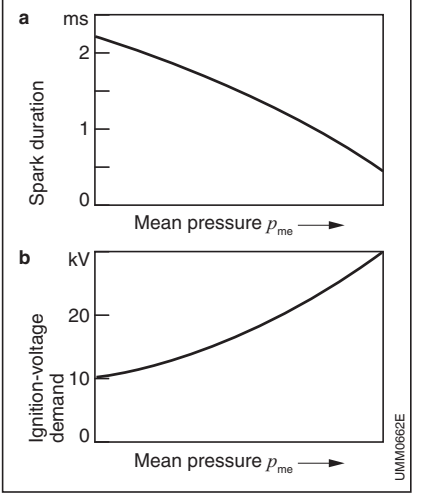
m Mass, D Diameter, and T Temperature of a vaporizing fuel droplet.
m and D are shown scaled to the maximum value. No scale is specified for T, because only the basic characteristic is involved.

a pressure level of 10 to 40 bar. This equates to a temperature level of 300 to 500 °C, depending first and foremost on the ambient temperature and the compression ratio.

The advantage of direct injection is that the fuel is metered exactly. Vaporization of the fuel in the combustion chamber also requires the cylinder charge to be adequately cooled. This enables the compression ratio to be increased by roughly one unit, resulting in greater efficiency.

Combustion in gasoline engines

In all combustion processes combustion – oxidation – occurs only at the end of the compression phase and in the early expansion phase. The subsequent combustion process differs depending on the nature of mixture formation (homogeneous or heterogeneous). An entirely homogeneous mixture reacts in a premixed combustion, an entirely heterogeneous mixture in a mixture-controlled combustion. During the stratified-charge operation of modern direct-injection engines, a large proportion (>50 %) of the injected fuel is likewise homogenized up to the start of combustion.



In both homogeneous and partly heterogeneous mixture formation, actual combustion is preceded by ignition and the ignition phase.

Ignition

Ignition is typically performed with the aid of an electrode spark plug. When a high voltage is applied, a sparkover occurs between the electrodes, depending on the mixture state (i.e. pressure, temperature, and mixture composition), the electrode gaps, and the air humidity. The high voltage is typically in the range of 10 to 40 kV. First and foremost the number of molecules between the electrodes influences the ignition-voltage demand (Paschen's law). The mixture ignited by the spark must in the course of its combustion release that amount of energy that is needed to ignite the immediately adjacent mixture. As leaning of the mixture increases, the energy content of this mixture decreases when the electrode gap remains constant. This is accompanied by an increase in the energy demand needed to ignite the adjacent – also lean – mixture. By enlarging the electrode gap, it is possible to increase the volume ignited by the spark and thereby raise the energy content. However, enlarging the electrode gap requires an increase in the ignition voltage. In this way, this increases for example in lean-combustion processes or in the event of a load increase. In the event of a load increase, the spark duration simultaneously decreases as the ignition-voltage demand increases (Figure 5). On account of heat losses at the spark-plug electrodes, heat-convection losses and cyclically fluctuating mixture states, the electrical ignition energy is above the theoretical minimum ignition energy by up to an order of magnitude (Figure 6). The stochastically fluctuating states (flow field and mixture state) between the electrodes are the main cause of large cyclic variations in a gasoline engine. This situation is improved by enlarging the electrode gap. Modern engines here already operate with a maximum value above 1 mm. Enlarging the electrode gap requires an increases in the ignition voltage.

Figure 5: Ignition sparks and ignition-voltage demand

a) Spark duration,
b) Ignition-voltage demand U_Z.
The ignition-voltage demand rises as exhaust-gas recirculation or leaning increases.

The purpose of ignition is to ignite the air/fuel mixture and thereby initiate the actual combustion process. Depending on the velocity of the subsequent combustion and on the piston speed (and thus on the engine speed), the point of ignition must be variably adapted (Figure 7).

Figure 6: Minimum ignition energy for a methane/propane mixture

1 Ignition energy for a static mixture,
2 Ignition energy for a mixture with a flow velocity of 6 m/s,
3 Ignition energy for a mixture with a flow velocity of 15 m/s.
With an increase in the proportion of inert gas the ignition-voltage demand increases for all the flow states shown.

Combustion of homogeneous mixtures

Propagation of the flame front

Ignition sets in progress the actual combustion in a homogeneously operated gasoline engine. Here the flame propagates from the spark plug. It is possible to define a flame-front velocity which is composed of the sum of the flame velocity and the flame-front movement (charge movement, expansion caused by density differences). In a homogeneously operated gasoline engine a good distinction can be made between the combusted and non-combusted mixture, since the flame continuously propagates outwards (Figure 8).

Figure 8: Flame propagation and premixed combustion

a) Flame-front propagation in a gasoline engine during homogeneous operation (the figures in degrees are calculated from the ignition point),
b) Temperature and substance concentrations along the flame-propagation direction.

It takes a few milliseconds for the flame to reach a radius of around one centimeter in order to propagate unhindered from the piston recess and cylinder head at a velocity well in excess of 10 m/s.

Influences on flame velocity

The decisive factor now is the propagation velocity of the flame, which is also referred to as the turbulent flame velocity. The faster the flame propagates, the better the combustion inside the engine. The following factors encourage a high flame velocity: a low proportion of inert gas, a temperature increase in the non-combusted mixture, a pressure increase, and a high turbulence level.

Most fuels have their maximum flame velocity in slightly rich-burn operation in the range of λ = 0.85 to 0.9. A further advantage of slightly rich-burn engine operation is the cooling effect provided by the excess fuel. Racing engines and passenger-car engines in the rated-output range are therefore operated with slightly rich mixtures.

Increasing the proportion of inert gas reduces the flame velocity. A practical application of inert-gas variation is exhaust-gas recirculation (EGR), in which combusted exhaust gas with the chief constituents CO_2, H_2O and N_2 is added to the air/fuel mixture. As a rule of thumb an exhaust-gas recirculation rate of 10 % already reduces the flame velocity by 20 %.

The reason why modern gasoline engines can nevertheless be operated with high internal exhaust-gas recirculation rates is the influence of temperature. Doubling the temperature increases the flame velocity by a factor of roughly 4.

Cylinder pressure has a lesser influence; an increase in pressure causes a slight acceleration of the flame velocity.

Turbulences in the combustion chamber

The turbulence level in the combustion chamber has the greatest influence on the combustion velocity. The flame velocity varies along roughly linear lines with the turbulence intensity. Turbulence intensity is a measure of the high-frequency change in flow velocity at a given point in the combustion chamber [1]. The turbulent kinetic energy is proportional to the square of the turbulence intensity.

Turbulence intensity is a three-dimensional quantity which is influenced above all by the flow profile of the charge movement in the combustion chamber. The velocity of the flow processes inside the engine that increases linearly to the greatest possible extent as engine speed increases is extremely important. As the flow velocity increases, so too does the turbulence intensity in the combustion chamber. This is the reason for stable engine operation over a very wide engine-speed range. The flame would otherwise no longer be able to burn cleanly at increasing engine speed and consistent flame velocity because of the shorter time available for combustion. However, the positive contribution of turbulence cannot equal completely the influence of speed, which is why combustion at high speeds nevertheless stretches over a wider crankshaft range. This is an additional reason why gasoline engines operate with less efficiency at higher speeds.

In gasoline engines the turbulence in the combustion chamber is vitally important to energy conversion. The decisive factor in causing turbulence is the charge movement in the cylinder, which is fundamentally influenced by the intake flow (depending on the configuration of the ports in the cylinder head) and the combustion-chamber shape (Figure 9).

Combustion causes a pressure increase which can also be simultaneously heard. For comfort reasons, suitable combustion-adjustment measures must be taken to minimize this pressure increase as much as possible. This poses a conflict of objectives with thermodynamic efficiency. The maximum pressure-increase gradient of gasoline engines is in the range of between 0.5 and 3 bar/°CA.

Combustion of partially homogeneous mixtures

Modern stratified-charge combustion processes facilitate operation with excess air in the part-load range. Effective mean pressures of p_{me} < 1 bar make even operation with a mean excess-air factor λ > 5 possible in stratified-charge operation. The main benefit here is the improved charge cycle, because throttling (which has a negative impact on overall efficiency) can be largely dispensed with.

Conventional operation is not possible without throttling in the lower part-load range, because homogeneous mixtures leaned in this way burn much too slowly and therefore incompletely. The solution is to provide local fuel stratification in the area of the spark plug by means of an optimized injection strategy in the late compression phase. The difficulty here lies in optimally matching the injection strategy and ignition, since the conditions between the electrodes change (Figure 10).

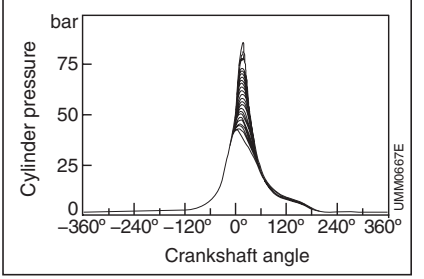
Charge movement
Large-scale, swirling and circular flows with diameters similar to the characteristic quantities of the combustion chamber provide the basis for the cylinder-charge movement. A basic distinction is made between flows about the vertical axis (cylinder axis), which are called swirl, and flows about the two lateral axes (crankshaft axis and perpendicular to this), which are called tumble (Table 2). In reality there is an overlap of the three basic flows, which gives rise to complex three-dimensional flow fields. Tumble and swirl essentially differ in their behavior inside the engine.

Tumble flow disintegrates up to the moment when compression dead center is reached and contributes primarily to flame propagation in the first combustion half.

Swirl flow lasts longer into the subsequent expansion phase. The disintegration of the large swirls into ever-decreasing, turbulent structures encourages the creation of turbulence. In the continuing process, however, the viscosity of the working medium results in a disintegration with a detrimental effect on the combustion velocity.

The creation of turbulence is assisted by the combustion-chamber geometry. In particular, flows in the piston-recess or squish-gap area (area between piston and cylinder head) support flame propagation (see e.g. [2]).



One of the greatest physical challenges associated with fashioning homogeneous combustion processes is the combustion behavior in the expansion phase, since typically over 10 % of the supplied fuel is still not converted 30° CA after TDC. At this point the non-combusted mixture is still only in the immediate vicinity of the wall and must still be converted after re-emerging from the top-land area between piston ring and cylinder wall (see e.g. [2]). This phenomenon results in incomplete combustion in the final phase.

Uncontrolled combustion
Numerous undesirable processes make it difficult to fashion a homogeneous combustion process. In addition to cyclic variations, knock and auto-ignition characteristics have detrimental effects. Extreme forms of advanced ignitions can occur, particularly in modern, highly turbocharged engines.

Cyclic variations
Cyclic variations are a consequence of the premixed combustion of homogeneous combustion processes which reacts sensitively to numerous disturbance values (Figure 11). Such disturbance values are, for example, the mixture composition, the residual-exhaust-gas content, the thermodynamic state variables, and the flow profile. All the values vary from working cycle to working cycle and cause noticeable cyclic fluctuations in energy conversion. In particular, leaning with excess air of more than 40 % increases the cyclic variations significantly. Initiation of ignition has the greatest influence on cyclic variations.

Knocking
Another challenge is posed by the undesirable phenomenon of knocking. Knocking occurs in response to increases in pressure and temperature after the onset of regular combustion until the local conditions stimulate auto-ignition. Here, the residual mixture in response to the temperature increase as a result of the

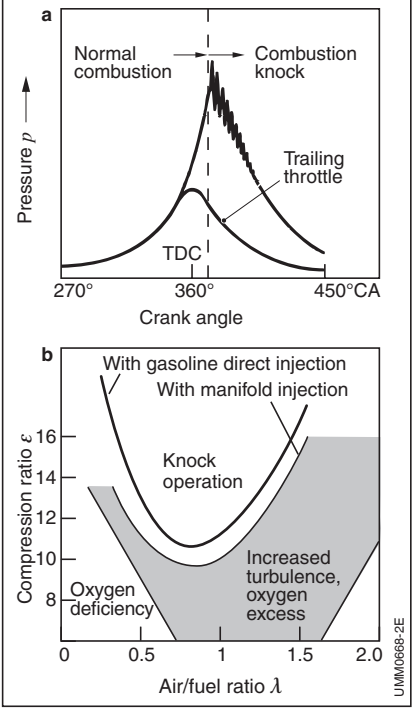


Figure 11: Cyclic fluctuations of the cylinder pressure of the individual working cycles during stoichiometric operation (λ = 1)

progressing combustion reaches the ignition temperature and burns almost simultaneously without a further controlled flame propagation. The pressure pulsations generated in the process result in material wear in the engine bearings and cause serious engine damage in the event of prolonged operation. The temperature peaks can also result in damage to components. Typically, knocking only then occurs in a working cycle if 80 % of the fuel in the combustion chamber has not been combusted. Knocking can be observed particularly at low engine speeds with suitably sufficient time for auto-ignition and at high loads with high combustion-chamber temperatures. Fuels with high ignition temperatures such as, for example, methane or ethane reduce knock sensitivity. Knocking combustion can be reduced by shifting the energy conversion in the retardation direction (ignition timing towards TDC). High-compression and turbocharged engines are more knock-sensitive because of their higher final compression temperatures (Figure 12). Useful measures to counter knocking include effective cylinder cooling of the hot areas, for example also by the vaporization effect of gasoline direct injection, increasing the turbulence, reducing the geometrical compression ratio, and optimizing the fuel, for example with additives.

Figure 12: Compression ratio, knocking and knocking combustion

a) Example of knocking combustion,
b) Effect of compression ratio and air/fuel ratio on the operating limits (knocking and engine misfires). Direct injection instead of intake-manifold injection and increased turbulence shift the operating limits.

Auto-ignitions

In contrast to knocking, auto-ignitions can occur quite perfectly even in very retarded compression situations. Possible causes of auto-ignitions are, for example:

– Over-retarded moment of ignition with incomplete combustion, thus fuel-film formation causing auto-ignitions,
– Full-load operation with high cylinder-component temperatures,
– Ignition caused by abrasion and hot particulates,
– Oil emissions caused by defective or worn piston rings.

Extreme forms of auto-ignition can occur in turbocharged and high-compression gasoline engines; these can result in peak pressures in excess of 150 bar and serious damage. However, these extreme auto-ignitions occur only very rarely with a probability of less than 0.01 per thousand.

Pollutant formation and pollutant reduction in gasoline engines

In addition to the unavoidable combustion products of carbon dioxide (CO_2) and water (H_2O), the concentration of which is dependent on the composition of the fuel, nitrogen oxides (NO_x), non-combusted hydrocarbons (HC) and carbon monoxide (CO) are the main emissions from gasoline engines (Figure 13).

Pollutants

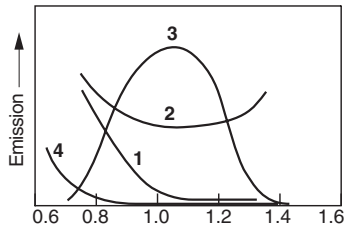
Nitrogen oxides

Nitrogen oxides (NO_x) require four factors in order to be created: oxygen, nitrogen, high temperatures, and time. Because oxygen and nitrogen are determined by the mixture composition in gasoline engines and the available time is defined by way of the engine speed, nitrogen oxides in gasoline engines can only be reduced by low maximum combustion-chamber temperatures (e.g. by means of ignition retardation and exhaust-gas recirculation).

Hydrocarbons and carbon monoxide

Hydrocarbons (HC) and carbon-monoxide emissions (CO) are the result of incomplete combustion. In rich-burn operation there is, on account of the lack of oxygen, an increase in both HC and CO emissions. In lean-burn operation with accordingly reduced flame temperature a more intensive extinguishing of the flame is encountered, above all in the fire-land area close to the wall, with a resulting increase in HC emissions. Because of the excess oxygen the slightly oxidizable CO emissions are nevertheless reduced.

Soot and particulates



Engines with intake-manifold injection cause – primarily in extreme rich mode – increased soot emissions. These are however lower compared with gasoline engines with direct injection. With the Euro 6c emission-control standard the particulate limit for gasoline engines with Direct Injection has been reduced to 1/10 of the value applicable to Euro 6b such that a particulate filter must be used in many vehicle models.

Sulfur oxide

Sulfur-oxide emissions are dependent on the sulfur content in the fuel. Currently only a sulfur content of 10 mg/kg is permitted in Europe so that sulfur-oxide emissions are of secondary importance.

Thanks to exhaust-gas treatment, modern homogeneous gasoline engines are, once they have reached the catalytic-converter operating temperature, virtually zero-emission machines. Three-way catalytic converters in operation at $\lambda = 1$ reduce the nitrogen-oxide emissions while simultaneously oxidizing HC and CO molecules (see Three-way catalytic converter). Alternative approaches are required in lean-burn operation. For this reason, NO_x storage catalytic converters are typically used for stratified-charge concepts. These catalysts store the nitrogen oxides. Rich-burn engine operation applied at regular intervals reduces the stored nitrogen oxides at high temperatures. Because NO_x storage catalytic converters are sensitive to sulfur contamination, desulfation cycles must additionally be completed in slight rich-burn operation at temperatures in excess of 600 °C (see NO_x storage catalytic converter).

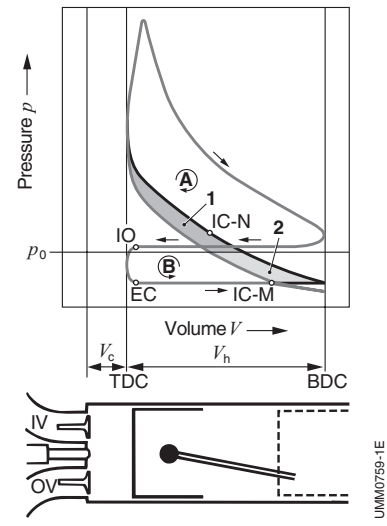
Load control in gasoline engines

In homogeneously operated gasoline engines the load is adjusted by means of the injected fuel mass. The corresponding air mass is adapted by means of the throttle-valve position for the required operation at λ = 1. This is known as quantity control. In the part-load range this causes induction throttling, which is detrimental to the overall efficiency. The cause of this is the work done during induction and emission of the gas, the share of which must be subtracted from the energy generated in the combustion process. This disadvantage can be partially compensated for by varying the valve timing. Advanced or retarded "intake closes", reduced valve lift or retarded "exhaust closes", in which hot exhaust gas is additionally inducted, are typical measures. Alternatively, external exhaust gas can be recirculated (exhaust-gas recirculation) in order to reduce throttling. In turbocharged gasoline engines the air flow rate and thus the fuel-mass flow rate is adjusted in the upper load range typically by means of the position of the wastegates on the turbocharger (see Exhaust-gas turbochargers).



In engines with stratified charge the injected fuel mass is adjusted by the load in unthrottled operation at part load. This is known as quality control. The transition between stratified- and homogeneous-charge operation in the mid-load range requires control-engineering complexity and expenditure.

Power yield and efficiency

The part-load performance of a gasoline engine deteriorates as a result of charge-cycle losses (throttling), poor process control (peak pressures below 30 bar), and an increasing amount of engine friction. Because even at passenger-car driving speeds in excess of 100 km/h most vehicle engines still operate in the part-load range, measures to increase the efficiency in this operating range prove highly successful. Examples of such measures are:

Figure 14: Miller process: Power yield and efficiency increase by dethrottling via valve timing

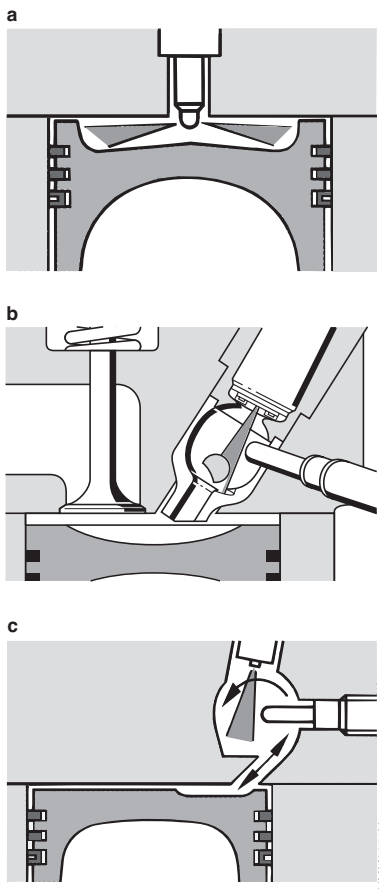
– Displacement reduction (downsizing),
– Cylinder shutoff (e.g. in V8 and V12 engines),
– Dethrottling (stratified charge, exhaust-gas recirculation, valve timing),
– Increased compression ratio,
– Longer transmission ratio to lower the engine-speed level.



In the Miller process the intake valve is closed at a very advanced stage. In this way, the throttle valve can remain open and the throttling losses are lower (Figure 14).

Diesel engine

A significant characteristic feature of diesel engines is the absence of external ignition. This is achieved by injecting the ignitable fuels into highly compressed and therefore hot air. High final compression temperatures and pressures to levels in excess of 600 °C and 100 bar in turbocharged engines provide for extremely stable engine operation. Fuel-spray formation, fuel vaporization, fuel mixing, and subsequent combustion can take place within a very short period of time.

Combustion processes with direct injection have in the last few decades established themselves as the favored choice over indirect combustion processes such as whirl-chamber or prechamber systems. In indirect combustion processes the local flow in the secondary volume is essentially responsible for fuel preparation (Figure 15).

Figure 15: Diesel-engine combustion processes

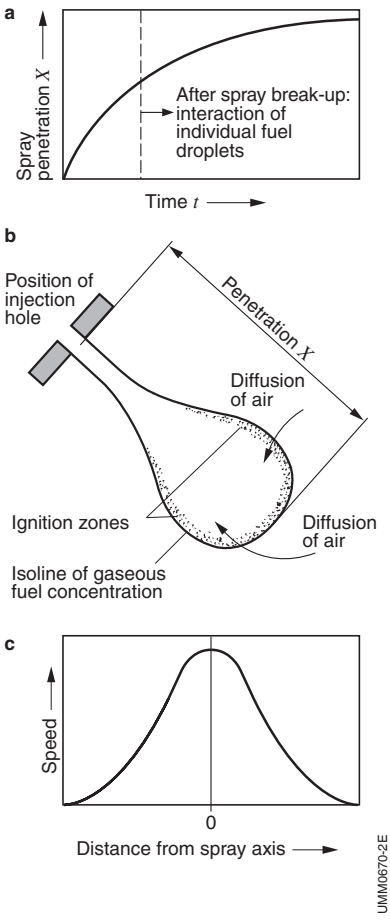
a) Direct injection,
b) Prechamber system,
c) Whirl-chamber system.

Mixture formation

Mixture formation is dominated by the interaction of the injection spray with the flow field in the combustion chamber. Here, the challenge consists in quickly injecting and preparing relative large masses of fuel of up to 200 mg per liter displacement. A typical injection duration is in the range of 1 ms. The term used in relation to the fuel mass flow into the combustion chamber is the injection rate (unit: kg/s). This fuel mass flow is typically injected by multihole injection nozzles.



A combination of between four and ten injection holes with a diameter of between 120 and 150 µm is commonly used. As well as the small hole diameter, the high injection pressure of over 2000 bar encourages fast fuel injection and mixture formation.

The diameter of a characteristic spray is initially the same as that of the nozzle hole. After it has traveled a few millimeters, the spray breaks up into individual droplets which interact with the flow field. The liquid phase of the fuel spray can, especially depending on the density of the working medium (air, air-fuel mixture or air with EGR), penetrate a few centimeters into the combustion chamber before the spray is completely atomized or vaporized (Figure 16).

Turbulences encourage the formation of droplets and the vaporization of the fuel. In modern diesel engines more than 80 % of the turbulence intensity in the area of the fuel spray is generated by the injection. This is further assisted by the charge movement, whereby diesel engines with flat cylinder head experience predominantly more swirl than tumble

flows. An additional contribution can be made by compression-induced air flows from the outer to the inner area of the combustion chamber ("squish flows") or by the combustion-chamber design, e.g. by vaporization-inducing contact with the hot piston-recess area.

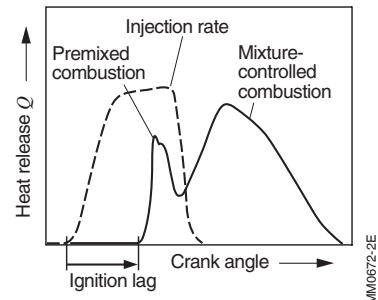
b) Typical injection-spray formation (the lean edge areas with infinite λ are outside the continuous line),
c) Velocity profile of injection spray.



Combustion in diesel engines
Combustion in diesel engines differs from conventional gasoline-engine operation in the compression-ignition behavior. In all, diesel-engine combustion can always be described in three consecutive processes: ignition lag, premixed combustion, and mixture-controlled combustion. Depending on the operating state and the map range, the three processes have different time components (Figure 17).

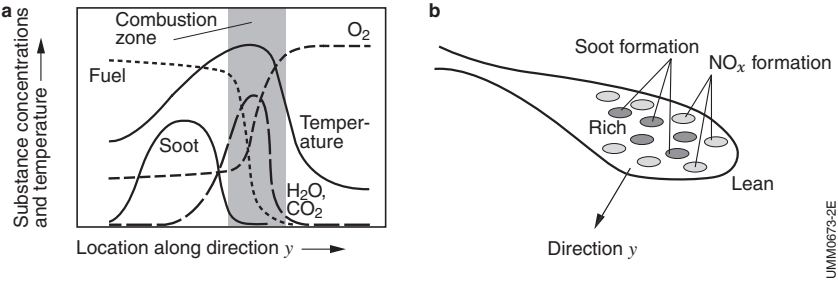
Ignition lag
Ignition lag refers to the period of time between start of injection and start of combustion. It is crucially dependent on the cylinder temperature, the cylinder pressure, and the combustibility of the fuel. Both mixture formation and the first chemical pre-reactions of the air/fuel mixture take place in the ignition-lag phase. The ignition lag is long during cold engine operation or when a low-quality fuel with a low cetane number is used. The influence of cylinder pressure is less dominant than that of temperature. Basically, however, an increase in cylinder pressure reduces the ignition lag. The fuel injected during the ignition-lag phase does not burn yet. The ignition lag can be between 0.1 ms in the rated-output range to over 10 ms in the cold-start range.

Premixed combustion
The ignition lag defines the phase of premixed combustion by means of the injected and as yet non-combusted fuel. The longer the ignition lag, the more fuel

Figure 17: Diesel-engine combustion

is premixed in combusted form. This fuel mass can perfectly well be over 20 mg per liter displacement. Combustion typically starts at the edge of the fuel spray, where the fuel has mixed very well with air and therefore optimum ignition conditions are present in terms of temperature and excess-air factor λ. The exothermic reaction results in a local temperature increase with temperatures above 2300 K, which quickly converts the as yet non-combusted premixed fuel in a chain reaction. Here, the chemical reactions that take place determine the rate of combustion. The self-accelerating chain reaction results in an extremely fast combustion with large pressure-increase gradients. For this reason, the premixed converted fuel mass must be kept to a minimum in diesel engines. This is typically achieved by means of a pilot injection whose local combustion exerts an initial temperature increase with a reducing effect on the ignition lag of the subsequent main injection.

Mixture-controlled combustion



The amount of premixed converted fuel can be between less than 1 % in the upper full-load range and 100 % in the lowest part-load range. The remaining amount burns in a mixture-controlled combustion. In contrast to premixed combustion, in the case of mixture-controlled combustion – also called diffusion combustion – the transfer of oxygen into the combustion zone defines the conversion rate. It is difficult to distinguish between a combusted zone and a non-combusted zone, because there is no precisely defined flame front. Basically, the diffusion flame establishes itself at the edge of the spray and burns in a limited range at $0.8 < \lambda < 1.4$. As the boundary conditions change (e.g. further fuel vaporization, oxygen transfer, wall contact), so too the reaction zone strays to where locally stoichiometric conditions prevail (Figure 18).

Turbulences

Mixture-controlled combustion dominates in the high load range, in which large quantities of fuel are injected. Here, the mixture-formation and combustion processes occur in parallel. As with premixed combustion, the conversion rate can also be influenced by the injection. A lesser influence, but also of an accelerating character, is exerted by increases in both temperature and pressure and by a reduction in the proportion of inert gas. The dominant factors are mixture formation and the transfer of oxygen into the combustion zone by a high local turbulence.

For this reason, turbulence intensity is the deciding variable in fashioning diesel-engine combustion processes and is reflected in ever higher injection pressures with a high kinetic energy on the part of the fuel spray, which is subsequently converted into turbulent kinetic energy. Local turbulence causes the vital transfer of oxygen into the local reaction zones. The cylinder-charge movement (swirl, squish flows) supports this phenomenon, the main contribution however being made by the pulse of the injection spray. As well

Figure 18: Mixture-controlled combustion
a) Substance concentrations and temperature distribution,
b) Formation of pollutants inside the injected spray.

as increasing the injection pressure, increasing the hole diameter or the number of holes is also conceivable. However, an increase in the injection rate results for the most part in a local over-enrichment with a negative impact on fuel conversion.

Particular characteristics of diesel-engine combustion

Cold-start processes

Cold-start processes in diesel engines pose a particular challenge, particularly at outside temperatures below –10 °C. At starter speeds down to below 100 rpm a large proportion of the cylinder charge escapes through the piston rings during the relatively slow compression phase. In addition, the cold cylinder temperatures give rise to increased wall heat losses. Results experienced are low peak pressures below 30 bar and, depending on the outside temperature, low peak temperatures below 400 °C.

Fuel vaporization at top dead center

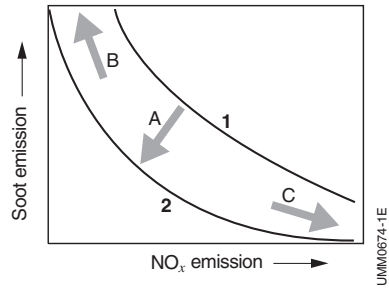
Fuel vaporization at top dead center causes further cooling. The outcome is very long ignition lags. In an extreme-case scenario there may be no ignition whatsoever with the result that fuel can accumulate in the cylinder on the cylinder wall and piston over several working cycles. Its ignition after a few working cycles can, on account of the fuel mass accumulated in the meantime, result in very high peak pressures above 150 bar.

Friction losses

Because the cold-start phase does not provide for enough time for an adequate hydrodynamic lubricating film to be built up at the appropriate bearing points of the crankshaft drive, the result is a negative effect on the mechanical engine systems. Typical measures to help improve the cold-start process include therefore preheating the intake air, the oil or the water. The latter, as well as influencing the combustion-chamber temperature, above all brings about lower engine friction and increased starter speeds.

Height dependence

A further phenomenon is encountered during operation at very hot outside temperatures or at high altitudes above 1000 m. Because the air has a lower density, its mass in the cylinder is reduced. The effect on combustion is initially not decisive. However, the exhaust-gas temperature rises as a result of the lower amount of excess air.



This phenomenon is also encountered with turbocharged engines. A power reduction above all during operation at altitude can therefore be a necessary application measure.

Deposits in the injection nozzles

A power drop in the order of 1 to 3 % is often observed in diesel engines after a break-in period. This is caused by the fuel-injection system. Deposits in the injection nozzles cause a slightly reduced nozzle-hole diameter, resulting in a smaller mass flow and thus a power loss. These deposits may be caused, for example, by copper, zinc or oil contaminants in the diesel fuel.

Figure 19: NO_x and soot emissions

1 Upper limit curve,
2 Lower limit curve.
A Decrease in soot and NO_x as a result of: exhaust-gas recirculation and injection-pressure increase, partial homogenization, H_2O injection.
B Increase in soot and decrease in NO_x as a result of: ignition retard, injection-pressure reduction, reduction of O_2 concentration, Miller process.
C Decrease in soot and increase in NO_x as a result of: ignition advance, injection-pressure increase, increase in O_2 concentration.

Pollutant formation and pollutant reduction

In contrast to gasoline engines, which are characterized with the introduction of the three-way catalytic converter during operation at $\lambda = 1$ by extremely low emissions, pollutant reduction inside the engine plays a much more important role in diesel engines. In addition to the emissions familiar from gasoline engines, i.e. CO_2, H_2O, NO_x, HC and CO, soot and particulate emissions must also be taken into consideration.

Pollutants

Nitrogen oxides

Measures which lower the combustion temperatures are useful in reducing the nitrogen oxides. This can be done effectively by reducing the oxygen concentration in the combustion zone. The combustion temperatures can also be reduced very easily by retarding injection or reducing the injection pressure.

Temperature-reducing measures such as exhaust-gas recirculation, Miller processes (see e.g. [2]) or partial homogenization reduce the nitrogen-oxide levels. This overcompensates for the slight increase in soot emissions that are often observed as well (Figure 19). The level of complexity and expenditure needed to reduce both these components is high. The measure currently used involves increasingly higher exhaust-gas recirculation rates for nitrogen-oxide reduction in combination with very high injection pressures (> 2000 bar) for soot reduction.

Soot and particulates

Reducing the injection pressure or the oxygen concentration typically causes an increase in soot emissions. The formation of soot is a complex process and is dependent on both fluid-dynamic and thermodynamic boundary conditions. Initially, the locally highly rich zones ($\lambda << 1$) produce considerable amounts of soot, which are then however substantially reduced by over 70 % in the subsequent combustion by oxidation processes. A high turbulence level, which encourages the soot to oxidize in the expansion phase, is crucially important. But the temperature level too is important. On account of important local interactions between the injection spray, the combustion zone, the non-combusted mixture and the recess geometry, how the combustion process is fashioned has a decisive impact on the production of emissions.

A distinction is made between soot and particulate emissions in this context. Soot consists of pure carbon compounds, whereas particulates also include fuel or lube-oil droplets, ash, rubbed-off metal, corrosion products, and sulfate compounds.

HC and CO compounds

HC and CO compounds are typically uncritical in diesel-engine emissions. The effect of hydrocarbons on particulate emissions must be taken into consideration. HC and CO increase in concentration in particular during a highly retarded combustion with incomplete burn behavior.

Mixed forms and alternative operating strategies

The classic diesel-engine operating strategy is characterized by one or more injections in the TDC range. Established gasoline-engine combustion processes are characterized by homogeneous or partially homogeneous (with charge stratification) operation. However, alternative forms of process control, which sometimes cannot be clearly assigned to the diesel-engine or the gasoline-engine process, are currently being developed.

Homogeneous-charge compression ignition in diesel operation
With the HCCI combustion process (Homogeneous Charge Compression Ignition), which is published in a wide range of variations [3], the motivation is, through the application of very advanced injection (at least 40 to 50° CA before TDC), to achieve homogenization, significant leaning and therefore a NO_x reduction. Reliable ignition nevertheless takes place on account of the high diesel-engine compression temperature. The compression ratio must be lowered to 14 to 16 in order to maintain control of the combustion process. Exhaust-gas recirculation is typically used to enable the temperature level in the cylinder to be increased at low loads. Nevertheless, obtaining this over the entire program map, particularly in the full-load range, is very demanding, since the pressure-increase gradients become extremely high and control of transient engine operation is highly complex in view of all the engine states that arise.

Compression ignition in gasoline operation
Gasoline-engine combustion processes have been further developed along similar lines to diesel-engine HCCI operation in order to achieve in the part-load range dethrottled lean-burn operation with corresponding fuel-consumption advantages over conventional, stoichiometrically operated engines. The disadvantages of lean-burn operation with regard to conversion in the catalytic converter are compensated by extremely low untreated NO_x emissions caused by leaning. Reliable ignition of the in itself hardly combustible mixture is achieved by a high compression ratio above 13. Optimally the compression ratio is variable and can be further decreased up to full load on account of the increased combustion-chamber temperatures.

Gasoline-engine stratified charge
Direct-injection, stratified-charge gasoline-engine combustion processes share much in common in terms of combustion with classic diesel-engine operation and therefore represent a mixed form of conventional gasoline-engine and diesel-engine combustion. Combustion processes of this type are becoming increasingly established thanks to their efficiency advantages by dethrottling in part-load operation.

Multifuel engines
Multifuel engines, which are characterized by compatibility with regard to the fuel used (alternatively operation e.g. with diesel fuels or kerosene, gasolines or diesel fuels and vegetable oils), no longer play a role today since the emission requirements for such engine concepts are no longer feasible.

Charge cycle and supercharging

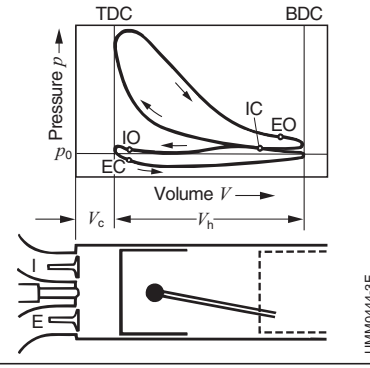
Charge cycle

In combustion engines employing open processes and internal combustion, the charge cycle (exhaust and refill) system must serve two decisive functions:
– Replacement is employed to return the gas medium to its initial (start of cycle) condition,
– The oxygen required to burn the fuel is provided in the form of fresh air.

The charge cycle – also called gas exchange – can be assessed with the aid of the characteristic quantities defined in DIN 1940 [1]. For overall air flow (air expenditure $\lambda_a = m_g/m_t$) the entire charge transferred during the working cycle m_g is defined with reference to the theoretical maximum m_t for specific displacement. In contrast, the volumetric efficiency $\lambda_{a1} = m_z/m_t$ is based exclusively on the fresh charge m_z actually present or remaining in the cylinder. The difference between this and the total charge transfer m_g consists in the proportion of gas that flows directly into the exhaust tract in the overlap phase, making it unavailable for subsequent combustion.

The retention rate $\lambda_a = m_z/m_g$ is an index of the residual charge in the cylinder.

The scavenge efficiency $\lambda_S = m_z/(m_z + m_r)$ indicates the volume of the fresh charge m_z relative to the existing total charge, consisting of the fresh charge and the residual gas m_r. Here, the parameter m_r indicates the amount of residual gas from earlier working cycles remaining in the cylinder after the exhaust process.



In a 2-stroke cycle, the gas is exchanged with every rotation of the crankshaft at the end of the expansion in the area around bottom dead center. In a 4-stroke cycle, separate intake and exhaust strokes provide a supplementary gas-exchange cycle.

4-stroke cycle

Valve timing – and thus gas exchange – are regulated by a control shaft (camshaft) rotating at half the frequency of the crankshaft by which it is driven. The camshaft opens the gas-exchange valves by depressing them against the valve springs to discharge the exhaust gas and to draw in the fresh gas (exhaust and intake valves respectively) (Figure 1). Just before piston bottom dead center (BDC), the exhaust valve opens and approx. 50 % of the combustion gases leave the combustion chamber under a supercritical pressure ratio during this predischarge phase. As it moves upward during the exhaust stroke, the piston sweeps nearly all of the combustion gases from the combustion chamber.

Shortly ahead of piston top dead center (TDC) and before the exhaust valve has closed, the intake valve opens. This crankshaft top dead center position is called the gas-exchange TDC (GTDC) or overlap TDC (OTDC) because the intake and exhaust processes overlap at this point) in order to distinguish it from the ignition TDC (ITDC). Shortly after gas-

exchange TDC, the exhaust valve closes and, with the intake valve still open, the piston draws in fresh air on its downward stroke. This stroke of the gas-exchange process, the induction cycle, is completed shortly after bottom dead center (BDC) is reached. The subsequent two strokes in the 4-stroke process (Figure 2) are compression and combustion (expansion).

On throttle-controlled gasoline engines during the valve overlap period, exhaust gases flow directly from the combustion chamber into the intake passage, or from the exhaust passage back into the combustion chamber and from there into the intake passage. This internal exhaust-gas recirculation increases the combustion-chamber-charge temperature and the proportion of inert gas in the cylinder. A consequence of this is non-optimum power utilization in the upper load range. With fixed valve timing it is important to maintain a compromise, which is dependent above all in gasoline-engine applications on matching the engine operating strategy with the turbocharging unit.

Early exhaust-valve timing allows sufficient time for the cylinder charge to escape, and thus guarantees low residual-gas compression as the piston sweeps through its upward stroke, although at the price of a reduction in the work index for the combustion gases.

The “intake valve closes” position (IC timing) exercises a decisive effect on the relationship between volumetric efficiency and engine speed. The maximum volumetric efficiency is achieved at low engine speeds when the intake valve closes early, and at high engine speeds when it closes late.

Obviously, fixed valve timing will always represent a compromise between two different design objectives: maximum brake mean effective pressure – and thus torque – at the most desirable points on the curve, and the highest possible peak output. The higher the engine speed at which maximum power occurs, and the wider the range of engine operating speeds, the less satisfactory will be the ultimate compromise. This tendency cannot be neutralized either by multi-valve cylinder heads with a larger intake-flow cross-sectional area.

At the same time, the demands for minimum exhaust emissions and maximum fuel economy mean that low idle speeds and high low-end torque (despite and along with high specific outputs for reasons of power-unit weight) are becoming increasingly important. These imperatives lead to the application of variable valve timing.

The advantages of the 4-stroke process are very good volumetric efficiency over the entire engine-speed range, low sensitivity to pressure losses in the exhaust system, and relatively good control of the speed-sensitive air expenditure through selection of appropriate valve timing and intake-system designs.

The disadvantages of the 4-stroke process are the high complexity of valve timing and the reduced power density of non-turbocharged 4-stroke engines because only every second crankshaft revolution is used for power output by combustion.

2-stroke cycle

To maintain gas exchange without an additional crankshaft rotation, the gases are exchanged in the two-stroke process at the end of expansion and at the beginning of the compression stroke. The intake and exhaust timing are usually controlled by the piston as it sweeps past the intake and exhaust ports in the cylinder housing near BDC (Figure 4). This configuration, however, requires symmetrical control times and involves the problem of directly flushing fresh mixture into the exhaust area (short-circuit scavenging). In addition, 15 to 25 % of the piston stroke cannot produce work because only charge volume V_f and not displacement volume V_h can be exploited for power generation (Figure 3).

As the two-stroke process lacks separate intake and exhaust strokes, the cylinder must be filled and scavenged using positive pressure, necessitating the use of scavenging pumps. In an especially simple and very frequently-used design, the bottom surface of the piston works in conjunction with a crankcase featuring a minimal dead volume to form a scavenging pump. Figure 4 shows a 2-stroke engine with crankcase scavenging and precompression along with the associated control processes. The processes which take place on the scavenging pump side are shown in the inner circle, while those occurring on the cylinder side are shown in the outer circle. The location of the intake and exhaust ports with the aim of maximum volumetric efficiency is also crucially dependent on the piston position. A hump-shaped increase in piston height can reduce direct throughflow from the intake area to the exhaust area.

The advantages of the 2-stroke process are high power output referred to engine weight and engine volume and a more uniform torque generation (one power stroke per revolution).

The disadvantages of the 2-stroke process are higher fuel consumption, lower mean pressures (due to poorer cylinder charge), higher thermal loads (due to the lack of a gas-exchange stroke), demanding mixture control, and higher HC emissions due to problematic cylinder scavenging. Two-stroke processes are no longer important due to the introduction of strict emission limits for most mobile applications.

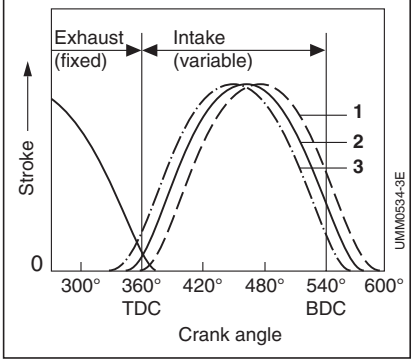
Variable valve timing

Variable valve timing in a number of design variations is gaining acceptance with different objectives. The motivations behind the use of variable valve timing are as follows: increased power and torque, dethrottling, control of the residual-exhaust-gas content, cylinder shutoff, charge movement, cold-starting and cold-running performance, control-engineering optimization (e.g. charge mass, residual-exhaust-gas content), influencing the rotational speed of the exhaust-gas turbocharger, and exhaust-gas temperature-management measures.

Today, different systems are used to provide variable valve timing. There are different motivations behind variable valve timing, depending on the combustion process and engine concept (homogeneous- or stratified-charge operation, diesel).

Camshaft adjustment

The concept of adjusting the intake and exhaust camshafts is increasingly becoming an accepted measure, offering a valuable degree of variability in the entire program map. This concept provides the option of adjusting the phase of the camshafts with respect to the crankshaft and thereby shifting the valve timing while maintaining the same form of opening. Electric or electrohydraulic activation of the camshaft adjuster is the state-of-the-art technology used.



In homogeneously operated gasoline engines the intake camshaft is subject to retarded adjustment for example in the low speed and load range while at the same time the exhaust valve is subject to very advanced closing (Figure 5). This minimal valve overlap delivers a minimal throughflow of fresh-air mixture into the exhaust area. At the same time the highly retarded opening of the intake valve also causes dethrottling by the associated retarded closing of the intake valve, because the cylinder charge is again discharged by the intake valve after bottom dead center. A rapid torque increase can be achieved for a desired load point by advancing the intake camshaft.

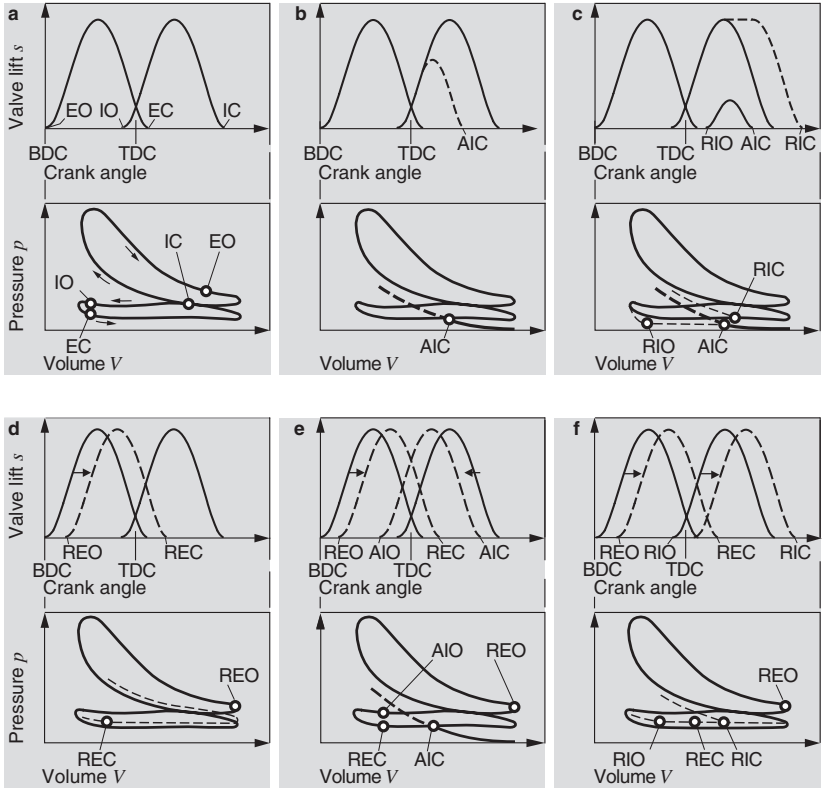
Exhaust-camshaft adjustment also provides for further degrees of freedom. Optimal adjustment of the intake and exhaust camshafts is dependent on numerous factors. The operating mode is crucial as well as the position in the engine map. For example, a significant factor is whether exhaust-gas turbocharging is used or whether lean-burn operation (diesel engine, gasoline-engine stratified-charge process, etc.) is applied. One example of the beneficial combination of camshaft adjustment with an exhaust-gas turbocharger is the map-dependent maximum valve overlap (very retarded closing of the exhaust valve and very advanced closing of the intake valve), at which a large proportion of mixture flows directly from the intake to the exhaust area. This can give rise to the beneficial effect of an increase in air-mass flow by the exhaust-gas turbocharger together with an advantageous increase in turbocharger speed. Rotating the intake and exhaust camshafts offers optimization opportunities for a large number of questions and is therefore being increasingly used at least in modern gasoline engines.

Systems with cam-shape control mechanism

As well as continuous phase adjustment, simpler systems are also available which alternate digitally between individual cam shapes. Typically, such systems adjust a very large cam and valve lift for ranges

Figure 5: Intake-camshaft rotation
1 Retard, 2 Standard, 3 Advance.

close to full load and a small cam and valve lift for dethrottling for part-load ranges. This is achieved for the most part by integrating a control mechanism on a rocker arm or bucket tappet, which thereby activates one or more (typically two) available cams on the camshaft.



Systems that can alternate between two camshaft rotation positions are also used. In contrast to fully variable systems, these systems omit an exact positioning command to the camshaft phase adjuster.

Other variable systems

Increasingly, fully variable systems for use in gasoline engines are being developed and are even already appearing in production vehicles. These systems focus on optimizing the charge-cycle phase. There are different successful approaches to suit the engine configuration and operating point, each approach optimizing charge-cycle losses, the residual-exhaust-gas content or engine power (Figure 6).

Mechanical, electromechanical, electrohydraulic or electropneumatic adjustment concepts can be used to provide a fully variable valve gear.

Mechanical systems
Mechanical, fully variable valve-gear systems typically consist of a combination of an adjustment mechanism, which permits variation of the valve lift, and a camshaft phase adjuster. The key function is the provision of variable cam lift.

A suitable design solution is provided in this case by a conventional camshaft, which does not however act directly on the valve via a bucket tappet or a rocker arm. The cam lift is adjusted by an intermediate lever whose fulcrum can be varied by means of an eccentric shaft (Figure 7 and Figure 8). Electric DC motors are typically used to drive such arrangements. BMW Valvetronic is an example of a fully variable mechanical valve gear [2]. Further advantages of a fully variable valve gear are the optimization of uniform charge distribution and the potential to increase charge movement by having the two intake valves opening at different times in the lower load range thanks to slightly differently ground eccentricities.

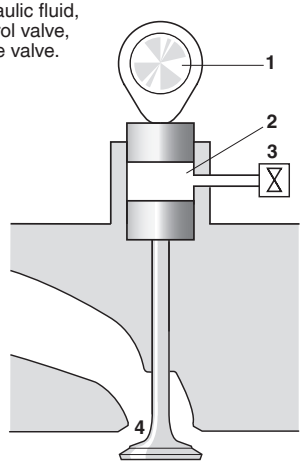
Electromechanical systems
Electromechanical systems (electromechanical valve gear) are still in the development stage. In an electromechanical valve gear, electrically actuated magnets are used as actuators for valve timing (Figure 9, see also [3]). The high power

Figure 9: Electromechanical systems
1 Compression spring,
2 Closing magnet,
3 Armature,
4 Opening magnet,
5 Compression spring,
6 Intake valve.

demand of the actuators must be noted in particular. The system, comprising valve, magnet and coil, is made to resonate in order to minimize this demand. Because of the high power demand and the complexity involved, electromagnetic valve gears have not yet made it to series production.

Electrohydraulic systems



Electrohydraulic systems (electrohydraulic valve timing) are an alternative to the fully variable mechanical valve gear. Different principles are applicable here.

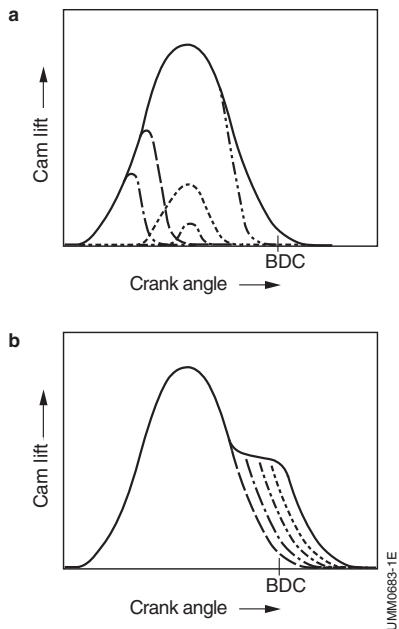
The principle of "lost motion" is an effective approach. A motion is stipulated by a hydraulic intermediate element via a camshaft (Figure 10). An electrically actuated hydraulic valve provides the opportunity of not transferring completely the motion stipulated by the cam. The cam shape therefore stipulates an envelope (Figure 11).

An alternative is presented by a system which directly actuates the gas-exchange valves via a hydraulic pressure accumulator and electronically controlled hydraulic valves. Systems of this type are still in the development stage and are not yet in series production.

Figure 10: Working principle of electrohydraulic systems

1 Camshaft,
2 Hydraulic fluid,
3 Control valve,
4 Intake valve.

Depending on the point and duration of activation, a proportion of the hydraulic fluid escapes through the hydraulic valve. Hydraulic power loss is therefore a drawback of this system.



Electrohydraulic systems have been deployed since 2004 in Caterpillar commercial-vehicle systems and since 2010 in Fiat's MultiAir system.

Electropneumatic systems

Electropneumatic systems are still in the development stage. The use of such systems in large-scale production is not anticipated at present. As well as exhibiting complex control characteristics, these systems above all demonstrate unfavorable pneumatic drive power. Current systems are used for research purposes. The power input of the compressed-air supply must be noted and necessarily included in an efficiency balance.

b) Variable retarded closing of intake valve.

Supercharging processes

The power of an engine is proportional to its air-mass flow. As this air throughput, in turn, is linearly dependent on air density, the power of an engine, given a specific displacement and engine speed, can be increased by compressing the air before it enters the cylinders, i.e. by supercharging. The supercharging ratio indicates the density rise as compared to a naturally aspirated engine.

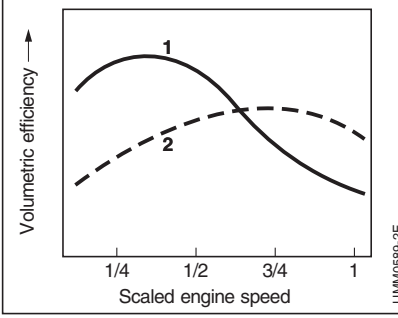
Thermodynamically speaking, the best results would be delivered by isothermal compression, but this cannot be technically achieved. Reversibly adiabatic compression in the supercharger unit serves as the ideal comparison process for the actual sequences; in practical terms, increased density is accompanied by losses.

The extent of the supercharging ratio is limited in gasoline engines by the occurrence of knocking combustion and in diesel engines by the maximum permissible peak pressure in the cylinder. To offset this limitation, supercharged engines usually have lower compression ratios than their naturally aspirated counterparts.

Dynamic supercharging

The gas-exchange processes are not only influenced by the valve timing, but also by the geometry of the intake and exhaust lines. Induced by the induction work of the piston, as the intake valve opens it initiates a suction wave in the intake manifold that reflects off the open end of the intake manifold and returns as a pressure wave to the intake valve. These pressure waves can be used to increase the air-mass intake (Figure 12). In addition to the geometry in the intake manifold, the impact of this supercharging effect based on gas dynamics also depends on the engine speed (see Ram-tube supercharging, Tuned-intake-tube charging, Variable-geometry intake-manifold systems).

Mechanical supercharging



In mechanical supercharging, the supercharger is driven directly by the internal-combustion engine (see Turbochargers and superchargers). The charger and the internal-combustion engine are mechanically coupled to each other. Types of mechanical supercharger unit are positive-displacement superchargers (compressors) of various designs (e.g. Roots superchargers, spiral-type superchargers) and hydrokinetic flow compressors (e.g. radial compressors).

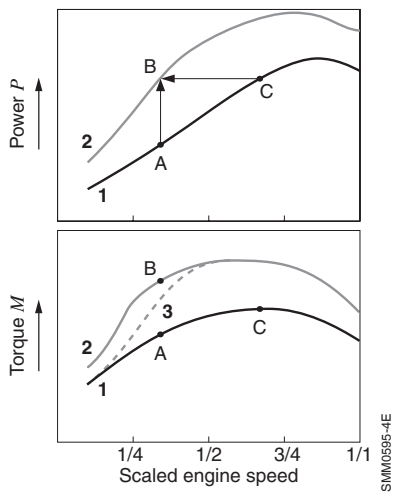
The crankshaft and charger shaft feature a fixed transmission ratio in system designs used up to now. Mechanical or electromagnetic clutches can be used to control supercharger activation. The boost pressure is generally adjusted by a bypass device with control flap (wastegate).

Advantages of mechanical supercharging
- The supercharger is installed on the cold side of the engine.
- The engine's exhaust system is not influenced by supercharger components.
- The supercharger responds almost immediately to load changes.

Disadvantages of mechanical supercharging
- The drive power must be branched from the effective power of the engine, which results in increased fuel consumption.

Figure 12: Increase of volumetric efficiency through dynamic supercharging
The engine speed is scaled to the nominal speed.
1 System with dynamic supercharging,
2 System with standard intake manifold.

– Low-noise performance can only be achieved by additional measures.
– Comparatively high structural volume and weight.
– The supercharger unit has to be positioned at the engine's belt level.



Exhaust-gas turbocharging

In exhaust-gas turbocharging, the power for driving the charger is extracted from the engine's exhaust gas, i.e. some of the energy contained in the exhaust gas is converted into mechanical energy by an exhaust-gas turbine. In this way, the process exploits some of the enthalpy that remains unused (owing to crankshaft-assembly expansion limits) by naturally aspirated engines. Exhaust backpressure however increases in the process. Hydrokinetic flow compressors are exclusively used to compress the induction air (see Turbochargers and superchargers).

Exhaust-gas turbochargers are usually designed to generate a high boost pressure even at low engine speeds. In other words, the turbocharger turbine is generally designed for an engine mid-speed range. However, without further measures, boost pressure at the high end of the engine speed range could increase to levels that would place excessive load on the engine. The turbine is therefore equipped with a bypass valve which, from a specific operating point, diverts some of the exhaust-gas mass flow past the turbine. However, the energy of this exhaust gas remains unutilized. Much more satisfactory results can be achieved with a compromise between high boost pressure in the low engine-speed range and avoidance of engine overload at the high end of the engine-speed range by employing a turbocharger with variable turbine geometry (VTG). The adjusting blades used for this purpose adapt the flow cross-section and the angle of impact to the turbine (and thus the exhaust-gas pressure applied to the turbine) by varying the position of the guide blades (see Turbochargers and superchargers).

Figure 13: Comparison of power and torque curves between naturally aspirated engine and turbocharged engine

The engine speed is scaled to the nominal speed.
1 Naturally aspirated engine in stationary operation,
2 Turbocharged engine in stationary operation,
3 Torque build-up of a turbocharged engine in transient operation.
A→B Higher torque and higher power at identical speed for turbocharged engine.
C→B Identical power for turbocharged engine at lower speed.

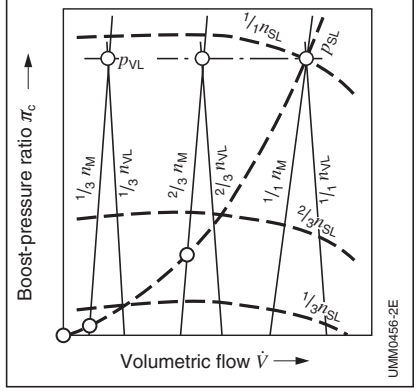
Advantages of exhaust-gas turbocharging
– Considerable increase in power output per liter.
– Improvement in fuel-consumption figures relative to naturally aspirated engines with the same output power.
– Improvement in exhaust-gas emission rates.
– Comparatively small structural volume.
– Can be used with low-pressure-side exhaust-gas recirculation.

Disadvantages of exhaust-gas turbocharging
– Installation of the turbine side of the turbocharger in the hot exhaust-gas system requiring materials resistant to high temperatures.
– Increased thermal inertia in the exhaust-gas system.
– Without further measures, comparatively low starting torque from low-displacement engines.

Special forms of supercharging

In electrically assisted exhaust-gas turbocharging systems, an additional electric motor serves to maintain the turbocharger at a high speed in the absence of exhaust-gas mass flow. The produces benefits above all in transient vehicle operation and at low engine speeds, but the complexity and the electric power consumption are very high. The drawbacks of the exhaust-gas turbocharger due to inertia can be reduced with electrically assisted exhaust-gas turbocharging.

A special but only theoretical form of supercharging is pressure-wave supercharging (Comprex); this however failed with regard to production maturity. The working principle is based on the reflection properties of pressure waves which propagate in a rotating cell rotor (see Turbochargers and superchargers). The chief advantage is the transient response, which facilitates a very rapid torque build-up. However, the costs involved with pressure-wave superchargers are high and the required drive necessitates additional packaging measures.



Volumetric-flow map

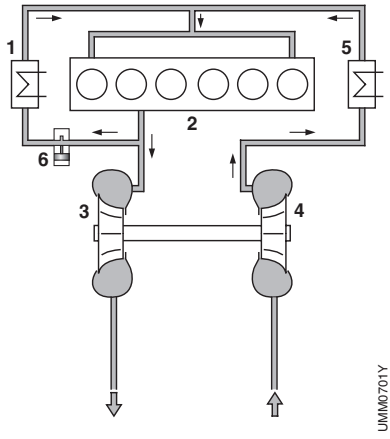
A clear illustration of the relationship between the engine and the supercharger is provided by the diagram for pressure vs. volumetric flow (Figure 14), in which the pressure ratio π_c of the supercharger is plotted against volumetric flow $\dot{V}$.

The curves for unthrottled 4-stroke engines (diesel) are particularly descriptive because they contain sloped straight lines (engine mass-flow characteristics) which represent increasing air-throughput values as the pressure ratio $\pi_c = p_2/p_1$ (where p_1 denotes the ambient pressure and p_2 the charge-air pressure) increases at constant engine speed.

Figure 14: Pressure vs. volumetric-flow map of mechanically driven positive-displacement supercharger and hydrokinetic flow compressor

n Speed, p_L Boost pressure.
Subscripts:
VL Positive-displacement supercharger,
SL Hydrokinetic flow compressor,
M Engine.

The diagram shows pressure ratios which result at corresponding constant supercharger speeds for a positive-displacement supercharger and a hydrokinetic compressor.



Only superchargers whose delivery rates vary linearly with their rotational speeds are suitable for vehicle engines. These are positive-displacement superchargers of piston or rotating-vane design or Roots blowers. Mechanically driven hydrokinetic flow compressors are not suitable.

Exhaust-gas recirculation

Operating principle
With exhaust-gas recirculation (EGR) hot exhaust gas is removed, cooled in an exhaust-gas cooler, mixed with fresh air, and returned to the combustion chamber. The exhaust-gas recirculation rate is adjusted by a valve. It is used in diesel engines and also increasingly in gasoline engines.

Exhaust-gas recirculation in diesel engines
In diesel engines the untreated emissions of NO_x are reduced significantly by exhaust-gas recirculation. Essentially this is done by lowering the peak temperature in the cylinder, which is obtained by the fact that the on the one hand the recirculated exhaust gas reduces the combustion velocity and on the other hand the exhaust gas on account of its now higher heat capacity – above all of the CO2 – for the same supplied energy does not become as hot as exhaust gas without exhaust-gas recirculation.

Figure 15: High-pressure exhaust-gas recirculation
The arrows denote the flow direction.
1 EGR cooler for high-pressure EGR,
2 Engine,
3 Exhaust-gas-turbocharger turbine,
4 Exhaust-gas turbocharger compressor,
5 Intercooler,
6 EGR valve.

Exhaust-gas recirculation in gasoline engines
In gasoline engines the idea is not to reduce the nitrogen oxides. The aim is primarily to reduce the exhaust-gas temperature to protect components (catalytic converter and turbocharger). This is very effective particularly in engine full-load operation because the otherwise usual process of enriching the air/fuel mixture to reduce the exhaust-gas temperature can be partially or completely dispensed with. This results in a dramatic improvement in fuel consumption.

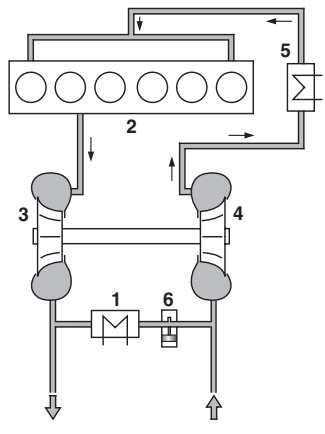
An additional consideration in gasoline engines the possibility of diluting the charge by means of exhaust-gas recirculation without compromising the function of the three-way catalytic converter. Engine dethrottling can be achieved by increasing the EGR rate particularly in engine part-load operation, which also results in improved fuel efficiency.

Exhaust-gas recirculation variants
Essentially, one of two variants – high-pressure and low-pressure recirculation – is used, depending on whether the exhaust-gas cooler is located upstream or downstream of the turbocharger. Whereas high-pressure recirculation is found primarily in commercial vehicles, both variants are used in passenger cars.

High-pressure EGR
With high-pressure recirculation (Figure 15), exhaust gas is recirculated on the high-pressure side, i.e. upstream of the turbocharger turbine. It has the advantage that the pressure difference required to transport the exhaust gas from the exhaust side to the intake side is higher and can even be altered by means of variabilities at the turbocharger (wastegate or variable turbine geometry). High EGR rates can basically be achieved because the EGR section is short and can therefore be filled and emptied quickly. Thanks to this dynamic advantage, the EGR system can respond relatively quickly to changing operating conditions.

Because the recirculated exhaust gas is not mixed with fresh air until downstream of the intercooler, the intercooler and the turbocharger compressor are not

permeated and thus not fouled by the exhaust gas. The performance of these components therefore remains constant over their full service lives. By contrast, significantly greater demands are placed on the EGR cooler on the high-pressure side. This can be put down to the higher pressures and temperatures during operation and to the already mentioned component sooting.



Low-pressure EGR

This form of exhaust-gas recirculation routes the exhaust gas only downstream of the turbine through the EGR cooler and mixes it with the inducted fresh air upstream of the turbocharger compressor (Figure 16). The exhaust gas arrives at the EGR cooler only after it has passed through the diesel particulate filter (DPF, not shown in the illustration) and the soot has been removed. Thus the EGR cooler is not fouled and performs consistently over its full service life. Because of the lower temperature in this area of the exhaust system the temperature stresses in the EGR cooler are also much lower than is the case for high-pressure recirculation. The lack of fouling together with a lower inlet temperature provide for a lower cooler outlet temperature than with high-pressure recirculation. The reduction in NO_x emissions that can thereby be achieved can be sufficient in many cases to eliminate the need for further exhaust-gas treatment, such as the SCR system for example.

One drawback of low-pressure recirculation is the reduced dynamic response. The system is relatively far removed from the engine and, due to the long distances involved, cannot adapt the exhaust-gas recirculation rate quickly. It is necessary to set the EGR rates slightly lower than for high-pressure recirculation so as to prevent the engine from being "flooded" with exhaust gas.

Reciprocating-piston engine

Components

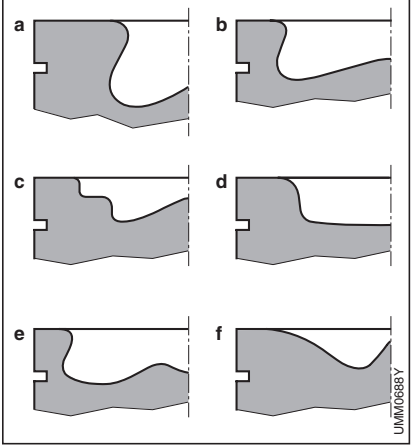
In addition to the crankshaft drive, which makes a vital contribution by generating torque, the significance of the cylinder head is crucial to the efficiency of an internal-combustion engine (Table 1).

Crankshaft drive and crankcase
The crankshaft drive comprises the following components: piston, piston rings, connecting rod, and crankshaft. What all the crankshaft-drive components have in common is a translational and rotational motion. The tribological design of the crankshaft drive is already hugely significant in view of its robustness and reduced engine friction.

Piston
Because of the mechanical and thermal loads to which it is subjected, the piston is a highly complex component in an internal-combustion engine. The recess and piston-surface geometries have a crucial impact on mixture formation and combustion. In addition, the primary function of the piston is to transmit force to the connecting rod. Complex mechanical stresses occur in the process with simultaneously very high local temperatures up to and in excess of 300 °C.

The role of the piston recess is even more important in diesel engines. With the high compression ratio and a typically flat cylinder head, the entire combustion chamber must be accommodated in the piston recess. Various piston-recess designs are successfully used. Figure 1 shows examples of the design variations used in diesel engines.

The piston recess decisively defines the combustion-chamber shape and at the same time influences the strength of the piston crown, a factor which is vital to the function of force input into the piston pin. Especially when it comes to aluminum pistons, which are currently the preferred choice mainly for weight reasons, the requirements of high heat resistance, low weight and cylinder peak pressure call for technically sophisticated solutions.



Brass bushings are used to accommodate the piston pin in diesel engines subject to high loads.

Diesel engines can also utilize steel and even gray-cast-iron pistons as well as aluminum designs. Steel pistons are used in applications with peak pressures well in excess of 200 bar. An important distinguishing feature of steel is its lower heat conduction.

Modern turbocharged engines with high cylinder peak pressures and high power outputs also require a piston spray injector with an additional piston cooling duct for cooling purposes (Figure 2). Here engine oil is sprayed through a vertically arranged piston spray injector into the piston cooling duct. The inlet and outlets for the piston cooling duct are located on the underside of the piston.

Piston rings form the sealing element between the combustion chamber and the crankcase (Figure 3). As well as providing the seal, the piston rings also perform the important tasks of conducting heat to the

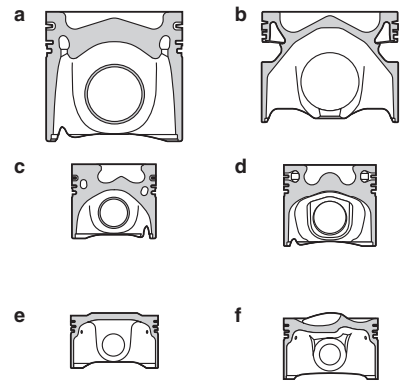
d) Dish recess,
e) Eccentric recess design,
f) W recess.

cylinder wall and controlling the entry of oil into the combustion chamber.

Three rings are typically used, the top ring acting as a compression ring and the bottom ring as an oil control ring. The middle ring frequently performs both functions. Because particulate filters become clogged with ash, which is also a product of burnt oil in the combustion chamber, oil consumption and therefore the coordination of the piston-ring set and honing are vitally important.

Table 1: Components of a 4-stroke reciprocating-piston engine



Assembly	Component	Purpose and function	Stress
Crankcase	Crankcase	– Housing for crankshaft drive – Accommodation of cylinder head and counterpart for accommodation of cylinder-head bolts – Accommodation of crankshaft bearings – Accommodation of accessories	Deformation – flow of force from cylinder-head bolts to crankshaft, bending moments, vibrations, oscillations and natural frequencies
	Bearing surface	Different approaches to structural solution of bearing surface: – Accommodation of liners with seal (wet liners) – Accommodation of cast liners (dry liners) – Piston bearing surface directly integrated in crankcase	Deformation (out-of-round), tribological counterpart to piston
Crankshaft drive	Piston	– Conversion of energy in combustion chamber (gas pressure) into a translational motion – Dissipation of heat from combustion chamber to cooling medium – Support of the normal forces occurring as a result of the connecting-rod inclination	Complex mechanical and local thermal stress above 350 °C in the recess area
	Piston rings	– Sealing of combustion chamber in relation to crankcase – Avoidance of oil entry into cylinder – Dissipation of heat to cylinder wall	High mechanical bending stress and high thermal stress, complex tribology
	Connecting rod and pin	– Absorption of the forces acting on the piston and transmission to the crankshaft for torque build-up	High mechanical compressive, tensile and bending stresses, complex tribological processes
	Crankshaft	– Absorption of the forces acting on the connecting rod and conversion of oscillatory to rotational motion. Thus build-up of a torque for transmission to the drivetrain	High mechanical compressive, tensile and bending stresses (buckling), complex tribological processes
Cylinder head	Cylinder head	– Control of charge cycle – Cooling of areas close to the combustion chamber – Accommodation of injectors (in diesel engine and gasoline engine with direct injection) and of spark plug (in gasoline engine)	High stress due to thermomechanical fatigue behavior and cold-hot expansion

Table 1: Components of a 4-stroke reciprocating-piston engine (continued)

Assembly	Component	Purpose and function	Stress
Cylinder head	Camshaft (typically in cylinder head)	– Conversion of a rotational motion into a translational motion to open and close the valves	Hertzian stress
	Valve control	– Conversion of a rotational motion into a translational motion to open and close the valves	High valve-closing speeds require large valve spring forces
	Valves	– Opening of passages to intake and exhaust ports – Sealing of combustion chamber during compression phase	Valve-seat wear due to high valve-closing speeds, thermal load at exhaust valve
	Ports/ passages	– Supply and discharge of cylinder charge – Provision of the desired cylinder-charge movement	Local thermal load
	Base plate	– Accommodation of combustion-chamber pressure and sealing	Local thermal load and bending
	Geartrain	– Driving of camshaft by belt, chain or gear wheels	Rotational irregularities with alternating contact flanks
Other components	Oil pump	– Provision of the required oil delivery rate and provisions of the required oil pressure	Torque particularly with viscous oil
	Oil filter	– Filtering of contaminants from engine oil	–
	Water pump	– Provision of the required cooling-medium delivery rate – Provision of the required cooling-medium mass flow	Cavitation

Connecting rod

The connecting rod (Figure 4) links the piston with the crankshaft. It transmits the piston's gas and inertial forces introduced into the piston pin to the crank pin. It is therefore subjected to tensile, compressive and bending stresses. It also carries the bearings for the crankshaft and usually for the piston pin. It must therefore be particularly stiff in its design, especially in the connecting-rod eyes, which accommodate the bearings. For this reason, it is usually designed with a double-T-shaped shank profile and drop-forged with tempering steels. Sintered materials can also be successfully used. Annealed cast iron can also sometimes be used in low-load applications (gasoline engines). Rarely encountered is the combination of a standard connecting rod and a forked connecting rod in V-engines which then permits an exactly opposed cylinder arrangement.

The length of the connecting rod is determined by the piston stroke and the counterweight radius (the geometric path of the outer contour is called the "connecting-rod violin"). In commercial-vehicle engines with a relatively large stroke/bore ratio of more than 1.1 and large bearing diameters an angled split of the big connecting-rod eye is customary. This enables the piston to be removed without the crankshaft having to be removed also. However, this angled split generates considerable shear forces even when the connecting rod is positioned vertically at top dead center. These forces are usually absorbed by toothing, groove and spring or by cracked surfaces. Cracking of the big connecting-rod eye is achieved by a "fracture separation" using extremely high (hydraulic) expansion forces and a targeted weakening of the cross-section at the big connecting-rod eye. The big-end bearing cap and the connecting rod can only be installed as a single unit.

The bolts are designed as through-bolts with or without nuts. Adapter sleeves or bolt adapter collars ensure that the bearing shells are aligned when seated.

Lateral guidance of the connecting rod can be performed in the crankshaft at the big connecting-rod eye or in the piston at the small connecting-rod eye.

The small connecting-rod eye must absorb considerable forces and is therefore often form-bored in order to avoid misalignment. For diesel engines with high peak pressures in particular and in accordance with high gas forces, a special

shape is chosen for the small connecting-rod eye which ensures a high contact surface on the pin without weakening the piston. This may be trapezoidal (narrow at the top, wide at the bottom) or stepped (narrow shoulder at the top, wide at the bottom).

The connecting rod is designed in line with the calculation of the gas and inertial forces (see Crankshaft-assembly design). The case of buckling is also calculated. Both buckling in the plane perpendicular to the crankshaft as a hinged beam and buckling in the crankshaft-axis plane (engine longitudinal plane) as a fixed beam must be checked. The critical cross-sections in the transition from the dimensionally stable connecting-rod eye to the double-T shank are usually recalculated with the aid of FEM simulations (finite-element method). The loads caused by the gripping of the bearing caps must not be underestimated and ignored.

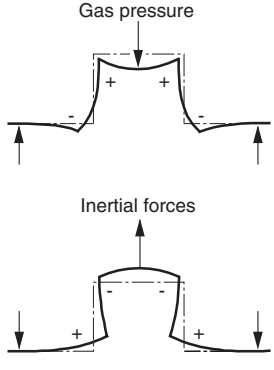
8 Counterweight (bolted).

Crankshaft

The crankshaft with its throws (Figure 5) converts the oscillating motion of the piston by way of the connecting rod into a rotatory motion. The translational energy is transformed into a rotating torque, which can be picked off by a coupling.

The main bearings of the crankshaft are fixed in the crankcase, while the crank pins in the throws run in the bearings fixed to the connecting rods. The counterparts to the throws with crank pins are the counterweights, which are either cast, forged or bolted on. Depending on the engine type, the crankshaft main bearings are arranged after each cylinder – particularly in in-line engines and diesel and gasoline engines subject to high loads – or only after every second throw (gasoline engines subject to low loads). V-engines usually feature one crank pin for two adjacent connecting rods on one throw. This also applies to forked connecting rods, which permit two exactly opposing cylinder banks. In order to facilitate a uniform ignition interval in V6 engines with a 90° bank angle, split-pin designs which permit a 30° offset of two crank pins in a very tight space without a main bearing in between are increasingly being used. This form of design is used even in commercial-vehicle diesel engines subject to high loads.

Crankshafts are usually forged (drop forgings or open-die forgings, depending on the size) and, in lower-load applications, increasingly cast (nodular graphite iron). Built-up crankshafts are also used in large engines. Bores for supplying lube oil to the connecting-rod bearings are incorporated in such a way as not to generate further increases in stress.



The gas and inertial forces (see Crankshaft-assembly design) subject the crankshaft to bending stress in particular (Figure 6). If a main bearing is incorporated after each throw, the bending loads on the crankshaft are low on account of tangential forces. However, particular attention must be paid to the transition between crank pin and web because this is where the greatest stresses occur. Because of the large number of main bearings, the clamping of the crankshaft represents theoreti-

cally a statically overdefined system – in the simulation, however, a statically defined state which correctly describes the critical state is assumed.

Another important factor is the torsional vibrations, which, on account of the alternating forces of each individual cylinder (torsional force, see Crankshaft-assembly design) excite the overall crankshaft-assembly system and, in view of the not inconsiderable length of the crankshaft, can approach the crankshaft's natural resonance.

The oscillatory system – consisting of piston, connecting rod and crankshaft – is a complex system of constantly changing torsional forces. The further the counterweights are arranged to the outside, the higher the excitation. For this reason, heavy-metal counterweights are also bolted on in some cases. A simple simulation can be performed by assuming a smooth, inertialess and elastic shaft with attached equivalent masses. The oscillation-equation system can then be set up with the aid of the torsion-spring rate of the torque shaft. Cast shafts are ascribed a certain level of intrinsic damping. The crankshaft is thus subjected to both a locally different and a time-varying torsional load.

Figure 6: Crankshaft throw
Primary stresses and deformations due to gas pressure and inertial forces.

The torsional vibrations of the crankshaft, which are also called 2nd-order torsional vibrations (see Crankshaft vibration damper) must be reduced by suitable vibration dampers. This is particularly necessary to protect the crankshaft against excessively high loads.

Crankcase

The crankcase supports the force-transfer mechanism between cylinder head and crankshaft assembly. It bears the crankshaft assembly's support bearings, and incorporates (or holds) the cylinder sleeves. Also included in the block are a separate water jacket and sealed oil chambers and galleries. Furthermore, it must absorb the torque reaction forces and provide locations for mounting many add-on components.

A rigid framework-like structure (support-beam concept) is normally used to absorb the forces; this structure is designed to ensure a direct, linear and bending-moment-free flow of force. This is usually achieved by walls with reinforcing ribs and in the case of the bolt-through design by through-bolts.

The cylinder head is usually bolted as a separate component – in larger engines also as an individual cylinder head – to the crankcase. Often four bolts per head are used, with adjacent cylinders usually sharing two bolts. Six or eight bolts may also be used in engines with high peak pressures, typically above 200 bar. The purpose of this in particular is to distribute as evenly as possible the pressure force of the cylinder-head gasket.

The crankshaft-bearing caps are usually bolted from underneath to the crankcase. In the bolt-through design a long bolt performs this function from the head to the bearing cap. The advantage of this design is that it permits the use of high-tensile steels, which can transmit tensile load better than casting materials.

The crankcase is usually drawn down at the sides to deep below the crankshaft bearings in order to provide sufficient rigidity. But sometimes a separate frame ("bed plate") may also be used which is designed to reduce weight and increase rigidity. Sometimes the side walls are additionally bolted horizontally at the sides

in the crankshaft-bearing area in order to achieve even greater rigidity. Bolted underneath is the oil pan, which can sometimes have a similarly bracing effect. However, this only applies to cast oil pans.

The piston bearing surface can be designed as a separate component (liner), particularly when replacement is not uncommon during the crankcase's service life, for example in commercial vehicles with high mileage ("wet liner" because coolant flows around it). However, the piston bearing surface can also be cast into the crankcase – particularly in cast-aluminum designs – or directly as a bearing surface in gray cast iron with strip hardeners.

Today's crankcases have attained a very high level of function integration and are therefore highly complex components. Frequently the oil-pump housing is also integrated in the casting, as are oil-cooler functions, the coolant-thermostat housing, the balancer-shaft locators, and all the brackets for the accessories.

Aside from the crankshaft, the crankcase is the component which contributes most to the engine weight. Many efforts are therefore made to reduce the weight by using materials other than the customary gray cast iron. These include aluminum materials, which, because of their thermally limited service life, are primarily used in smaller engines, particularly in passenger-car applications. Die casting has become an accepted cost-saving process for manufacturing aluminum, while sand casting is otherwise the regular process used. An "open-deck" construction is used to manufacture diecast crankcases efficiently, i.e. the joint face with the cylinder head features large pass-through cross-sections for the water jacket and the oil return. When cast-iron materials are used, on the other hand, the upper crankcase is closed to make the structure as rigid as possible.

Efforts are also being made to manufacture crankcases from magnesium in order to further reduce weight – but this comes at the expense of a high manufacturing cost. For this reason, a "hybrid" material concept is used where the bearing functions are performed by aluminum and the shielding functions by magnesium inserts. Further increases in strength are provided by other cast-iron variants, compacted graphite iron (CGI) being one such variant which has been more widely used in recent years. Special heat treatment and specific cooling can be used to create in cast iron high-strength (and hard-to-machine) spheroidal graphite instead of the customary lamellar graphite. This makes it possible to produce thinner walls and higher strength with reduced weight.

The crankcase is assigned the most important function of noise emission. Because the crankcase is often joined directly to the combustion chamber, absorbs the high periodic gas and inertial forces and has a relatively large surface, it is extremely important for this surface to be rigid. The standard design methods used to provide high rigidity are ribbing and barreling, which also help to prevent a membrane effect.

Variable compression ratio

A variable compression ratio is desirable both in gasoline engines to reduce the knock tendency close to full load and in diesel engines to reduce the peak pressure at full load. However, up to now no mechanical or hydraulic system has successfully managed to provide this variability in diesel engines. The reason for this is the high loads to which diesel engines are subjected on account of the higher peak pressures and higher pressure gradients compared with gasoline engines.

The designs for variable compression ratio (VCR) can be categorized as follows:

- Solutions which are integrated into the piston (hydraulic actuation of a piston upper section that moves axially in relation to a fixed lower section)
- Solutions which alter the length of the connecting rod (sliding solution, articulated connecting rod, eccentric connecting-rod bearing in the small or big connecting-rod eye)
- Formulations for an altered crankshaft position relative to the cylinder head (swiveling or axial movement of the crankcase, eccentric crankshaft bearing)
- Coupling lever for varying the effective piston stroke (multilink, crankshaft-drive lever system, displacement alteration with ε variation)

– Additional volumes which are increased or decreased (variable additional volume in the cylinder head)

Formulations for variable compression ratios in gasoline engines cover a range of approx. $\varepsilon = 7$ to 14.

Cylinder head

The main functions of the cylinder head are to supply the cylinder with fresh mixture, to discharge the exhaust gas, and to absorb the cylinder pressure forces.

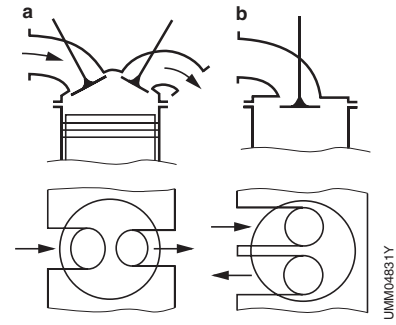
Cylinder head

The cylinder head seals off the upper end of the crankcase and the cylinder barrel. It houses the gas-exchange valves and the spark plugs in gasoline engines, the fuel injectors in direct-injection gasoline engines, and the fuel injectors and possibly the sheathed-element glow plugs in diesel engines. Together with the piston, it also provides the desired combustion-chamber shape. In the vast majority of passenger-car engines, the entire valve gear is also mounted in the cylinder head.

The cylinder head performs a large number of functions and exhibits complex load profiles. The challenge faced here, as well as precisely controlling gas exchange and charge movement, which directly influence engine emissions, efficiency and power output, is above all to cool the hot side of the cylinder head and maintain control over the complex mechanical and thermal loads involved.

Based on the gas-exchange concepts, a distinction is made between two basic design configurations. In the counterflow cylinder head intake and exhaust passages open into the same side of the cylinder head (Figure 7b). This limits the space available for the intake and exhaust-gas passages, but due to the short flow tracts, this represents a substantial advantage in supercharged applications without intercooling. This design, with the gas supply and discharge tracts on a single side, also provides practical advantages in transverse-mounted engines.

In the crossflow cylinder head intake and exhaust passages are located on opposite sides of the engine (Figure 7a), providing a diagonal flow pattern for the intake and exhaust gases. This layout's advantages include more freedom in intake and exhaust-tract design as well as less complicated sealing arrangements. Typically, vehicle-specific boundary conditions are crucial to determining whether a counterflow or crossflow cylinder head is used.

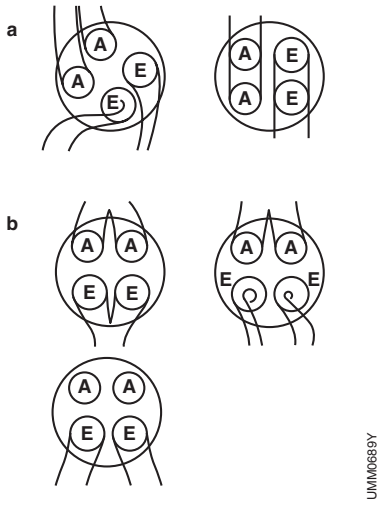


This decision also determines the valve arrangement used. Counterflow applications require a twisted valve arrangement in today's typical multi-valve designs. The main advantage of a twisted valve arrangement is that it is a simple way of delivering high cylinder-whirl values. A parallel valve arrangement requires greater efforts at the passage end to deliver a high cylinder whirl (Figure 8).

Today's passenger-car applications use almost exclusively a continuous single-piece cylinder head. In V-engines one cylinder head per cylinder bank is used. Individual cylinder heads are frequently still used in commercial-vehicle engines, which sometimes still feature a block-mounted camshaft with a push-rod assembly.

In contrast to passenger-car applications, in which the cylinder head is often made from aluminum, which as well as weight advantages improves heat transfer from the combustion chamber, commercial-vehicle applications utilize gray-cast-iron designs in view of the fact that

Figure 7: Cylinder-head identification according to intake and exhaust-tract location



a) Crossflow design,
b) Counterflow design.

resistance to fatigue cannot be achieved by light alloys at hight peak pressures and with large cylinder diameters.

The cylinder head is subject to very high loads. On the one hand, frequently varying temperatures and the accompanying expansions give rise to stresses which can only be absorbed by appropriate design measures (individual cylinder head, suitable cavities in a multi-cylinder head). Thermomechanical strength is determined by the number of cold-hot load profiles.

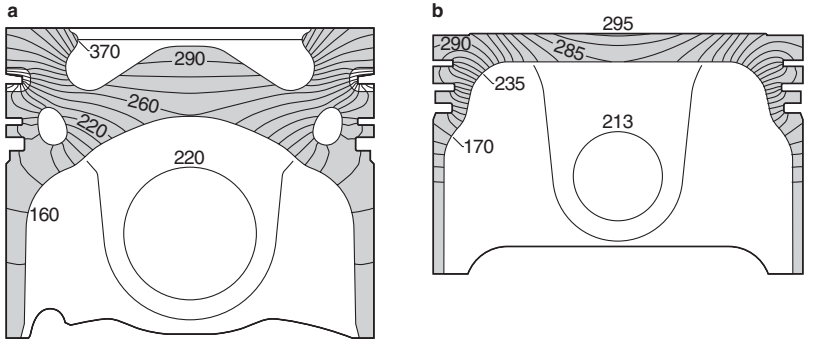


Figure 8: Valve arrangements
a) Twisted valve arrangements,
b) Parallel valve arrangements.
E Intake, A Exhaust.

In multi-valve designs the land between the exhaust valves is subjected to particularly high temperatures. At full load slightly critical temperatures above 350 °C are reached here. Similarly high temperatures are encountered in the recess-edge area (Figure 9). Gray-cast-iron designs are especially prone to the risk of hot-gas corrosion, an oxidation of the surface which can culminate in component-jeopardizing cracking.

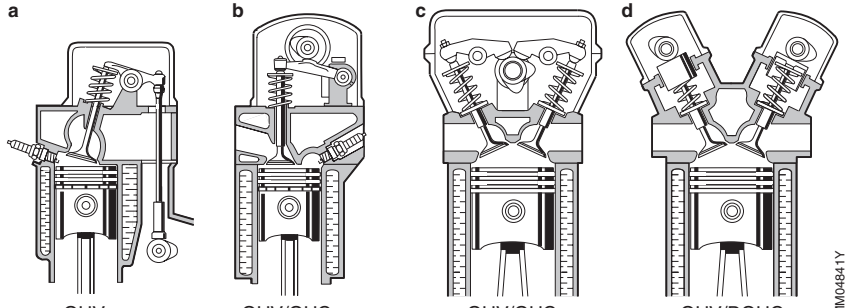
The cylinder-head gasket, which is located between the crankcase and the cylinder head, performs an important function. Firstly, it must seal the combustion chamber even in the case of high cylinder pressures and, secondly, it must ensure the flow of engine oil and cooling water between crankcase and cylinder head. Typically, metal materials are used to seal the combustion chamber; these metals adapt to the surface by means of plastic deformation and establish the seal through their elasticity. Elastomer gaskets or geometrically optimized metal-sheet steel gaskets are used.

Figure 9: Piston operating temperatures in motor-vehicle engines at full load (schematic), values in °C
a) Passenger-car diesel-engine piston, 16 MPa ignition pressure, 58 kW/*l*,
b) Passenger-car gasoline-engine piston, 7.3 MPa ignition pressure, 53 kW/*l*.

To provide a uniform downward pressure on the cylinder-head gasket, it is possible to increase the number of cylinder-head bolts to such an extent that already commercial-vehicle engines with eight bolts per cylinder head are in use.

Engines without cylinder-head gaskets are the exception and require the crankcase deck and the underside of the cylinder head to be finished to very high levels of accuracy.

Valve gear



It is the function of the valve-gear assembly in a 4-stroke engine to permit and to control the exchange of gases in the internal-combustion engine. The valve gear includes the intake and exhaust valves, the springs which close them, the camshaft drive assembly, and the various force-transfer devices (Figure 10). In various widely-used designs, the camshaft is located in the cylinder head.

When the camshaft is installed within the block, the rocker arm is actuated not directly by the cam lobe, but by the intermediate action of a push rod and a lifter (push-rod assembly, Figure 10a).

In the case of the cam-follower or single rocker-arm assembly actuated by an overhead cam, the cam lobe's lateral and linear forces are absorbed and relayed by a cylinder-head mounted lever rocking back and forth between the cam lobe and the valve. In addition to transferring forces and absorbing lateral forces, the intermediate rocker arm can also be designed to magnify the cam pitch effect (Figure 10b).

In the case of the twin rocker-arm assembly actuated by an overhead cam, the rocker arm acts as the force-transfer element with its tilt axis located between the camshaft and the valve. Here, too, the rocker arm is usually designed as a cam-

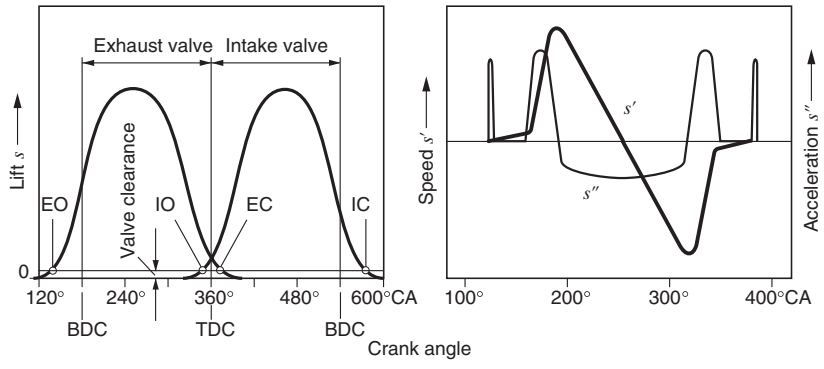
lift multiplier to produce the desired valve travel (Figure 10c).

In the case of the overhead bucket-tappet assembly, a "bucket" moving back and forth in the cylinder head absorbs the cam lobe's lateral force, while transferring its linear actuating pressure to the valve stem (Figure 10d).

Valve arrangements

The valve-control arrangement and the design of the combustion chamber are closely interrelated. Today, nearly all valve assemblies are overhead units mounted in the cylinder head. In diesels and simpler spark-ignition (gasoline) engines, the valves are parallel to the cylinder axis, and are usually actuated by twin rocker arms, bucket tappets or single rocker arms. With increasing frequency, current spark-ignition (SI) engines designed for higher specific outputs tend to feature intake and exhaust valves which are inclined towards each other. This configuration allows larger valve diameters for a given cylinder bore, while also providing greater freedom for optimizing intake and exhaust passage design. Twin rocker-arm assemblies actuated by overhead cams are used most often here. High-performance and racing engines are increasingly using four valves per cylinder and overhead bucket-tappet valve assemblies.

The valve-timing diagram (Figure 11) for an engine shows the opening and closing times of the valves, the valve-lift curve, the maximum valve lift, and the valve velocity and acceleration.



Typical valve-acceleration rates for passenger-car OHC (overhead camshaft) valve assemblies:
s'' = 60…65 mm (b/ω^2) → 6,400 m/s^2 at 6,000 rpm for single and twin rocker-arm assemblies.
s'' = 70…80 mm (b/ω^2) → 7,900 m/s^2 at 6,000 rpm for overhead bucket-tappet assemblies.
For heavy-duty commercial-vehicle engines with block-mounted camshafts:
s'' = 100…120 mm (b/ω^2) → 2,000 m/s^2 at 2,400 rpm.

Valve, valve guide and valve seat

The materials employed in manufacturing valves are heat and scale-resistant. The valve seat's contact surface is frequently hardened. Another proven method for improving the thermal-conductivity characteristics of exhaust valves is to fill their stems with sodium. To extend service life and improve sealing, valve-rotating systems (rotocaps) are also in common use.

The valve guides in high-performance engines must feature high thermal con-

Figure 11: Valve-timing diagram

IC Intake closes, IO Intake opens, EC Exhaust closes, EO Exhaust opens,
BDC Bottom dead center, TDC Top dead center.

ductivity and good antifriction properties. They are usually pressed into the cylinder head and are often supplemented by valve-stem seals at their cold ends for reducing oil consumption.

Valve-seat wear is generally reduced by making the valve-seat inserts of cast or sintered materials and shrink-fitting them into the cylinder head.

Cam-lobe design and timing dynamics

The cam lobe must be able to open (and close) the valve as far, as fast and as smoothly as possible. The closing force for the valves is applied by the valve springs, which are also responsible for maintaining contact between the cam lobe and the valve. Dynamic forces impose limits on cam and valve lift.

Rarely encountered are designs which use their own mechanism (Desmotronic) to restore the valves with the advantage of increased valve velocities and thus lift curves which more closely resemble the ideal rectangular case. Conventional springs must always ensure a frictional connection between camshaft, intermediate elements and valve while adhering to the permissible surface load. A slight clearance can be encountered only when cam lift is not active. Modern engines operate here with hydraulic valve-clearance compensation. Otherwise valve clearance must be regularly checked; measurements of 0.1 to 0.2 mm are common at the intake and exhaust valves.

Camshaft drive

To drive the valve gear, the camshaft must be connected to the crankshaft in such a way that one crankshaft revolution results in a one half camshaft revolution in a 4-stroke engine.

For passenger-car applications with overhead camshaft(s) either timing-chain or toothed-belt drives are used in modern engines. Both drives require a tensioning device, which acts on the free running length, the loose side, to prevent uncontrolled vibration.

In view of the fully utilized minimum space between piston and valve in modern engines, it is very important for the camshaft drive to operate safely and reliably, because in the event of damage contact can have serious consequences for the valve gear.

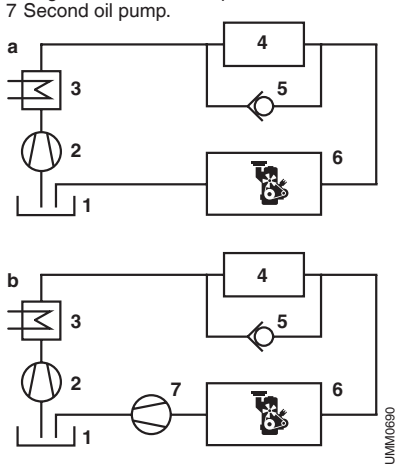
For this reason, the pressure pins for the tensioning rails in a chain drive or the toothed belt are wearing parts which must be replaced on a regular basis. Modern duplex chains are highly durable and are only subject to minimal wear. The drawbacks of a timing chain are its need to be lubricated and its elongation during operation. Some major advantages, however, are that it cannot jump off the gear wheel and it is not subject to the risk of cracking.

Transmission by gear wheels in a geartrain is typically used in commercial-vehicle engines or engines with block-mounted camshafts. In engines with overhead camshafts in particular, this is a very expensive solution, but one which provides for extending engine running times on account of the reliable transmission.

Expensive vertical shafts, whose axes run at right angles to the crankshaft and camshaft, are rarely used.

Oil supply

As well as lubricating the tribologically critical pairings of the crankshaft drive, the cylinder head and other components, the oil supply serves to remove local contaminants, combustion residues and wear particles which are filtered out in the oil-filter unit. Additional functions include the dissipation of heat in areas subject to thermal load, such as the friction bearings in the crankshaft drive or for oil-cooled pistons, and damping of vibrations in bearings.



With the system of forced-feed lubrication conventionally used (see also "Engine lubrication"), the oil pump, a gear pump that typically operates as a positive-displacement pump, delivers a defined volumetric flow from the oil sump through an oil-filter unit (Figure 12a). For safety reasons, the oil-filter unit is often equipped with a bypass valve and a pressure valve in a full-flow design. The oil cooler provided in engines subject to higher loads is cooled by either air or coolant. The engine oil flows though oil ducts and by the force of gravity back into the oil sump and into the oil pan typically located underneath the crankcase. That is why forced-feed lubrication is also known as wet-sump lubrication. In addition to the direct supply of oil by the oil pump, the rotational motion of the crankshaft effects a fine conditioning of the oil mist in the crankcase.

The opposite system to conventional wet-sump lubrication is the more expensive dry-sump lubrication, because it requires a second oil pump to remove the oil from the engine compartment (Figure 12b). The advantages are a constantly guaranteed lube-oil supply under conditions of high lateral acceleration or inclination and freedom in deciding on where to locate the oil-supply system. These give rise to lower engine heights and a possible increase in the engine-oil quantity, which is beneficial to engine cooling.

The mixture and total-loss lubrication frequently used in 2-stroke and Wankel engines is no longer relevant to present-day automobile applications.

7 Second oil pump.

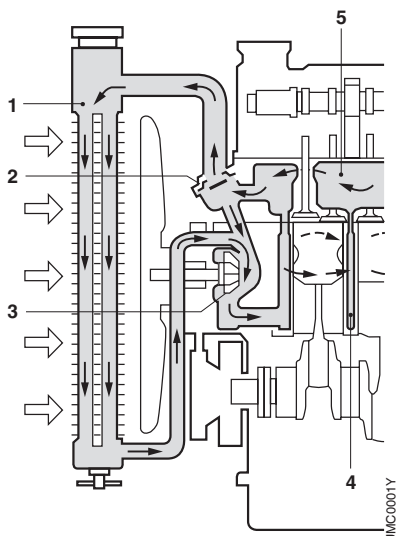
Cooling

In order to avoid thermal overload, combustion of the lubricating oil on the piston's sliding surface, and uncontrolled combustion due to excessive component temperatures, the components surrounding the hot combustion chamber (cylinder liner, cylinder head, valves and in some cases the pistons themselves) must be intensively cooled (see also "Engine cooling").

As water has a high specific heat capacity and provides efficient thermal transition between the materials, most contemporary vehicle engines are water-cooled. Moreover, it is possible, under very hot local boundary conditions when the cooling medium is locally evaporated, to achieve through the heat of evaporation an additional cooling effect which together with the condensation behavior in colder adjacent areas reduces unwanted high local temperature gradients.

Air/water recirculation cooling is the most prevalent system (Figure 13). It comprises a closed circuit allowing the use of anticorrosion and antifreeze additives. The coolant is pumped through the engine and through an air/water radiator. The cooling air flows through the radiator in response to vehicle movement and/or

is forced through it by a fan. The coolant temperature is regulated by a thermostatic valve which bypasses the radiator as required.



Air-cooled concepts still play a subordinate role today. Modern emission regulations call for effective engine cooling with simultaneously high specific power output. This can practically no longer be achieved with air cooling, a system which is indeed robust and low-maintenance, but is also not as effective. A crucial drawback of air-cooled concepts is their acoustic performance. The cooling fins act like a resonator and therefore result in a marked increase in sound emissions.

Crankshaft vibration damper

The crankshaft is subjected to high-frequency vibrations (2nd-order torsional vibrations), particularly in the region of resonant frequencies. Vibration dampers are therefore used to moderate dangerous crankshaft resonance phenomena.

Figure 13: Water cooling system with coolant circuit

1 Radiator,
2 Thermostat,
3 Water pump,
4 Water passages in cylinder block,
5 Coolant passages in cylinder head.

The choice of vibration-damper design ranges from simple flywheel masses, which through elastically damping layers – e.g. rubber – provide a countervibration system, through more sophisticated oil-damped flywheel masses, in which the viscosity of the oil and friction surfaces provide the damping effect, up to complex pendulum adsorbers. The vibration damper is generally mounted at the free crankshaft end (front).

1st-order torsional vibrations, i.e. vibrations resulting from ignition and inertial forces, which can result in excitation of transmission and input-shaft vibrations, are reduced by dual-mass flywheels or other damping technologies. Phenomena such as clutch grabbing, transmission chatter and starting jerks can be optimized by such vibration absorbers, since all the following components – clutch, transmission and input shafts – likewise represent an oscillatory system. In a dual-mass flywheel the two flywheel masses are coupled to each other by means of springs. Torsional-vibration dampers are also commonly featured in clutches – both components must naturally be tuned together.

Design and tuning are difficult to simulate and must in the final analysis be conducted in tests, both in the vehicle with the entire drivetrain (1st order: low-frequency drivetrain resonance phenomena) and on the test bench (2nd order: high-frequency crankshaft resonances).

Reciprocating-piston engine types

The internal-combustion engine is characterized by its great variability and application-specific adaptability. In particular, the arrangement of the individual cylinders provides for numerous variants.

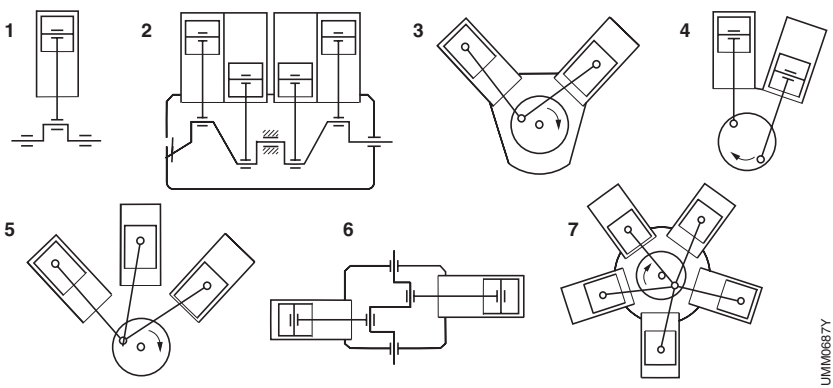
Arrangements

In principle, a huge number of possible cylinder arrangements is conceivable. Few of these arrangements have proven to be particularly effective for automotive applications (Figure 14).

Radial engines are not suitable for automotive applications on account of their height and are therefore not used.

It is important to note the difference between the opposed-cylinder (boxer) engine and the V-engine with 180° included angle between cylinder banks. In the boxer engine the pistons always move in opposite directions, which is why the inertial forces cancel each other out. In the V-engine, on the other hand, the pistons of two opposed cylinders always move in the same direction.

It is also important to note the design of V- and W-engines, in which the connecting-rod/crankshaft link (large connecting-rod eye) of associated cylinders is effected at slightly offset crank pins.



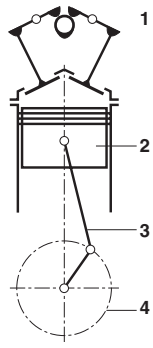
In multi-piston units compression is typically generated by several working pistons. In the U-engine the pistons undertake an approximately parallel motion. In the opposed-piston engine the pistons undertake a typically opposed motion. Engine variants with more than one piston per combustion chamber have not gained acceptance. Weight and engine size are not suitable for automotive applications.

Definitions

The following definitions in accordance with DIN 73021 [2] as viewed looking at the end opposite the power-output end apply only to motor-vehicle engines. For internal-combustion engines for general and marine use, the reverse direction – i.e. as viewed looking at the power-output end – is standardized (ISO 1204 [3]).

Figure 14: Reciprocating-piston engine types

1 Single cylinder (individual cylinder),
2 In-line engine (arrangement of individual cylinders in line),
3 V-engine (arrangement of individual cylinders in two banks in a V-shape),
4 VR-engine (arrangement of individual cylinders in two banks in a V-shape, where the two banks are particularly close to one another),
5 W-engine (arrangement of individual cylinders in three banks in a W-shape),
6 Opposed-cylinder (boxer) engine (arrangement of individual banks opposing one another),
7 Radial engine (radial arrangement in one or more planes).



Clockwise rotation
The direction of rotation is clockwise, as viewed looking at the end opposite the power-output end.

Counterclockwise rotation
The direction of rotation is counterclockwise, as viewed looking at the end opposite the power-output end.

Numbering the cylinders
The cylinders are numbered consecutively 1, 2, 3, etc. in the order in which they would be intersected by an imaginary reference plane, as viewed looking at the end of the engine opposite the power-output end. This plane is located horizontally to the left when numbering begins; the numerical assignments then proceed clockwise about the longitudinal axis of the engine. If there is more than one cylinder in a reference plane, the cylinder nearest the observer is assigned the number 1, with consecutive numbers being assigned to the following cylinders. Cylinder 1 is to be identified by the number 1.

Firing sequence
The firing sequence is the sequence in which combustion is initiated in the cylinders. Engine design configuration, uniformity in ignition intervals, ease of crankshaft manufacture, optimal crankshaft load patterns, etc. all play a role in defining the firing sequence.

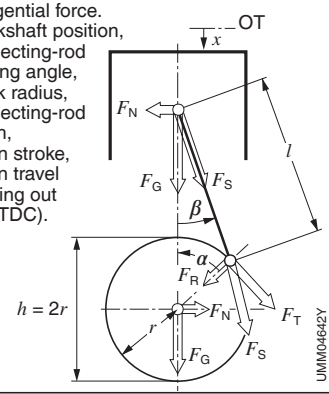
Crankshaft-assembly design

Crankshaft-drive kinematics
The kinematics of the single-cylinder crankshaft assembly can be determined from the geometrical assignments of piston and piston-pin axis, connecting rod and crankshaft (crankshaft radius equal to one half stroke) (Figure 15). If piston travel x at top dead center is assumed to be zero, the following is obtained with crank radius r and connecting-rod length l (Figure 16):



$$x = r\,(1 - \cos\alpha) + l\,(1 - \cos\beta)\ .$$

Where
$r \sin\alpha = l \sin\beta$
and
$\lambda = r/l$
the following is obtained:

$$x = r\left(1 - \cos\alpha + \frac{1}{\lambda}\left(1 - \sqrt{1 - \lambda^2 \sin^2\alpha}\right)\right)$$

An offset of the piston pin is performed by some manufacturers. Noise and friction advantages can be expected on account of the changing piston location and depending on the position of the connecting rod. The offset can be effected either in the piston by shifting the piston pin from the center position or by offsetting the crankshaft.

Figure 16: Gas-force components shown on a basic crankshaft drive
F_G Piston-pin force (gas force),
F_S Connecting-rod force, F_R Radial force,
F_N Piston normal force,
F_T Tangential force.
α Crankshaft position,
β Connecting-rod pivoting angle,
r Crank radius,
l Connecting-rod length,
h Piston stroke,
x Piston travel (starting out from TDC).

If the offset for positive crank angles is assumed to be positive and the quantity

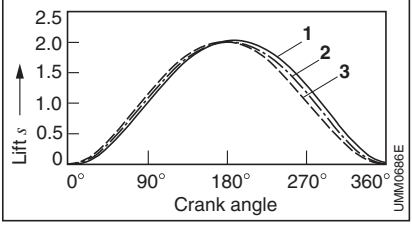
$$\delta = \frac{\text{Offset}}{\text{Connecting-rod length}}$$

is introduced, this leads to the following function of the piston travel:

$$x = r\left(1 - \cos\alpha + \frac{1}{\lambda}\left(1 - \sqrt{1 - (\lambda \sin\alpha - \delta)^2}\right)\right)$$

Figure 17 shows by way of example the influence of the stroke/connecting-rod ratio and the offset. However, the differences with normal offset values in the millimeter range ($\delta < 0.04$) are clearly smaller.

By developing the root function into a Taylor series (around $x = 0$: Maclaurin series) and replacing the powers of the trigonometric functions with the multi-harmonic functions, the following expression can be obtained [4]:



$$x = r\,[1 + \tfrac{1}{4}\lambda + \tfrac{3}{64}\lambda^3 + \ldots - \cos\alpha - (\tfrac{1}{4}\lambda + \tfrac{3}{64}\lambda^3 + \ldots)\cos 2\alpha + (\tfrac{3}{64}\lambda^3 + \ldots)\cos 4\alpha + \ldots]\,.$$

This expression shows that there are higher harmonics on account of the crankshaft-drive kinematics, and these are also called engine orders (multiples of the engine speed).

Because normal values for λ are around 0.3, the higher-level λ terms are readily ignored and the following simplified function is assumed for further calculations:

$$x = r\,[1 + \tfrac{1}{4}\lambda - \cos\alpha - \tfrac{1}{4}\lambda\cos 2\alpha\,]\,.$$

Figure 17: Piston-travel function
1 $\lambda = \infty$,
2 $\lambda = 0.3$,
3 $\lambda = 0.3$, $\delta = 0.1$.

This simplification may not be used if detailed vibration analyses and resonance phenomena are to be examined.

From the simplified equation the following piston speeds v and accelerations a are obtained, where the angular velocity $d\alpha/dt = \omega = 2\pi n$ (n speed) was introduced:

$$v = r\omega\,(\sin\alpha + \frac{\lambda}{2}\sin 2\alpha)\,,$$

$$a = r\omega^2\,(\cos\alpha + \lambda\cos 2\alpha)\,.$$

Here too there are higher harmonics (orders), which must not be disregarded when resonances are examined.

Crankshaft-assembly kinetics

The forces acting on the crankshaft assembly and the resulting moments can initially be derived without inertial forces as follows (Figure 16).

The piston-pin force results as gas force from the combustion-chamber pressure and the piston area. The following applies:

$$F_G = (p - p_{KGH})\,A_{piston}\,.$$

The connecting-rod force is obtained from the vectorial analysis of the piston-pin force in the direction of the connecting rod. The following applies:

$$F_S = \frac{F_G}{\cos\beta} = \frac{F_G}{\sqrt{1 - \lambda^2\sin^2\alpha}}$$

The piston normal force F_N is the vectorial component of the piston-pin force normal to the cylinder wall and for balancing the connecting-rod force:

$$F_N = F_G \tan\beta = \frac{F_G\,\lambda\,\sin\alpha}{\sqrt{1 - \lambda^2\sin^2\alpha}}\,.$$

This force contributes significantly to the friction of the piston on the cylinder barrel. The side which is touched by the piston after top dead center on account of the combustion pressure is termed the major thrust face, the opposite side the minor thrust face. The greatest friction is therefore created shortly after TDC on the major thrust face.

The tangential force at the crankshaft crank pin contributes to an acceleration of the crankshaft and thus to the build-up of torque at the crankshaft. It is created from the vectorial analysis of the connecting-rod force.

$$F_T = \frac{F_G \sin(\alpha+\beta)}{\cos\beta} = F_G\left(\sin\alpha + \frac{\lambda}{2}\sin 2\alpha/\sqrt{1-\lambda^2\sin^2\alpha}\right).$$

Here too the radicand can be simplified in a series expansion as

$$F_T \approx F_G\,(\sin\alpha + \frac{\lambda}{2}\sin 2\alpha).$$

The radial force F_R at the crankshaft crank pin is:

$$F_R = F_G\frac{\cos(\alpha+\beta)}{\cos\beta} = F_G\left(\cos\alpha + \lambda\frac{\sin^2\alpha}{\sqrt{1-\lambda^2\sin^2\alpha}}\right)$$

or approximately

$$F_R \approx F_G\,(\cos\alpha - \frac{\lambda}{2} + \frac{\lambda}{2}\cos 2\alpha).$$

The inertial forces can be split into oscillating and rotating components. The piston, piston-ring and piston-pin weights m_K belong to the oscillating component and can be punctually assigned to the piston pin.

The crankshaft web with crank pin belong to the rotating component. Here the mass is usually reduced to the crank radius and punctually assigned to the crank-pin center point. The following applies:

$$m_W = \Sigma\,\frac{m_i\,r_{si}}{r},$$

where m_i is the respective mass component of web, pin, etc. and r_{si} is the corresponding center-of-mass radius.

Because of the connecting rod's swinging motion, it is useful to split the connecting-rod mass into an oscillating component and a rotating component. This is done exactly where the connecting-rod-mass center of gravity and mass moment of inertia are known by assuming two dynamically equal individual masses at the small and big connecting-rod eyes and by calculating the equilibrium formulation of force, moment and mass inertia. Usually one third of the connecting-rod mass m_{Pl} can be assumed to be oscillating and two thirds to be rotating. Then, with $m_o = m_K + 1/3\ m_{Pl}$ as the oscillating mass and the piston acceleration (see below), an oscillating inertial force is obtained at:

$$F_o \approx m_o\,r\,\omega^2\,(\cos\alpha + \lambda\cos 2\alpha).$$

The oscillating inertial force therefore increases quadratically with the engine speed ($\omega = 2\pi n$) and has a first-order component and a lower second-order component.

The rotating inertial force is obtained as centrifugal force from the reduced mass $m_r = m_W + 2/3\ m_{Pl}$ and the rotation speed at:

$$F_r = m_r\,r\,\omega^2.$$

The rotating inertial force likewise increases with the square of the speed, but has not higher orders. The rotating inertial force can therefore be easily balanced by counterweights which rotate at engine speed. The rotational irregularities of the crankshaft are so small compared with these forces that they can be ignored in the balancing of masses.

As shown in the crankshaft-assembly kinematics, higher harmonics – higher engine orders – occur on account of the crankshaft-drive geometry. Aside from the 1st and 2nd engine orders, however, the amount of the 4th order and the higher components decreases rapidly, and is generally ignored for a balancing of masses.

Balancing of masses in a single-cylinder engine

The component of rotating masses in a single-cylinder engine can be fully balanced by appropriate counterweights on the crank pin. Weights are normally provided for on both sides and the weights must be balanced merely with the center-of-mass radius. The oscillating forces can be represented with force vectors (Figure 18) when they are modeled rotating in the opposite direction in each case with half the amount.

Therefore two contra-rotating shafts with weights can be used to balance the oscillating inertial forces. The horizontal component then cancels out and at least the first order of the oscillating inertial-force component can be compensated.

A virtually full balancing of masses requires further balancer shafts, which must rotate at twice the engine speed in order to balance completely the second-order component of the oscillating mass component.

A compromise is often reached due to the fact that the expenditure associated with contra-rotating shafts is high and at least with the first order already not inconsiderable weights would have to be realized in the shafts. For example, half the oscillating mass can be integrated in the counterweights. The free inertial forces acting outwards are now reduced in the cylinder longitudinal direction by one half; however, additional transverse forces are now created on account of the excessive rotating components (see Table 2). A half compensation of this kind is termed a 50 % balancing rate. Usual figures are 100 % rotatory and 50 % oscillatory balancing of masses.

Balancing of masses in a multiple-cylinder engine

The inertial forces of a multiple-cylinder engine are composed of the inertial forces of each individual cylinder which are superimposed according to the crankshaft throw. In addition, free moments of inertia are created on account of the cylinder spacing. Table 3 shows a summary of the possible transverse and longitudi-

Figure 18: Complete balancing of 1st- and 2nd-order masses in a single-cylinder assembly

nal tilting moments that occur and the free inertial forces.

The mutual balancing of the inertial forces is one of the essential factors determining the selection of the crankshaft's configuration, and with it the design of the engine itself. The inertial forces are balanced if the common center of gravity for all moving crankshaft-assembly components lies at the crankshaft's midpoint, i.e. if the crankshaft is symmetrical (as viewed from the front). This is represented with the 1st-order and 2nd-order star diagrams (Table 4).

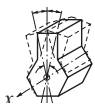
The 2nd-order star diagram for the four-cylinder in-line engine is asymmetrical, meaning that this order is characterized by free inertial forces. These forces can be balanced using two countershafts rotating in opposite directions at double the rate of the crankshaft (Lanchester system).

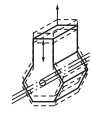
Table 5 shows a summary of free forces and moments based on balancing of masses for different numbers of cylinders and throw variants.

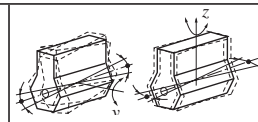
Torsional force

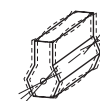
Moving masses are exposed to constantly changing acceleration, thereby generating inertial forces. The cyclically occurring pressure forces in the cylinders are termed gas forces. Both form in total internal and external forces and moments. The internal forces and moments must be

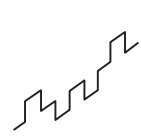
Table 3: Transverse and longitudinal tilting moments, free inertial forces in multiple-cylinder engines

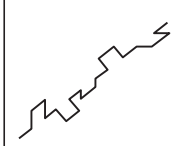


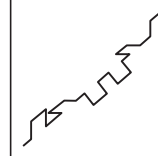


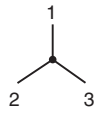


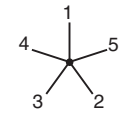


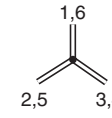


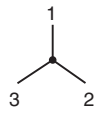


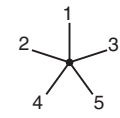


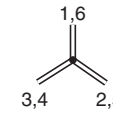












Forces and moments at the engine				 UMM0469Y

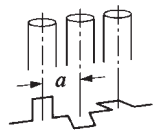
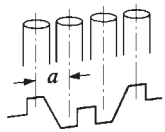
absorbed by the components, especially the crankshaft and crankcase, while the external effects act via the engine bearings on the support structure and impart oscillations to the chassis or engine foundation.

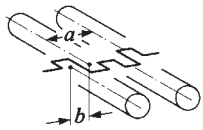
If the periodic gas force acting on the piston and the periodic mass inertial forces acting on the piston, connecting rod and crankshaft assembly are grouped together, they generate a sum of tangential force components at the crankshaft journal. When multiplied by the crank radius, this produces a periodically variable torque value.

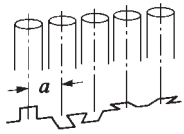
With multiple-cylinder engines, the tangential-pressure curves for the individual cylinders are superimposed with a phase shift dependent on the number of cylinders, crankshaft-journal configuration, crankshaft design, and the firing sequence. The resulting composite curve is characteristic for the engine design, and covers a full working cycle (i.e. two crankshaft rotations for 4-stroke engines, Figure 18). It can be depicted in a torsional-force diagram. This variable torsional force and the resulting torque generate, depending on the available moment of inertia J, a variable rotation speed ω:

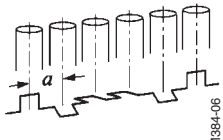
$$\frac{d\omega}{dt} = \frac{M(t)}{J}$$











with all the superimposed and newly created engine orders (there are also half orders). This deviation from the speed constant is called the coefficient of cyclic variation and is defined as follows:

$$\delta_S = \frac{\omega_{max} - \omega_{min}}{\omega_{min}}.$$

This coefficient of cyclic variation is reduced to a level suitable for the application by energy-storage mechanisms, such as a flywheel mass for example. The torsional vibrations which can be traced back to the torsional force depicted are also called 1st-order torsional vibrations. These are not to be confused with the (high-frequency) torsional vibrations resulting from elastic deformations and natural resonances of the crankshaft (Table 5), which are referred to as 2nd order.

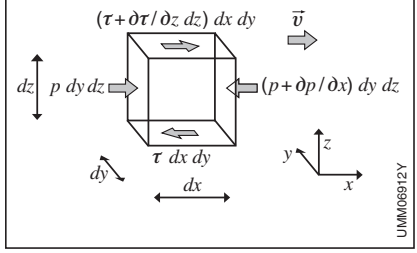
Tribology and friction

The piston with piston rings and bearing surface is a self-contained and highly complex tribological system. This also applies to the piston pin and the crankshaft friction bearings. Detailed simulation formulations are necessary in view of the periodically changing application of force both in terms of amount and direction.



To be able to ensure wear resistance, it is necessary to build up a hydrodynamic lubricating film which is higher than the surface roughness of the two contact surfaces (see also Stribeck curve). The oil film either is already present in the lubricating gap (friction bearing with compressed-oil supply) or must be built up dynamically as an oil wedge (cambered piston ring on liner). However, the oil wedge always collapses when the relative speed of the contact surfaces assumes a value of zero. This is the case for piston rings at the piston reversal points (top and bottom dead centers), and for the piston pin between these positions. It is therefore also important to ensure that a sufficient oil-retaining volume can be maintained in the contact surfaces in order to retain by forces of adhesion in the short time of standstill as much oil as to avoid seizing or minimize increased wear. In the tribological system for the piston this is bearing-surface honing, and for the piston pin shaping of the piston-pin bearing.

Traced back to Newton is the formulation to the effect that the friction between two adjacent oil elements is virtually independent of the prevailing pressure and only proportional to the change in speed from one element to the next.

$$\tau = \frac{\eta\, dv}{dz}.$$

$\tau = F/A$ Shear stress,
F Shear force,
A Contact surface,
v Speed,
z Coordinate direction normal to speed direction v.

Figure 19: Pressure forces in a one-dimensional stress state

Sometimes the kinematic viscosity v is also used; this corresponds to the dynamic viscosity referred to density and is defined by

$$v = \frac{\eta}{\rho}\ [\mathrm{m^2/s}].$$

The dynamic viscosity η [N s/m^2 or Pa · s] decreases sharply with temperature. It is important to see to it that the oil temperature ensures a viscosity η which facilitates sufficient shear stress to build up a supporting oil film. It is also necessary to provide for a sufficiently high relative speed v on the part of the contact surfaces. It can be recognized from the formula that hydrodynamic shear stress collapses when the speed assumes a value of zero (reversal point of the piston, pivoting-angle end of the small connecting-rod eye). If can further be recognized that the lubricating film Δy must not become too large, as otherwise the shear stress will become too small and the lubricating film will break.

The equilibrium of forces for the simplified case of a one-dimensional stress state in the x direction (Figure 19) shows that $\partial p/\partial x = \partial\tau/\partial z$ must apply and thus $\partial p/\partial x = \eta\, \partial^2 v/\partial z^2$. It is thus demonstrated on the one hand that the pressure loss of a flow is dependent on the viscosity and the speed. In addition, the speed profile can thus be derived.

On account of the adhesion condition which states that the speed of the oil on the wall is identical to the wall speed, a speed distribution (linear for laminar flow) and a pressure distribution build up in the lubricating gap (see Friction bearings).

It is attempted with the aid of (thermo-) elastohydrodynamic simulation (EHD, elastohydrodynamics) to determine the lubricating-film thickness by solving the mathematical equations in the multi-dimensional case for mass balance and momentum equilibrium.

– Mass balance: supplied oil mass and oil quantity escaping through the bearing gap in equilibrium.
– Momentum equilibrium: equilibrium of forces from direct stress (pressure force from oil pressure), shear stress (viscosity force from oil viscosity) including apparent viscosity stresses on account of turbulent flow and the inertial force (acceleration component).

The equation system is established as a Reynolds differential equation or a Navier-Stokes equation to solve the flow problem. By using a finite-element simulation, the bearing deformations are added and the highly complex equations (because they are simultaneous) are numerically solved.

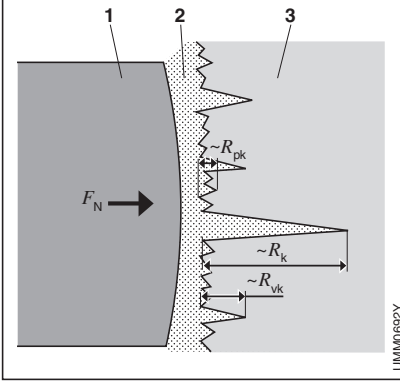
An adequate supply of oil must be guaranteed in the bearings, since generally the oil pressure in the bearings (> 100 bar) far exceeds the static oil pressure provided by the oil pump (< 10 bar). This is achieved by means of pressure-oil bores and special grooves in friction bearings or by means of initial forces at the piston rings.

Attempts have also been made in the meantime to simulate the case of mixed friction. The influence of surface fine geometry (consideration of roughness on microhydrodynamics by “flow tensors”) is taken into account in an extended Reynolds differential equation. By using contact-pressure models of rough surfaces, it is possible to determine, as well as the hydrodynamic contact-area ratios, the solid contact-area ratio and to take this into account accordingly. Intensive work is being conducted on models to determine the running-in behavior of contact surfaces. This will finally enable the wear behavior to be assessed.

Because the shear stresses and thus also the frictional forces are proportional to the speed, the share of friction of the piston assembly at the dead centers and that of the piston-pin bearing is small. Instead, the wear parameters are decisive here.

Sliding bearings

The bearings most commonly encountered in an internal-combustion engine are friction (sliding) bearings. Crankshaft main bearings, big-end bearings, piston-pin bearings, and camshaft bearings are generally oil-lubricated friction bearings (see Friction bearings).



It is important to ensure that the seating pressure is precisely configured in both split bearings (crankshaft, connecting rod) and non-split bearings (piston pin, camshaft) so as to prevent them from jamming and rotating also at higher temperatures or under emergency-lubrication conditions. However, material overloading must also be reliably prevented.

The lubricating gap of the crankshaft main bearings changes in response to the constantly varying bearing forces (see also Crankshaft-assembly design). This generates a kind of pumping effect and the oil in the bearing is constantly replaced.

The swinging motion of the connecting rod effects an increased relative speed when the piston travels up the cylinder and a reduced relative speed when the piston travels down the cylinder in the lubricating gap of the big-end bearing or crank pin. This alone causes oil to be pumped into the oil gap. Furthermore, naturally periodic forces acting on the bearing cause the connecting rod to change position constantly and thereby assist the build-up of lubricating-film pressure.

The small-end bearing is merely subject to a swinging motion. A supply of oil is therefore particularly important, but difficult to achieve. In practical terms, mixed friction cannot be avoided. If the arrangement involves a floating pin bearing (bearing in the piston and connecting rod), the pin performs a slight rotary motion in the

Figure 20: Roughness values and oil-film theory (roughness definitions, see DIN 4760 [5])
1 Piston, 2 Oil film, 3 Liner.

piston bearing of just a few degrees – here too a good supply of oil to the bearings must be ensured.

Oil is generally supplied as splash oil, and partly also via a specific locating bore or via a pressure-oil supply from the crankshaft through grooves in the crankshaft-journal bearing and a vertical bore in the connecting rod.

Rolling pairs
Ball, roller or needle bearings are used in 2-stroke engines or sometimes in camshafts (see Roller bearings).

A roller follower or the roller of an injection-pump plunger-and-barrel assembly is a special case in point. The system of rotating roller and moving cam is a rolling-element pair with linear contact. A characteristic load variable is the Stribeck rolling-contact pressure:

$$K = \frac{F}{D_l \, l_{eff}},$$

F Force load,
$\varphi = D_l/D$ Osculation coefficient,
D_l Substitute diameter,
D Roller diameter,
l_{eff} Effective roller width.

The effective substitute diameter D_l is obtained from the instantaneous bend radius of the cam R_{cam} and the roller radius R_{roller}:

$$D_l = 2 \, \frac{R_{cam} \, R_{roller}}{R_{cam} + R_{roller}}.$$

It takes into account the osculation of the two rolling bodies.

The Hertzian stress p_{Hertz} is also relevant:

$$p_{Hertz} = \sqrt{\frac{KE}{2.86}}.$$

with modulus of elasticity E:

$$E = 2 \, \frac{E_{cam} \, E_{roller}}{E_{cam} + E_{roller}}.$$

By slightly angling the roller in relation to the cam or by offsetting the stroke function, it is possible to ensure that an oil wedge can be built up and the roller rotates continuously. Pitting is a typical indicator of overloading in rolling pairs that are subject to high loads. It results from molecular deformations of the metal and possible embedding of oil, which gives rise to extremely high local pressures and plastic deformations or material erosion. Harder materials and decreasing the load reduce the tendency to pitting.

Piston ring and bearing surface
The piston rings together with the bearing surface constitute a complex tribological system. On the one hand, the pressure force of the piston ring is very much dependent on the cylinder pressure and thus on the crank angle and the power stroke. On the other hand, the piston rings make axial secondary movements in their grooves which also have a significant impact on the lubricating-film thickness.

The oil is generally applied as splash oil to the bearing surface (crankshaft churning or splash oil for piston cooling and pin lubrication) and allowed back through the oil control ring as a thin film. The oil-retaining volume of the liner is dependent on the honing. This includes the surface roughness (furrow depth) and the honing pattern (cross-furrow angle).

Honing the bearing surface serves two functions. Firstly, it is intended to ensure with the aid of honing furrows of sufficient depth that oil can be retained by adhesion forces for an adequate length of time (Figure 20). Secondly, surface roughness must be so low as to prevent contact with the piston ring. Various roughness

values are used to characterize honing; these values are standardized on a generic level in DIN 4760 [5] and in detail in DIN EN ISO 13565 [6]. For initial wear and initial friction the R_{pk} value ("reduced peak height", see DIN 4760 and DIN EN ISO 11562 [7] or DIN EN ISO 13565 for an explanation) is decisive – but the value is swiftly and drastically minimized after run-in (e.g. from a few micrometers to 0.2 to 0.8 µm). The R_{vk} value (1.0 to 3.5 µm) is the decisive parameter for the possible oil-retaining volume after run-in. It is to be noted that the honing usually takes the form of a cross-shaped furrow system. In this form, the furrows constitute a communicating system of oilways and the oil pressure is partly forced out of the gap, but this also permits a uniform distribution of the oil film over the surface. Flat honing angles (referring to the angle formed by the cross-shaped furrows) reduce the amount of oil forced out, but there is a tendency to seizing on account of the unsatisfactory axial oil distribution. Steep honing angles result in increased oil consumption. Honing angles between 30° and 90° are customary.

Mixed friction occurs at any rate at the piston reversal points. The least that is required in this area is micro-pockets of oil, which can be produced for example by laser honing or by bringing out amounts of alloy during the honing procedure.

Usually, such high temperatures are generated during the combustion stroke of a piston engine that much of the bearing-surface oil vaporizes or in diesel engines even burns off. This vaporized oil constitutes the majority of the oil consumption by modern-day internal-combustion engines.

The special shape of the piston rings is designed to facilitate the build-up of an oil wedge. A critical factor is, on the one hand, the piston speed, which must not be allowed to become too high, as otherwise the shear forces can no longer be absorbed by the oil and the oil film will break. On the other hand, the reversal points, particularly at top dead center, must be classed as critical with regard to wear.

Empirical values and data for calculation

Characteristics

Fuel consumption

Figure 1 shows in a diagram nine different specific consumptions plotted against the effective mean pressure p_{me}. Since p_{me} has a proportional effect on the equation of energy ($E_E = i\,p_{me}\,V_H$; $i = 1$ for two-stroke engines, i = 0.5 for four-stroke engines), the absolute consumption rises with increasing p_{me}. This situation is illustrated for example by straight line 1.

The specific consumptions rise from straight lines 1 through 9. In other words, for the first process 200 g of fuel are needed to obtain 1 kWh of energy. For 9, 500 g of fuel already are expended for 1 kWh.

The y-axis is normalized to the working cycle and the displacement (swept volume). In other words, the energy E_E is directly dependent on p_{me}. When p_{me} increases, so too the energy increases. More fuel is needed when the energy increases. If a certain p_{me} is taken – e.g. 15 bar, which corresponds to a defined energy – significantly more fuel is required for straight line 5 than for straight line 1 (roughly 120 mg as against 80 mg) to generate the same amount of mechanical energy. This is also discernible from the gradient of the straight line.

Characteristic values of gasoline and diesel engines

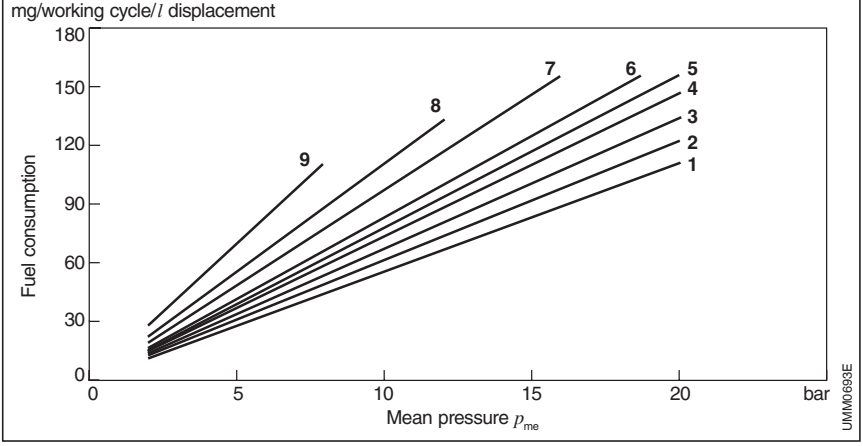


Table 1 shows characteristic values in a comparison of gasoline and diesel engines. What is noticeable at the outset is the large differences in rpm between gasoline and diesel engines. The compression ratios too are – by the nature of the process – much higher for diesel engines than for gasoline engines. Due to the higher compression pressure, greater mean pressures p_{me} are possible. Since diesel engines attain lower speeds (rpm), they have a lower power output per liter (power output per displacement). Due to the lower power output per liter and the resulting higher weight for durability reasons, diesel engines have the higher weight-to-power ratio (vehicle mass per power output). Due to the lower compression ratio, gasoline engines have an unfavorable specific consumption.

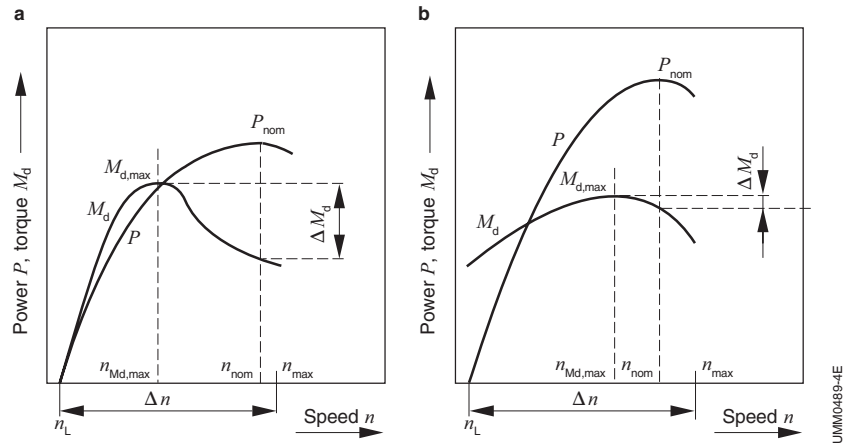
Torque position

The torque position denotes the position on the engine-speed curve (Figure 1) at which maximum torque ($n_{Md,max}$) is developed, relative to the rated-power speed

Figure 1: Fuel consumption

1 200 g/kWh, 2 220 g/kWh, 3 240 g/kWh,
4 260 g/kWh 5 280 g/kWh, 6 300 g/kWh,
7 350 g/kWh, 8 400 g/kWh, 9 500 g/kWh.

(n_{nom}) in percent ($n_{Md,max}/n_{nom}$). For typical values, see Table 2.



Useful speed range
The useful speed range Δn shows the range in which an engine is operated. For example, a gasoline engine with a maximum speed n_{max} of 7000 rpm and an idle speed of 800 rpm has a useful speed range of 6200 rpm. The figures for useful speed range in Table 2 are given in rpm x 1000.

b) Gasoline engine (naturally aspirated engine).
n_L Idle speed, $n_{Md,max}$ Engine speed at $M_{d,max}$, n_{nom} Nominal speed, n_{max} Maximum engine speed, Δn Useful speed range, P_{nom} Rated power, $M_{d,max}$ Maximum torque.

Torque rise
The torque rise ΔM_d denotes the difference between the maximum torque $M_{d,max}$ and the torque at the rated-power point. The values in Table 3 are given in percent.

Torque increase
The torque increase is the gradient of the torque curve between maximum torque and the torque at rated power.

Engine output and atmospheric conditions
The torque and thus the power output of an internal-combustion engine are essentially determined by the heat content of the cylinder charge. The flow rate of air (or, more precisely, of oxygen) in the cylinder charge provides a direct indication of heat content. The change which the engine will display at full power can be calculated as a function of variations in the condition of the ambient air (temperature, barometric pressure, humidity), provided that engine speed, air/fuel (A/F) ratio, volumetric efficiency, combustion efficiency, and total engine power loss remain constant. The A/F mixture responds to lower atmospheric density by becoming richer. The volumetric efficiency (ratio of pressure in cylinder at BDC to pressure in ambient air) only remains constant for all atmospheric conditions at maximum throttle-valve aperture (WOT). Combustion efficiency drops in cold thin air as vaporization rate, turbulence, and combustion speed all fall. Engine power loss (friction losses + gas-exchange work + boost power drain) reduces the indicated power.

Table 2: Typical values for useful speed range and torque position

Engine type		Useful speed range Δn_N (×1000 rpm)	Torque position [%]
Diesel engine	Pass. cars	3.5…5	15…40
	Comm. veh.	1.8…3.2	10…60
Gasoline engine		4…7	25…35

Table 3: Typical values for torque rise

Engine type		Torque rise ΔM_d [%]
Diesel engine, pass. cars	SCE and IC	25…35
Diesel engine Comm. veh.	SCE and IC	25…40
Gasoline engine	Nat. asp. engine	25…30
	SCE and IC	30…35
SCE Supercharged engine; IC Intercooling (charge-air cooling)		

Effect of atmospheric conditions
The quantity of air which an engine draws in, or is inputted to the engine by supercharging, depends upon ambient-air density; colder, heavier, denser air increases engine output. As a rule of thumb: Engine power drops by approximately 1 % for each 100 m rise in elevation. Depending upon engine design, the cold intake air is normally heated to some degree while traversing the intake passages, thereby reducing its density and thus the engine's ultimate output. Humid air contains less oxygen than dry air and therefore produces lower engine power outputs. The decrease is generally modest to the point of insignificance. The warm humidity of air in tropical regions can however result in a noticeable engine power loss.

Definitions of power
The effective power is the engine's power as measured at the crankshaft or ancillary mechanism (such as the transmission) at the specified engine speed. When measurements are made downstream from the transmission, the transmission losses must be factored into the equation.

The rated power is the maximum effective power of the engine at full throttle. The net power corresponds to the effective power.

Conversion formulas are used to convert the results of dynamometer testing to reflect standard conditions, thereby negating the influences of such factors as time of day and year while simultaneously allowing the various manufacturers to provide mutually comparable data. The procedure converts air density – and thus the effective volume of air in the engine – to defined "standard conditions" for air mass.

Table 4: Power-output correction factors

Gasoline engines, naturally aspirated and supercharged		
	EEC 80/1269 [9], JIS D 1001 [10], SAE J 1349 [11]	DIN 70020 [12]
Correction factor α_a	$\alpha_a = A^{1.2} \cdot B^{0.5}$ $A = 99/p_{PT}$ $B = T_p/298$	$\alpha_a = A \cdot B^{0.5}$ $A = 101.3/p_{PF}$ $B = T/293$
Corrected power: $P_0 = \alpha_a P$ (kW) (P measured power)		
Diesel engines		
Atmospheric engine correction factor f_a	$f_a = A^{0.7} \cdot B^{1.5}$ ($A = 99/p_{PT}$; $B = T_p/298$) (turbocharged engines with/without intercooling)	As α_a for gasoline engines
Engine correction factor f_m	$40 \le q/r \le 65$: $f_m = 0.036\,(q/r) - 1.14$ $q/r < 40$: $f_m = 0.3$ $q/r > 65$: $f_m = 1.2$	$f_m = 1$
$r = p_L/p_E$ Charge-air pressure response, with p_L absolute charge-air pressure, p_E Absolute pressure upstr. of compressor, q Spec. fuel consumption (SAE J 1349, [8]), p_{PT} Barometer pressure dry, p_{PF} Barometer pressure absolute, T_P Test-dynamometer temperature. 4-stroke engines: $q = 120{,}000\ F/DN$; 2-stroke engines: $q = 60{,}000\ F/DN$, with F Fuel flow [mg/s], D Displacement [l]; N Engine speed [rpm].		
Corrected power: $P_0 = P f_a^{f_m}$ (kW) (P measured power)		

The comparison data in Table 4 show the most important factors for these power-output corrections.

Displacement
The displacement – also referred to as the swept volume – is characterized by the total vertical stroke of the piston multiplied by the cylinder diameter. The displacement of an individual cylinder is characterized as V_h. The displacement V_H of an engine corresponds to the sum total of all the displacements V_h of its cylinders.

Compression volume
The compression volume V_c corresponds to the compression space in the cylinder when the piston is at TDC.

Combustion chamber
The combustion chamber is obtained from the sum total of displacement and compression volume.

Compression ratio
The compression ratio describes the ratio of the combustion-chamber volume when the piston is at BDC to the volume when the piston is at TDC.

Piston stroke
The piston stroke is a function of the crank angle. It is not uniform over one revolution and varies. Thus, the piston moves from TDC towards BCD up to 90° CA after TDC much faster downwards than from 90° to BDC. The mean piston speed is the average speed of the piston stroke over one complete revolution.

Efficiency
The efficiency describes the ratio of the mechanically supplied power to the energy supplied chemically by the fuel.

Calculations
Table 6 shows calculation formulas for some quantities in the engine. The quantity equations are universally valid, the numerical values in the given unit are inserted in the numerical-value equations. These equations tend to be applied in practice.

The frequently used quantities and their units are set out in Table 5.

Table 5: Quantities and units

Quantity		Unit
a_K	Piston acceleration	m/s²
B	Fuel consumption	kg/h; dm³/h
b_e	Spec. fuel consumption	g/kWh
d	Cylinder diameter	mm
d_v	Valve diameter	mm
F	Force	N
F_G	Gas force in the cylinder	N
F_N	Piston side thrust	N
F_o	Oscillating inertial force	N
F_r	Rotating inertial force	N
F_s	Connecting-rod force	N
F_T	Tangential force	N
M	Torque	Nm
M_o	Oscillating moments	Nm
M_r	Rotating moments	Nm
M_d	Engine torque	Nm
m_p	Weight-to-power ratio	kg/kW
n	Engine speed	rpm
n_p	Fuel-injection pump speed	rpm
P	Power	kW
P_{eff}	Effective power	kW
P_H	Power output per liter	kW/dm³
p	Pressure	bar
p_c	Final compression pressure	bar
p_e	Mean piston pressure (mean pressure, mean working pressure)	bar
p_L	Charge-air pressure	bar
p_{max}	Peak injection pressure in the cylinder	bar
r	Crankshaft radius	mm
s_d	Injection cross-section of the nozzle	mm²
S, s	Stroke, general	mm
s	Piston stroke	mm
s_f	Induction stroke of a cylinder (2-stroke)	mm
s_F	Induction stroke, 2-stroke engine	mm
S_k	Piston clearance from TDC	mm
S_s	Slot height, 2-stroke engine	mm
T	Temperature	°C, K
T_c	Final compression temperature	K
T_L	Charge-air temperature	K
T_{max}	Peak temperature in combustion chamber	K
t	Time	s
V	Volume	m³
V_c	Compression volume of a cylinder	dm³
V_E	Injected fuel quantity per pump stroke	mm³
V_f	Charge volume of a cylinder (2-stroke)	dm³
V_F	Charge volume of a 2-stroke engine	dm³
V_h	Displacement of a cylinder	dm³
V_H	Displacement of the engine	dm³
v	Velocity	m/s
v_d	Mean velocity of injection spray	m/s
v_g	Gas velocity	m/s
v_m	Mean piston speed	m/s
v_{max}	Max. piston speed	m/s

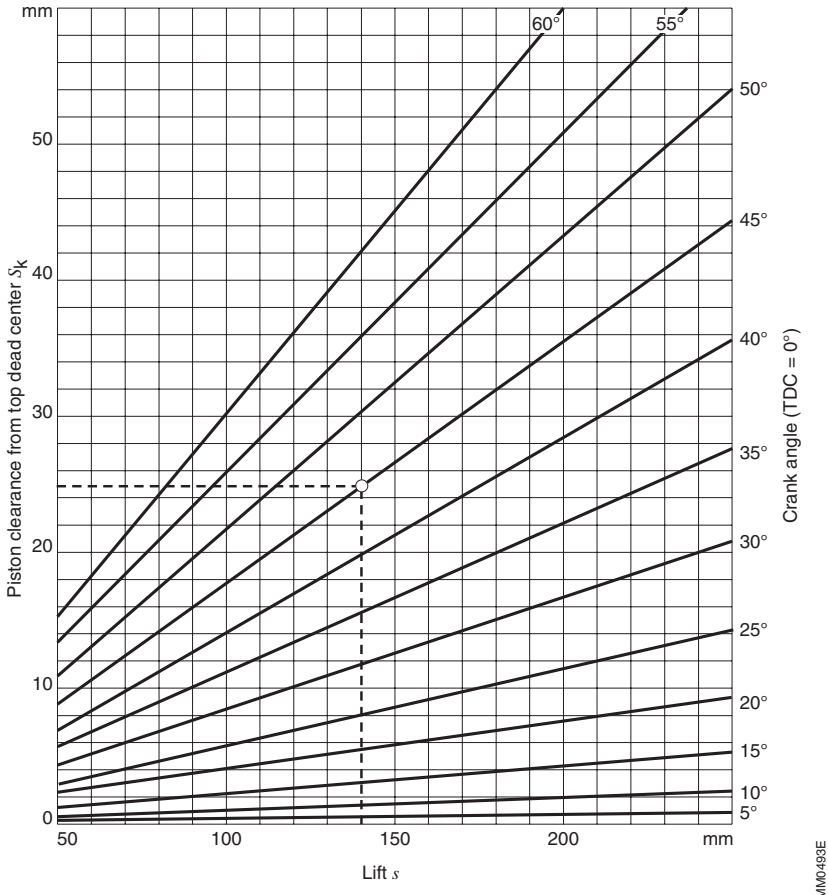

Figure 3: Displacement and compression space
The diagram applies to the displacement V_h and the compression space V_c of the individual cylinder and to the total displacement V_H and the total compression space V_C.

Displacement and compression space
In Figure 3 the displacement is plotted on the x-axis and the compression space is plotted on the y-axis. The straight lines show lines with a constant compression ratio. As the displacement increases, so too the compression space increases. If the compression ratio is raised, the compression space must become smaller for the same displacement.

An engine with a displacement of 1.2 dm³ and a compression ratio ε = 9 has a compression space of approximately 0.15 dm³.

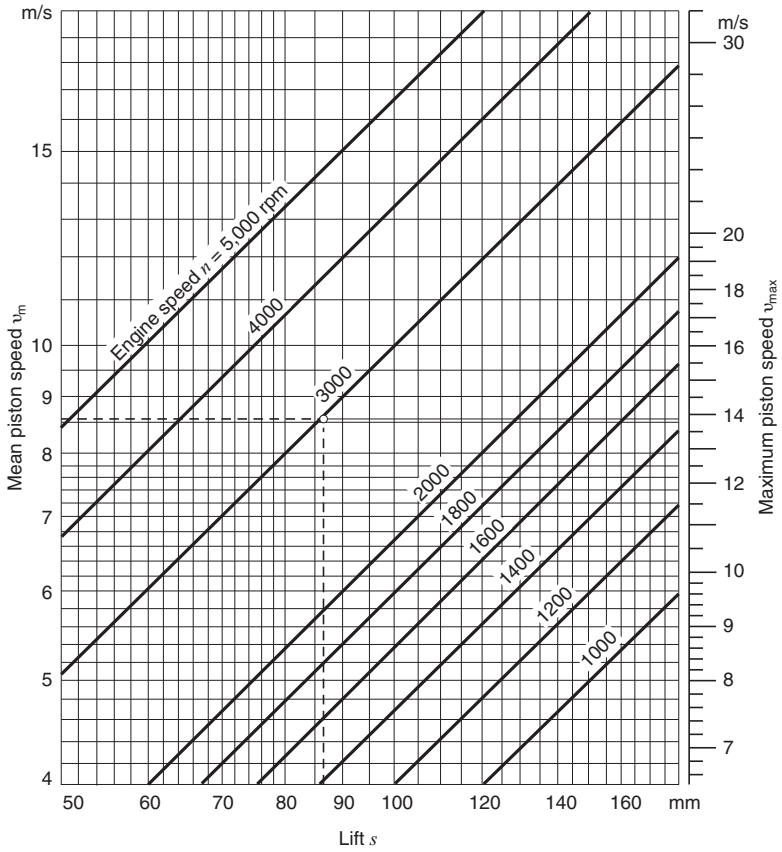

Figure 4: Piston clearance from top dead center
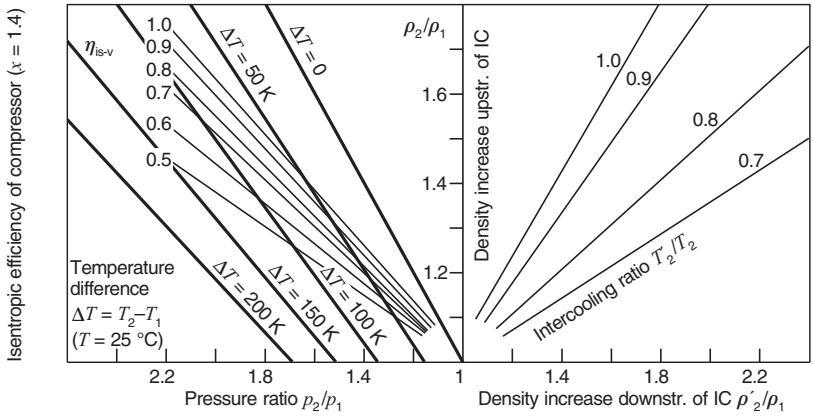
Conversion of degrees of crankshaft angle to mm piston travel.

Determining the piston clearance
Example
For a stroke of 140 mm the piston clearance from top dead center at 45 °CA is 25 mm (Figure 4).

The diagram is based on a crank ratio $l/r = 4$ (l connecting-rod length, r on half of the stroke length). However, it applies with good approximation (error less than 2 %) to all crank ratios l/r between 3.5 and 4.5.

Figure 5: Piston speed



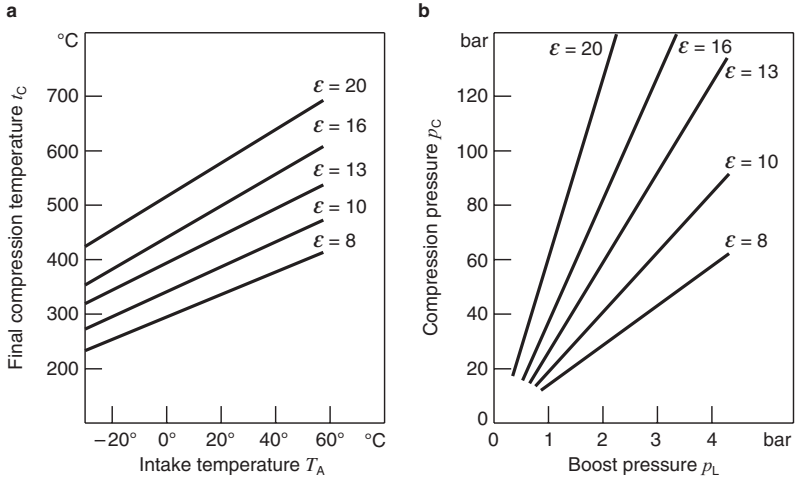
Determining the piston speed
The x-axis in Figure 5 shows the stroke in millimeters. The left y-axis shows the mean and the right y-axis the maximum piston speed. In addition, lines of constant speed are marked. It can clearly be seen that both piston speeds increase as the stroke increases. The same applies to increasing speeds.

Example
For the stroke s = 86 mm and at an engine speed of n = 3000 rpm the mean piston speed v_m = 8.7 m/s and the maximum piston speed
v_{max} = 13.8 m/s.

The diagram is based on $v_{max} = 1.62\, v_m$.

Figure 6: Density increase of combustion air in cylinder on turbo/supercharging

Increase in density on supercharging as a function of the pressure ratio in the compressor, of the compressor efficiency, and of the intercooling rate for intercooling (IC).



$p_2/p_1 = \pi_c$ = Pressure ratio during precompression,
ρ_2/ρ_1 = Increase in density, ρ_1 = Density upstream of compressor, ρ_2 = Density downstream of compressor in kg/m³,
T_2'/T_2 = Intercooling rate, T_2 = Temperature before IC, T_2' = Temperature after IC in K,
η_{is-v} = Isentropic compressor efficiency.

UMM0495-3E

Figure 7: Final compression pressure and final compression temperature

a) Final compression temperature as a function of compression ratio and intake temperature,
b) Final compression pressure as a function of compression ratio and charge-air pressure.

$t_c = T_c - 273{,}15$ K, $T_c = T_A\, \varepsilon^{n-1}$, n = 1,35

$p_c = p_L\, \varepsilon^n$, n = 1.35

UMM0496E

Determining the density increase of the combustion air

Figure 6 shows that as the pressure ratio increases, depending on how strongly the air is heated and cooled in the intercooler, the density of the gas increases. The hotter the gas after the intercooler, the smaller the density increase.

Determining the final compression pressure

Figure 7a shows on the x-axis the intake temperature and on the y-axis the final compression temperature. In addition, lines of a constant compression ratio are marked. It can be seen that the final compression temperature increases as the intake temperature increases. The same applies to increasing compression ratios, where here the straight-line gradient increases with a higher compression ratio. This graphic shows why lowering the compression ratio can reduce the knock tendency.

Figure 7b shows the final compression pressure as a function of compression ratio and charge-air pressure. If both increase, the final compression pressure also increases. However, a significant effect on the final compression pressure can be seen by increasing the compression ratio.

Exhaust-gas emissions

Historic measures

Endeavors at controlling air pollution are an absolutely integral element of environmental protection. It successes since the mid-20th century are thanks in particular to the economic analysis of the generation of pollutants and the derived further development of the combustion process, the consistent improvement of fuel quality, and the technical development of exhaust-gas treatment.

Smog and acid rain are still today common catchwords that have their origin in the second half of the 20th century. On region hugely affected by smog in that period was the US state of California. In order to reduce air pollution in areas of high population density such as Los Angeles, California had already enacted the first laws in the early 1960s (see [1]). Other states followed California's example. In 1970 the European Community for its part passed its first emission regulations. These legislative measures induced automobile manufacturers to fit their motor vehicles with exhaust-gas treatment systems in the markets affected. This has resulted in today's global market for exhaust-gas treatment systems.

Constituents of engine exhaust gas

Major constituents

Various combustion products are produced in internal-combustion engines during the combustion of fuel. Exhaust gas comprises primarily the non-toxic major constituents:

– nitrogen N_2 (constituent of the intake air),
– water vapor H_2O,
– carbon dioxide CO_2,
– oxygen O_2 (in diesel engines and gasoline engines with lean-burn operation).

Carbon dioxide is present in the air as a natural constituent and is not categorized as a pollutant in respect of exhaust-gas emissions for motor vehicles. However, it is considered to be one of the causes of the greenhouse effect and the associated global climate change. Since industrialization, the CO_2 content in the atmosphere has risen by roughly 40 % to today's figure of 400 ppm.

The amount of released carbon dioxide is directly proportional to fuel consumption. Measures taken to reduce fuel consumption are therefore becoming increasingly significant.

Pollutants

The above-mentioned constituents are the components of exhaust gas that would be produced in a complete, ideal combustion of pure fuel – i.e. in the complete combustion of fuel with oxygen without unwanted secondary reactions. However, minor constituents are also produced in real vehicle operation.

The quantity of minor constituents produced during combustion is very much dependent on the engine operating status. For the gasoline engine, the quantity of untreated exhaust gas (exhaust gas after combustion and before exhaust-gas treatment) amounts to approximately 1 % of the total amount of the exhaust gas for an engine at normal operating temperature and with a stoichiometric mixture composition (where $\lambda = 1$). The compo-

sition of diesel exhaust gas is very much dependent on the excess air.

The essential pollutants produced directly during the in-engine combustion of fuels are described in the following.

Hydrocarbons
Fuels that contain hydrocarbons never combust absolutely completely in engines. The incompletely combusted hydrocarbons emitted from an engine and their concentrations are determined in particular by the combustion and engine applications with injection strategy, injected fuel quantity, injection pressure, point of injection, etc., and by the air-fuel ratio λ, by the combustion temperature, and by further engine influencing factors.

Aliphatic hydrocarbons (alkanes, alkenes, alkines as well as their cyclic derivatives) are very nearly odorless. Cyclic aromatic hydrocarbons (e.g. benzene, toluene, polycyclic hydrocarbons) exude an odor. Partially oxidized hydrocarbons (e.g. aldehydes, ketones) have an unpleasant odor and form derived products when exposed to sunlight.

Carbon monoxide
Carbon monoxide is formed during the incomplete combustion of fuel due to an insufficient oxygen supply. This can be caused by locally rich areas as a result of insufficient mixture preparation (e.g. unvaporized fuel droplets or fuel film on the wall of the combustion chamber).

Carbon monoxide is a colorless, odorless, and tasteless gas. It is toxic since it binds to the hemoglobin in blood and thereby inhibits oxygen transport.

Particulates
Unlike gaseous exhaust-gas constituents, particulates are not a clearly defined chemical species. All solid or liquid combustion residues which can accumulate in a defined sampling process on a sample filter are called particulates. These are, aside from soot particles – consisting of a solid soot core and adherent incompletely combusted hydrocarbons resulting from fuel and lube oil – droplets of hydrocarbons, water and sulfurous acids (sulfates) as well as ash particles and abraded metal.

Sulfur oxides
The term sulfur oxides (SO_x) denotes a mixture of sulfur dioxide (SO_2) and sulfur trioxide (SO_3). Sulfur oxides are almost inevitably formed during the combustion of fuel containing sulfur. The sulfur content in the fuel must always be taken into consideration in the choice and design of exhaust-gas treatment systems in order to guarantee their long-term effectiveness.

Nitrogen oxides (nitric oxides)
The nitrogen content in fuels is generally low and plays a subordinate role in the formation of nitrogen oxides. During the combustion of fossil fuels nitrogen oxides are produced from reactions of intermediately formed hydrocarbon radicals and oxygen (O_2) with atmospheric nitrogen (N_2). Phenomenologically these reactions have hitherto not been explained in every detail despite broad empirical knowledge. The layout of the combustion chamber and the combustion application have a large influence, e.g. guidance of the flame front and its local temperatures.

The produced mixture of strongly oxidizing nitrogen oxides is termed “nitrous gases” and comprises nitrogen monoxide (NO), nitrogen dioxide (NO_2) and various dimers (e.g. N_2O_3, N_2O_4) which are in thermodynamic equilibrium. Laughing gas (N_2O) is not strongly oxidizing and is not classified as a nitrous gas. It is a strong greenhouse gas. When it comes to the frequently used generic term NO_x, it is always necessary to define whether laughing gas is included or not. Both definitions are common.

Basic principles of catalytic exhaust-gas treatment

It seems advantageous to convert the pollutants formed in the engine with each other or with another substance contained in the exhaust gas into less harmful substances. The following challenges must be surmounted for this purpose:

– In the fewest engine operating states the exhaust gas contains equivalent proportions of the substances to be able to convert these with each other.
– The exhaust-gas temperature is too low at many engine operating points to be able to get over the activation barrier of the desired reactions.

The strategy of catalytic exhaust-gas treatment starts at this point.

Catalytic exhaust-gas treatment
A catalyst is scientifically defined as a substance in the presence of which a certain reaction or a reaction sequence takes place more quickly under kinetically limited reaction conditions and which itself emerges unchanged. In other words, the catalyst reduces the activation barrier of the reaction catalyzed by it. However, the components of exhaust-gas treatment systems designated in the technical sense as a catalyst furthermore perform further functions (see Exhaust-gas treatment, Catalytic converter).

Catalyst components
Catalysts for exhaust-gas treatment consist of complex-structured, highly porous ceramics which are in the main applied as coatings (catalyst coating) to honeycombed carrier structures. A distinction is made between the following catalyst components.

Catalytically active components
Catalytically active components (e.g. noble metals) increase the speed of the desired reactions under suitable conditions.

Storage components
Storage components (e.g. zeolites) absorb certain substances from the exhaust gas and store them until suitable conditions exist to convert them.

Carrier components
Carrier components (e.g. Al_2O_3) form a ceramic matrix in the large inner surfaces of which catalytically active components are present in finely dispersed form.

Stabilizing components
Stabilizing components protect the carrier and storage components as well as the catalytically active components against excessive thermal and chemical impairments.

Honeycombs
The honeycombs to be coated in the main exhibit 10 to 250 parallel channels per square centimeter. They are usually extruded from a ceramic, e.g. cordierite, or manufactured as a special form from metal foil.

Arrangement in the exhaust-system branch
The catalysts are preferably integrated into the exhaust-gas system in such a way that the gases flow through them as uniformly as possible. Each deviation from the ideal distribution of the gases reduces the theoretically possible conversion of a catalyst such that the nonuniform flow necessitates an accordingly more powerful, i.e. larger catalyst for example.

The volume of the honeycombs, which in the technical sense is termed the catalyst volume, depends in particular on the required quantity of catalytic components which is required for the desired reduction of pollutants. A limiting factor in this respect is often the quantity which can be applied per unit of volume to the honeycomb. On the engine side the exhaust-gas back pressure of the coated honeycomb constitutes a limitation. On the vehicle side the available installation space frequently limits the catalyst volume. In Euro 6 exhaust-emissions standard diesel vehicles the total catalyst volume is often three to six times the engine displacement.

Catalytic processes for exhaust-gas treatment

Boundary conditions

Catalysts (catalytic converters) are the basis of modern processes for treating the exhaust gases of motor vehicles. Boundary conditions must be satisfied to guarantee their effectiveness in the long term. For example, the quality of the operating fluids must be matched to the respective catalysts. Leaded fuel can cause a rapid deactivation of the catalysts. Sour fuel (i.e. containing sulfur), heavy metals from the engine oil, inorganic additives, and other not completely combusted substances in the engine can cause progressive contamination of the catalysts quickly or slowly over the vehicle's service life. In this way, the efficiency of the exhaust-gas treatment system is drastically reduced in part.

In the case of the catalyst requirements imposed on the engine and vehicle applications it is also essential to adhere to certain exhaust-gas composition limits and the exhaust-gas temperature, even if critical conditions in some cases only occur on a limited basis in terms of time and space on the catalyst surface. For example, temperatures which lead to local fusing and thus destruction of a particulate filter are to be avoided during soot burn-off. This necessitates, for example, a limitation of the amount of soot to be stored.

Generally speaking, a faster progression of the catalyzed reaction can be achieved in a catalytic process with a larger quantity of active components – if the activation barrier is exceeded and if substance-transport processes do not limit the reaction speed. But even when large quantities are used the exhaust-gas temperature is always too low directly after engine starting to achieve significant pollutant conversion. The catalyst heats up with a constant exhaust-gas flow. The temperature at which 50 % of the pollutant emitted by the engine is converted is called the light-off temperature. During cold starting of a diesel engine several minutes regularly elapse before the catalysts achieve optimum operating conditions. This is counteracted by applications with engine heating measures. Electrical heating measures have also been implemented in special applications. Storage components of the catalysts converter moreover store pollutants in the cold-start phase and desorb them once the light-off temperature is exceeded. An example: Special zeolites are suitable for storing some hydrocarbons in such a way.

Belt drives

Friction belt drives

Application

Friction belt drives are used in automobiles predominantly to drive accessories (Figure 1). These drives had previously been driven primarily by V-belts. However, the significantly higher power density required in today's applications, e.g. due to space restrictions and higher power consumption of the accessories, have resulted in these having been replaced in the meantime almost exclusively by serpentine drives with ribbed V-belts (Micro-V® belts). They are typically used to drive the alternator, the A/C compressor, the power-steering pump, but also fans, mechanical chargers, or pumps for secondary air injection.

Ribbed V-belts are also used to start engines in hybrid or in start/stop systems. Here, the conventional starter is replaced by a starter alternator, and the belt transmits the starter torque to the crankshaft to start the engine. As well as starting, supplementary functions such as additional engine acceleration (boost mode) and energy recovery by engine braking (recuperation) can be realized.

Forces and loads in the belt drive

The transmittable power is determined from (quantities, see Table 1)

$$P = (F_1 - F_2) \cdot \frac{v}{1000}\ ,\ P \text{ in kW.}$$

Table 1: Symbols and units

Quantity		Unit
F_1	Belt-run force on load side	N
F_2	Belt-run force on slack side	N
F_U	Peripheral force	N
F_{HL}	Pretensioning force or "hubload"	N
F_B	Loading of belt by wrap	N
F_C	Loading of belt by centrifugal forces in wrap angle	N

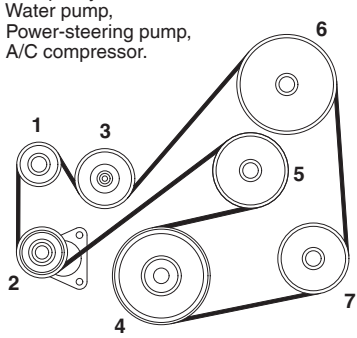

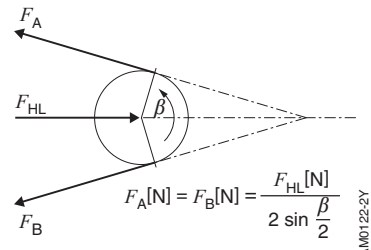

Figure 2: Forces on an unloaded belt pulley

β Wrap angle,
F_A Belt-run force, F_{HL} Hubload, F_B Belt-run force.

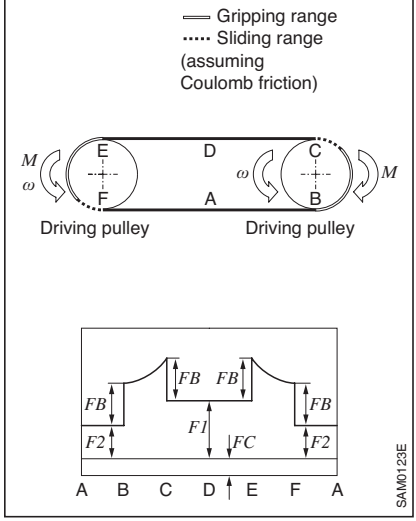
The transition from static friction to sliding friction is obtained from the Eytelwein equation:

$$R = \frac{F_1}{F_2} = e^{\mu' \beta},$$

where $\mu' = \frac{\mu}{\sin\frac{\alpha_s}{2}}$.

As long as the belt-run forces are in this ratio, there will be no slip when power is transmitted. Belt run refers to that section of the belt between the belt inlet and outlet areas of two adjoining belt pulleys. A typical ratio for ribbed V-belts is $R = 4$ with a wrap angle of $\beta = 180°$.

To transmit the peripheral force



$$F_U = F_1 - F_2$$

the pretensioning force F_{HL} ("hubload") is required (Figure 2). At high rotational speeds, the centrifugal force component F_c (centrifugal force) of the belt must also be taken into consideration.

Slip occurs on account of the change in tension within the belt during alternation between load and slack runs.

In spite of a constant transmitted torque, the belt tension decreases at the driving pulley and increases at the driven pulley (Figure 3). This variation in tension causes the belt to elongate over the respective pulley. In this elongation range, the belt loses its grip on the pulley and passes into a sliding state. The belt will slip if this sliding range stretches over the entire pulley wrap. In correctly configured drives the slip is under 2 % and the ribbed V-belts operate with an efficiency of more than 96 %. This configuration must be taken into account particularly in the case of belt-driven functions, such as engine starting and engine acceleration, since driving-half and undriven-half forces are reversed for this situation.

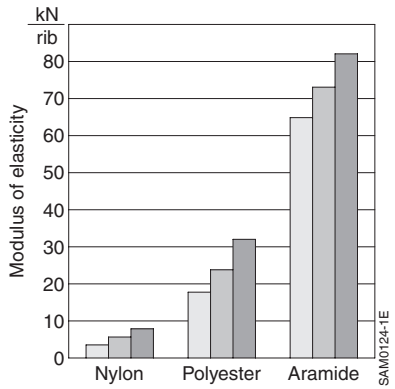
Design of ribbed V-belt

The ribbed V-belt is a composite of three components (Figure 4):
– fiber-reinforced rubber compound,
– tension members,
– backing or rubber coating.

The rubber compound forms the ribs and transmits the drive forces from the pulleys to the tension members. The main material used here is Ethylene Propylene Diene Monomer rubber (EPDM), and the rubber compound is fiber-filled for reinforcement.

The tension members accommodate the dynamic forces and transmit the drive power from the driving shaft (usually the crankshaft) to the accessories. They are usually made of nylon, polyester or aramide. These tension member materials

Figure 4: Structure of ribbed V-belt (cross-section)
1 Backing or rubber coating,
2 Tension members,
3 Rubber compound, fiber-filled.



differ primarily in their very different moduli of elasticity (Figure 5).

The dynamic matching of the system can be optimized by selecting the appropriate tension member material. Tension-member materials with a high modulus of elasticity (e.g. aramide) are used in highly dynamic applications to influence the resonant frequencies of the belt drive. Depending on the choice of tension-member material, maximum dynamic belt forces of 390 N (for polyester) or up to 600 N (for aramide) per rib can be absorbed.

The back of the belt can be designed as a backing or as a rubber coating. The back of the belt forms a protective layer for the tension members. In most applications, it serves only to guide the belt quietly via the idler and tension pulleys. In some applications, however, it also serves to drive accessories which are subject to low load (e.g. water pump).

The rib profile can be manufactured by grinding, cutting or molding in a tool. The latter delivers the greatest precision in the rib geometry, helping to improve running time and noise generation. Fabric layers on the rib side additionally help to increase robustness.

Figure 5: Moduli of elasticity of different tension-member materials
The three columns for each material represent the spread.

Ribbed V-belt profile and belt pulleys
Usually the PK profile in accordance with ISO 9981 [1] is used in automobile applications (Table 2 and Figure 6).

The reference belt length L_B is determined on a two-pulley test rig under a defined pre-tension (ISO 9981). Here, the reference circumference U_B of the measurement belt pulleys is 300 mm (Figure 7). The reference belt length is then calculated according to

$$L_B = U_B + 2E .$$

Because the belt and pulley geometries in ISO 9981 are encumbered with a tol-

Drive system: accessory drive

The most important requirement of the accessory drive system is that it should drive all the accessories without slip. This must be guaranteed for all load states and under all ambient conditions over the entire service life of the engine. In modern engines with full drives – i.e. all the accessories are driven via an individual belt drive – maximum torques of up to 30 Nm (70 Nm for start/stop systems) and maximum outputs of 15to20 kW with all the accessories at full load are consequently transmitted via a five- or six-ribbed V-belt. The temperatures in the engine compartment are around –40 to +140 °C.

It is essential to utilize optimum system design to eliminate in particular slip noises, such as, for instance, the familiar V-belt squeaking in cold and damp weather conditions. It is also necessary to utilize design already to avoid belt noises caused by pulley misalignment. For belt-driven starting applications the shear loads to be transmitted by the ribs must most also be taken into account. Specially developed belt designs fulfill these requirements without damage caused by ribs shear off. In order to assess the service life, appropriate fatigue tests according to Wöhler must be carried out (see Wöhler fatigue tests).

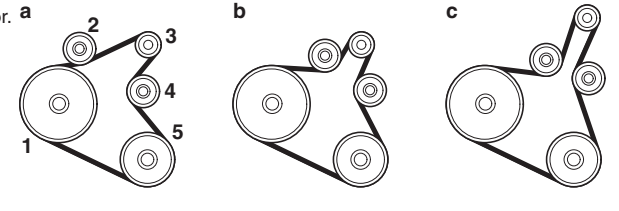
Figure 7: Belt-length measurement acc. to ISO 9981

F Measurement force (pre-tension): 100 N per rib.
E Spacing of measurement belt pulleys, Reference circumference U_B of measurement belt pulleys: 300 mm.

Design criteria
Both manufacturer's own and cross-manufacturer computing programs are used to design accessory drives. Important input parameters are the arrangement of components, i.e. the drive configuration, the torque curves, the moments of inertia of the components, the torsional vibration of the crankshaft, and the belt data. With these data, it is possible to calculate and optimize the system geometry, such as, for example, belt-run lengths and wrap angle, the system natural frequencies, the slip limit angles, the belt-run forces, the belt-run vibrations, and also the service life of the belt.

Recommended minimum wrap angles

Crankshaft	150°
Alternator (I < 120 A)	120°
Alternator (I > 120 A)	160°
Power-steering pump, A/C compressor	90°
Tension pulley	60°



Misalignment and entry angle
In order to avoid unacceptable belt wear and noises, it is important that the entry angle of the belt into the grooved pulleys, depending on the belt design and the required service life, does not exceed 1.2 to 1.5°.

System natural frequency
The system natural frequency of the belt drive should not coincide in the idle range with the engine's ignition frequency as otherwise strong belt vibrations could occur on account of natural resonance.

Minimum diameters of pulleys and idler pulleys
In practice the smallest belt pulley is often located on the alternator in order to facilitate the high rotational speeds that are required there. Typical alternator pulleys have a diameter of 49 to 56 mm. Belt fatigue increases exponentially when very small pulleys are used; this must be taken into account when the belt is designed. Diameters not less than 60 mm are recommended for idler pulleys which generate strong belt-back deflection.

Belt-tensioning systems
Belt tension in accessory drives is today usually provided by way of automatic tension pulleys. These tension pulleys ensure that the belt is almost constantly pretensioned over the belt's service life by compensating belt elongation and belt wear. The design of the tension pulleys is significantly dictated by the space available. The system tensions are usually 40 to 70 N per rib.

Figure 8: Application examples for belt tensioner in start/stop systems
a) Two-belt-tensioner concept,
b) Pendulum belt tensioner variant 1,
c) Pendulum belt tensioner variant 2,
1 Crankshaft,
2 Tension pulley,
3 Starter-alternator unit,
4 Tension pulley,
5 Refrigerant compressor.

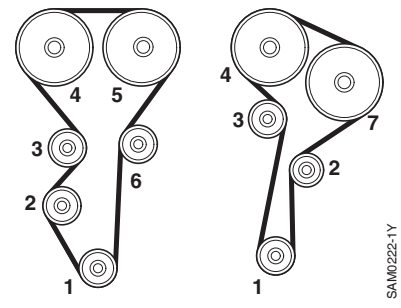
To monitor the dynamic response of the belt drive, common tensioning systems have a mechanical spring which works in combination with a damping unit.

Two tension pulleys are used in belt-driven start/stop systems. The tension pulleys either each have an independent spring element (two-belt-tensioner concept) or are connected to each other only by a torsion spring (pendulum belt tensioner). Start/stop belt drives with pendulum belt tensioners can be implemented with low belt pre-tension (Figure 8).

Stretch Fit drives

Elastic ribbed V-belts are also used occasionally in less complex belt drives. These use nylon as the tension-member material and do not require belt-tensioning systems. This belt type is pulled during fitting onto the pulleys by overstretching. The belt length must be designed in such a way that the belt pretensioning force is so high after fitting that, while wear and elongation over the required service life as well as the relevant ambient conditions are taken into account, sufficient pre-tension is still maintained without retensioning. Today, belt drives with up to four pulleys, i.e. up to three driven components, are possible.

Positive belt drives



Application

Toothed belts in accordance with ISO 9010 [2] are used in timing drives to drive camshafts or the high-pressure fuel-injection pump synchronously with the crankshaft. The main advantages over competing means of drive – such as the gear drive or the chain – lie in the simplicity of the drive, the flexibility of the belt guidance, the low friction, the low noise emissions, and the capacity to compensate for high dynamic peak loads. Accessories such as oil or water pumps can be integrated into the drive or driven individually (Figure 9).

In modern applications, in contrast to earlier applications, it is possible in many cases to dispense with a replacement interval because of the use of innovative belt technologies and optimized design of the overall system. The low weight and the low costs also militate for the use of a toothed belt.

Figure 9: Application examples for toothed-belt drives

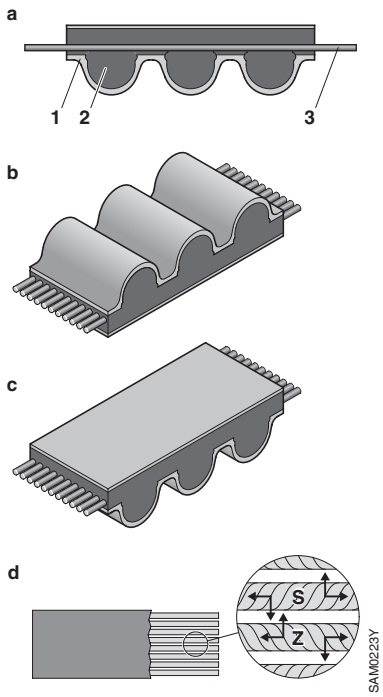
2 Water pump,
3 Tension pulley,
4 Camshaft 1,
5 Camshaft 2,
6 Idler pulley,
7 High-pressure fuel-injection pump.



Forces and loads in the belt drive

In positive belt drives the torque is transmitted by the meshing of the toothed-belt teeth and a special toothed-belt pulley from the crankshaft to the toothed belt and from the toothed belt to the output components (e.g. camshaft, high-pressure fuel-injection pump or water pump). The actual power transmission is performed by the tension members embedded in the toothed belt. The toothing renders slip impossible, which means that toothed-belt drives can be used for synchronization.

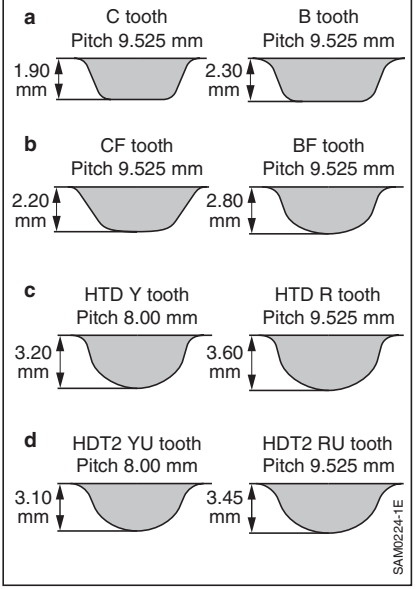
b) Overhead view, tooth side,
c) Overhead view, back side,
d) Overhead view with depiction of tension members twisted in S- and Z-shapes.
1 Nylon fabric,
2 Rubber compound,
3 Tension member.

Structure of toothed belt



The toothed belt is a composite of three components (Figure 10):
– nylon fabric,
– rubber compound, and
– tension member.

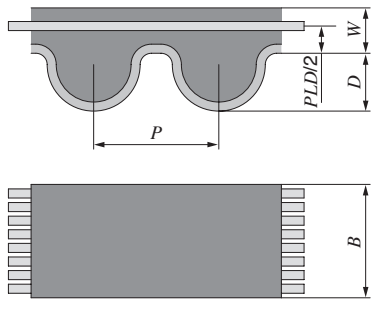
The fabric is made of high-strength nylon and has an abrasion-proof and wear-resistant coating. It protects the rubber teeth against wear and from being shorn off, and improves the running performance.

The rubber compound consists of a high-strength polymer, and encloses the tension member on both sides. Polychloroprene (CR) was used in the original applications. The high demands placed on resistance to temperature and aging and dynamic strength means that today only Hydrogenated Nitrile Butadiene Rubber

Figure 11: Development of toothed-belt profiles

a) Power-Grip trapezoidal profile,
b) Power-Grip Power Function profile,
c) Power-Grip HTD profile,
d) Power-Grip HTD2 profile.

materials (HNBR) are still used in today's motor vehicles.



In some high-load applications belts with backing can also be used for increased reinforcement. This fabric reduces the risk of the belt running in the axial direction. It also improves belt service life in very cold ambient conditions (down to –40 °C), for example when the engine is started.

The tension member consists of twisted glass fibers – a material which is characterized by high tensile strength together with a high willingness to bend. As a result of the production process, the tension members are arranged in a spiral shape in the belt in the effective line, and twisted in pairs in S- and Z-shapes (Figure 10d). This ensures that the belt is subject to predominantly neutral running.

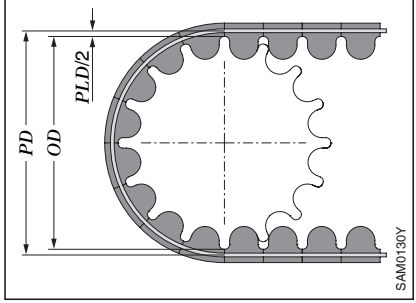
Toothed-belt profiles

The first camshaft belts were based on the classic Power Grip trapezoidal-tooth shape (Figure 11a), as was already known in industrial applications. On account of the increasing demands with regard to load transmission, jump protection and noise, circular-arc-like profiles (e.g. Power Grip HTD 2, High Torque Drive, Figure 11c and 11d) are almost exclusively used today. Compared with trapezoidal teeth, the forces with circular profiles are introduced more uniformly into the tooth, and stress concentrations are thereby avoided.

Figure 12: Characteristics, toothed belt
a) Longitudinal section, b) Overhead view.
P Pitch, *D* Addendum, *W* Rib thickness, *B* Width, *PLD*/2 Effective line distance (half the distance from outside diameter to effective line)

The pitch (Figure 12) is, in most cases, 9.525 mm for diesel engines, and 8.00 mm for gasoline engines. Higher forces can be transmitted with a larger pitch, while a smaller pitch has advantages with regard to noise and space.

Double-sided toothed belts can be used for applications where the direction of rotation is reversed (e.g. balancer-shaft drives).



Toothed wheels

The associated toothed wheels are specified in ISO 9011 [3]. For the toothed wheel, the profile must be determined as a function of the diameter. The effective diameter *PD* is obtained from the number of teeth and the pitch, the outside diameter of the toothed wheel is accordingly reduced by the *PLD* (see characteristics in Figure 12 and Figure 13).

Drive system: toothed belt

The most important requirement of the toothed-belt drive system is that it should synchronize the camshaft in relation to the crankshaft over the service life of the engine. This is an important criterion for adhering to the consumption and emission values. It is possible to keep the elongation of the toothed belt under 0.1 % of the belt length by selecting the appropriate materials for the toothed belt, and by using an automatic tensioning system and optimized system dynamics. This results in 4-cylinder engines in a timing deviation of 1 to 1.5° referred to the crankshaft.

Figure 13: Characteristics, toothed wheel
PD Effective diameter, *OD* Outside diameter, *PLD*/2 Effective line distance.

The service-life requirements are currently in the range of 240,000 to 300,000 km, while the temperature requirements range from –40 °C in the cold state up to 150 °C engine-compartment temperature. Conspicuous noises caused for example by meshing are perceived to be offending and are therefore not acceptable. The efficiency of a toothed-belt drive is approx. 99 %. New materials and manufacturing processes today permit the use of toothed belts in an oil environment to drive oil pumps or to control the timing of camshafts. For the latter, it is possible to dispense with leading the camshaft out of the engine block and hence with the customary shaft seal on the main bearing. The advantages of this technology are the potential friction and noise reductions. The oil environment has not only a friction-reducing, but also a damping effect. This in turn has a positive impact, particularly for highly dynamic downsizing engines.

Design criteria

Both manufacturer's own and cross-manufacturer computing programs are used to design timing drives.

Important input parameters are the arrangement of components, i.e. the drive configuration, the torque curves of the components, and calculated from these the dynamic peripheral forces, as well as the belt data. With these data, it is possible to calculate and optimize the system geometry, such as, for example, belt-run lengths and wrap angles, and the system dynamics.

Recommended minimum wrap angles

Crankshaft	150°
Camshaft, high-pressure pump	100°
Accessory wheel	90°
Automatic tension pulley	50°
Idler pulley	30°
Damping pulley	10°

Periodic meshing

To avoid uneven belt wear, it is important to prevent the same belt teeth from engaging in the same wheel gaps. To assess this periodic meshing the tooth ratio of the number of teeth of the belt and the belt pulleys and the number of engine cylinders or the number of pistons in the high-pressure pump are considered.

Z	Tooth ratio
AM	Number of engine cylinders
AHD	Number of pistons in the high-pressure pump
ZR	Number of teeth on the belt
ZSNW	Number of teeth on the camshaft disk
ZSHD	Number of teeth on the high-pressure pump disk

$Z = ZR \cdot AM/ZSNW$
$Z = ZR \cdot AHD/ZSHD$

Periodic meshing does not occur when the following decimal values are avoided for the tooth ratio:

Z.0; Z.25; Z.33; Z.5; Z.66; Z.75.

Belt-run lengths
In order to avoid resonance noises at idle speed, it is important to ensure that free belt-run lengths are not in the area of 75 mm and 130 mm.

Minimum number of teeth and minimum diameters of toothed wheels and idler pulleys

Pitch 9.525 mm	17 teeth
Pitch 8.00 mm	17 teeth
Non-toothed idler pulleys	dia. 50 mm
Damping pulleys	dia. 28.5 mm

Tolerances of toothed wheels and idler pulleys
Concentricity, lateral running:
dia. ≤ 100 mm 0.1 mm
dia. > 100 mm 0.001 mm per mm dia.

Conicity of outside diameter
≤ 0.001 mm per mm wheel thickness.

Parallelism of bore to toothing
≤ 0.001 mm per mm wheel thickness.

Surface roughness
$R_a \leq 1.6$ µm.

Pitch error
– dia. ≤100 mm:
  ±0,03 mm gap/gap,
  max. 0,10 mm over 90°.
– dia. > 100 mm:
  ± 0.03 mm gap/gap,
  max. 0.13 mm over 90°.

Axial guidance
A toothed belt must be guided at least at one wheel on both sides with flanged wheels to prevent it running off the belt run. Essentially, it is important to ensure that toothed wheels with flanged wheels are exactly flush with the other wheels so that the belt is not deflected from its course. Limit values for belt-edge wear caused by excessively high run-off forces must be taken into consideration.

Belt-tensioning systems
The required constantly high belt tension, and compensation of the tension increase over temperature and belt elongation are usually provided in today's timing drives by tension pulleys. The design of the tension pulleys is significantly dictated by the space available. The most widely used system is the mechanical, friction-damped compact tensioner.

Essential design parameters for monitoring the system dynamics are the spring moment and the damping characteristic. Hydraulic tension pulleys are also used in some applications in the event of very high dynamic forces in the toothed-belt drive. These are characterized by their asymmetrical damping performance.

Tensioning systems can also be used in an oil environment if an appropriate adaptation of the damping level is taken into consideration.

Chain drives

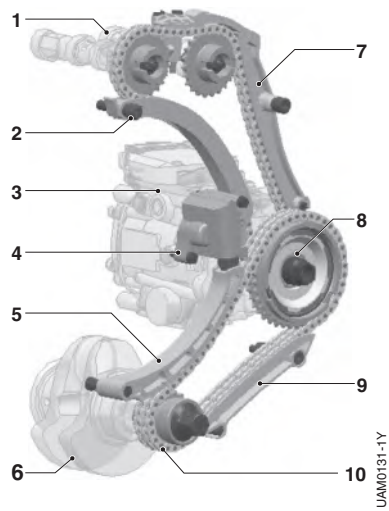
Overview

Camshafts are used to control the gas exchange valves; these camshafts open and close the valves by means of direct actuation via bucket tappets or lever assemblies. Camshafts are driven on modern overhead valve engines, i.e. overhead camshafts, with the aid of a belt drive, while side-mounted camshafts are connected via a geartrain to the crankshaft pinion. Toothed belts, roller- or sleeve-type chains, and tooth-type chains are used to drive overhead camshafts. For fast-running assemblies – such as motor-racing engines for example – the drive is also effected with spur gears.

The most important criteria in deciding on the type of drive are costs, space, ease of maintenance, service life, and noise buildup. The great advantage of chain drives over toothed-belt drives is that they are completely maintenance-free over the entire service life of the engine, while toothed belts, depending on the application, have to be retensioned or changed according to the maintenance interval.

In addition to the camshaft, timing drives in modern engines frequently drive other assemblies, such as the oil pump and the high-pressure pump for gasoline direct injection or for common rail (Figure 1).

As both camshaft and crankshaft rotate nonuniformly and are exposed to torsional vibrations, the drive is subject to highly complex dynamic stresses. Furthermore, the torque demand of the high-pressure pump is subject to very strong periodic fluctuations, and thus generates further excitation of the timing-chain drive.



Timing chains

Designs of steel-link chains
In the case of standard chains, a distinction is made between roller- and sleeve-type chains. There are also simplex and duplex chains. The tooth-type chain is a special type of chain.

Roller-type chain
A steel-link chain is composed of inner and outer links. The inner link of a roller-type chain consists for example or two inner plates and two sleeves pressed into the plate eyes (Figure 2a). The outer link consists of two outer plates and two link pins which connect the inner and outer links. In a roller-type chain a roller is fitted over the sleeve.

The rotating rollers of a roller-type chain located over the sleeves roll with little friction on the tooth flanks of the sprocket

Figure 1: Timing-chain drive

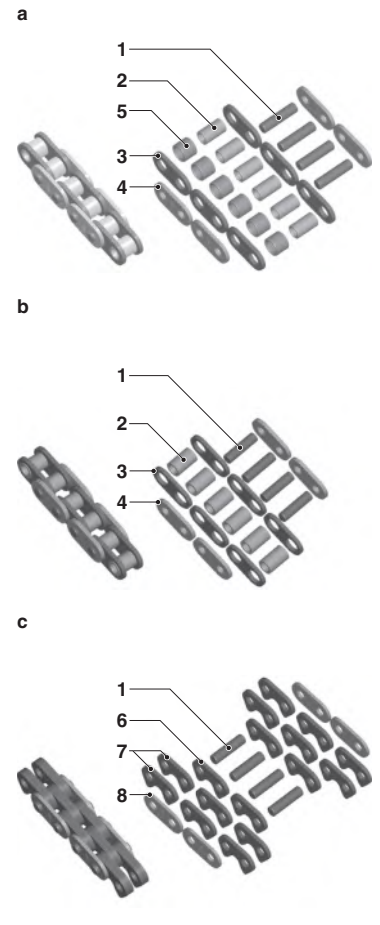
8 Intermediate-shaft sprocket group,
9 Guide rail,
10 Crankshaft sprocket.

such that a different point on the circumference is always contacted. The lubricant between the rollers and sleeves helps to muffle noise and dampen shocks.

Sleeve-type chain
In the case of a sleeve-type chain (Figure 2b), the tooth flanks of the sprocket constantly touch the fixed sleeves at the same point such that the sleeves are subjected to an additional load. Perfect lubrication is therefore particularly important for these drives.

While having identical pitch – the chain pitch defines the distance from pin center to pin center – and force at break, sleeve-type chains have a larger joint surface than the corresponding roller chains, since the omission of the roller means that the pin diameter can be enlarged. A larger joint surface results in a lower joint-surface pressure and thus lower wear in the joints and a longer service life for the chain timing drive.

Sleeve-type chains have proven useful in camshaft drives subject to high loads in diesel engines, because increased wear resistance is called for here on account of the increased entry of soot into the engine oil.



Tooth-type chain
A special design of steel-link chain is the tooth-type chain. On a tooth-type chain (Figure 2c), the plates are set out in such a way that they can transmit the force between the chain and the sprocket, whereas, in the case of roller- or sleeve-type chains, the connection with the sprocket is established via pin, sleeve, or roller.

Tooth-type chains can be built to virtually any desired width without the need for fundamental structural change. Guide plates, which are located either in the middle or on the outside (on both sides), are fitted to prevent the sprocket from running off.

A further variant of the tooth-type chain is the design that is toothed on both sides, which can then be used like a roller- and sleeve-type chain.

Sleeve-/tooth-type chain
Combining the advantages of a sleeve-type chain and a tooth-type chain creates a new type of chain for timing drives, a sleeve-/tooth-type chain (Figure 3). On the one hand, its special arrangement of tooth plates permits a smooth run into the sprocket; on the other hand, the use of sleeves reduces the wear on pins and

Figure 2: Chain designs

c) Tooth-type chain.
1 Link pin, 2 Sleeve, 3 Inner plate,
4 Outer plate, 5 Roller, 6 Tooth center plate,
7 Tooth inner plate, 8 Guide plate.

plates. This chain variant is recommended in all applications where excellent wear resistance and good acoustic and dynamic performance are important.

Selecting chain types

When choosing the chain types (construction and pitch), it is important, while adhering to the maximum sprocket diameter, to aim for numbers of teeth of more than 18 teeth in order to reduce dynamic influences by the polygon effect. The polygon effect occurs when a traction mechanism (chain) is positively driven by a drive wheel. With the sprocket at constant angular velocity the chain is accelerated and decelerated and consequently dynamically loaded.

Decades of experience have shown that some dimensions for roller-, sleeve- and tooth-type chains are particularly suitable for timing drives. These are 3/8" sleeve-type chains for diesel engines and 8 mm sleeve-type chains and 8 mm roller-type chains for gasoline engines. If in the development of a gasoline engine particular demands are made with regard to engine acoustics, 8 mm or 6.35 mm tooth-type chains should be used.

Requirements of chains

Four important factors determine the usage characteristics of timing chains: ultimate tensile strength, fatigue strength, resistance to wear, and acoustic behavior. A break may be caused by the static or dynamic load at break being exceeded. Especially in the case of timing drives, no uniform load will be encountered such that the fatigue strength of the chain is the strength-limiting quantity. The chain is subjected to a dynamic load as a result of the pulsating torques of the camshafts, the high-pressure pump, the rotational non-uniformity of the crankshaft, and the pulsating axial chain force caused by the polygon effect. Here, the safety limit to the fatigue strength of the chain must not be exceeded, since the number of such load alternations during an engine's service life is in each case greater than 10^8 load alternations (Figure 4).

In today's engines with precise timing and minimal clearance between piston and valve, minimal elongations due to chain wear can be achieved. Length increases caused by wear of just 0.2 to 0.5 % of the chain length for an engine mileage of up to 350,000 km are ensured today by the optimization of the pin/sleeve joint.

In particular direct-injection turbodiesel engines but also the latest models of direct-injection gasoline engines require timing chains that exhibit the highest levels of wear resistance.

To improve the wear resistance, the link pins are coated in a final operation with a layer of hard material, either chromium carbide or chromium nitride.

3 Roller-type chain for high-performance timing drives in gasoline engines,
4 Roller-type chain for oil-pump drives.

Design criteria for chain timing drives

A chain timing drive is with mass, rigidity, and damping an oscillatory system with several degrees of freedom. If subjected to corresponding excitation for example by the camshaft, crankshaft or high-pressure pump, this can, on account of interactions, cause resonance effects which lead to extreme timing-drive load.

A range of design criteria must be taken into account in the development of chain timing drives. These are:

– Chain length with an even number of links.
– Free run length (unguided chain section) if possible three to five chain links.
– Large radii at tensioning and guide rails for reducing friction.
– Inward tensioning direction of the chain tensioner.
– Floating mounting of the tensioning and guide rails.

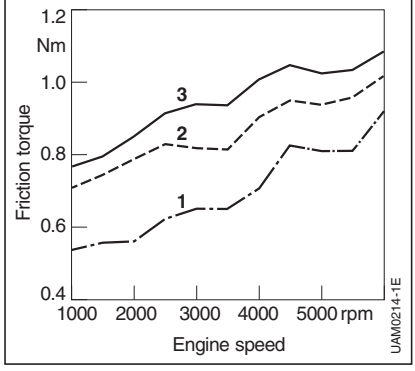
Computational check of chain timing drives

Layout drawings are taken as the basis to create a chain-drive model which is used for the dynamic computation of timing drives. The timing drive is described by mass parameters, chain stiffness, and damping values.

Tensioning and guide rails are modeled as elastic bodies, the tensioning element is depicted with all the function elements. The simulation calculation delivers the necessary torsional-vibration angle deviations and all the force and moment characteristics.

Friction reduction of chain timing drives

To reduce the CO_2 emissions from an internal-combustion engine, every savings potential must be utilized to reduce fuel consumption. In this way, a friction-optimized timing-drive design can also make a contribution to reducing the CO_2 emissions.



The decisive factor is the optimal layout of the chain line. Avoiding pronounced curvatures of the tensioning and guide rails reduces the normal forces and hence reduces the friction.

Chain-plate quality is of crucial importance to the frictional behavior of timing chains. The manufacture of chain plates involves the use of different blanking processes which create textures on the surface based on the manufacturing process used. Chains with precision-blanked plates deliver the best values.

Due to their internal friction and the contact of pins and plates, even timing chains of the most important types exhibit different frictional behavior. Figure 5 clearly shows the disadvantages of the tooth-type chain with identical overall width.

Figure 5: Friction torque of different chain designs

Chain pitch is the same for all designs at 8 mm.

2 Roller-type chain,
3 Tooth-type chain.

Sprockets

The tooth shape of the sprockets is standardized for roller-, sleeve- and tooth-type chains (DIN ISO 606, [1]). DIN permits considerable degrees of freedom in the precision design of the sprocket toothing such that a tooth-space shape can be created between a minimum space and a maximum space. As a rule, sprockets with maximum tooth-space shape are used. This design permits, as a result of the low addendum and the larger tooth-space opening, the chain to enter and exit undisturbed even at higher chain speeds.

In fashioning the tooth shape of tooth-type chains each manufacturer applies its own design philosophy (e.g. noise- or wear-optimized) such that these chains do not conform to the standard. The design of the sprockets is dependent on the space conditions, the operating conditions, and the power transmission of the chain drive (Figure 6).

Sprockets made of carbon steel (e.g. Ck45) and alloyed steels (e.g. 16MnCr5) and wheels made of sintered materials (e.g. Sint D11) are used. Precision-blanked and machine-cut wheels with the heat treatment appropriate for the material are used.

Chain-tensioning and chain-guide elements
