Today's standard is represented by remote keys, which at the touch of a button by the user send a coded data packet at a UHF frequency (433 MHz or 868 MHz) to the vehicle. This data packet changes with each actuation in order to prevent “eavesdropping” (see Immobilizer). These data packets typically consists of a fixed-code part and a rolling-code part which are generated according to an algorithm. The receiver decrypts this code with the same algorithm and thereby identifies permissible combinations. Each code can only be used once. Once the received data packet is identified as permissible, the locks are electrically unlocked and the vehicle owner can open the doors by pulling on the outer control. The mechanical key now only acts as an emergency actuator in the event of a remote-key malfunction or a power failure.

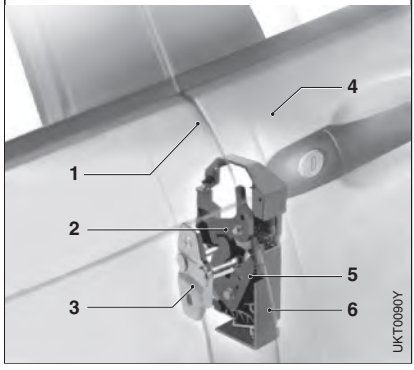
Keyless entry
So-called passive-entry or keyless-entry access systems are becoming increasingly popular. These do not require any electrical-unlocking action by the vehicle owner. It is enough for the owner to be carrying the ID transmitter about their person. A chip inserted in the remote key or a suitable smart phone can serve as the ID transmitter (Near Field Communication). With these systems the opening request is automatically detected by the vehicle – for instance when approaching a capacitive sensor in the outer door handle, when pulling on the outer door handle, or when operating a pushbutton in the handle. The central ECU in the vehicle sends a signal at a low frequency (125 kHz with a range of around one meter) to the chip in the ID transmitter. The latter reacts to a UHF frequency with a range of up to 20 meters and sends back a coded reply sequence to the vehicle. Access is authorized and the doors are unlocked.

The opening speed is crucial to the user's comfort and convenience. Both the response time of the identification protocol and the unlocking of the doors must be so short that there is no waiting time. The user should not have to pull repeatedly on the outer door handle before the door opens.

In a passive-entry system the reply sequence also changes with each request so as to prevent “eavesdropping”. However, a security risk is posed by so-called “relay-station attacks”. In such attacks the range of the signals of vehicle and ID transmitter are extended with portable transmit/receive stations. One of these devices must be close to the vehicle to be able to receive and boost the low-frequency signal. In this way, the ID transmitter can also be scanned unnoticed by the user over large distances and the vehicle unlocked or started. In newer systems the passive-entry function can be deactivated to prevent such manipulations.

Lock design

Locking mechanism and lock holder



Interaction

The locking mechanism (Figure 2) in the lock establishes a separable connection with the lock holder mounted on the body. Indirectly locking systems have gained acceptance on the market. The holding-closed and locking functions are split between two components – the spagnolet (holding closed) and the locking pawl (locking). The lock holder is enclosed by the spagnolet when the door is closed. The spagnolet is driven by the lock holder, rotated, and locked in the door opening direction by the spring-loaded locking pawl. These indirect systems require only minimal opening forces.

During the closing operation the locking mechanism must be able to compensate door tolerances in relation to the body. The position of the door in the closing direction is determined by the lock holder. This is adjusted once during vehicle assembly in order to set the door alignment and the gap dimensions.

Figure 2: Sectional view of a typical locking mechanism with lock holder

1 B-pillar,
2 Locking pawl (in the door),
3 Lock holder (in the B-pillar),
4 Front passenger door,
5 Spagnolet,
6 Lock housing.

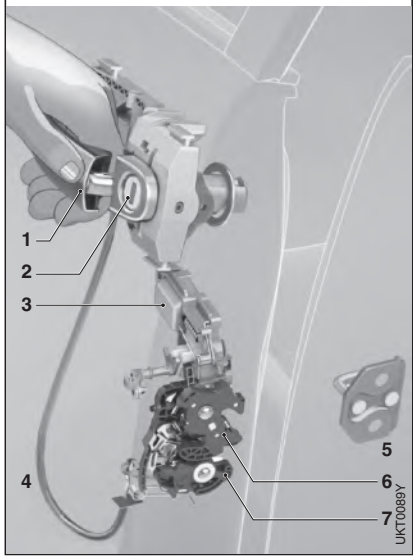
Preliminary detent and primary detent

Statutory requirements such as two-detent capability, tensile values, and 30-*g* strength must be satisfied when it comes to locking-mechanism design. Two-detent capability means that the spagnolet can be held in two positions by the locking pawl – the preliminary and the primary detent. In the primary detent the door is in the desired closing position, i.e., flush with the body, and the door seals are fully compressed. The preliminary detent is a position roughly 5 to 7 mm before the primary detent; in this case the door is not fully closed and the door seals are only partly compressed. In this position watertightness is not guaranteed and driving noises can be clearly heard.

The preliminary detent fulfills two main functions: If the lock inadvertently leaves the primary-detent position, the door is caught again and does not swing open. If the swing is too small when closing, the door remains at least in the preliminary detent and cannot open again inadvertently. Premium locks with an electric closing aid go a step further: They move the door with the aid of an additional motor automatically from the preliminary to the primary detent, slamming the door shut is no longer necessary.

Opening chain

To open the door, the locking of the spagnolet by the locking pawl must be removed. The system here is strained by the pressure of the compressed door seals. The locking pawl is connected with the door handles via a lever chain of connecting elements such as rods or Bowden cables. This is also known as the opening chain, which transfers the handle travel up to the locking pawl. The action of swinging out the locking pawl disengages the tension generated by the seal pressure, the door is released, and the typical opening sound can be heard.



Aside from the pull (Figure 3) and flipper-type variants, the outer handle can also feature pushbuttons or proximity-type sensors. This provides solutions in the lock in which a motor lifts out the locking pawl and thereby opens the lock. This is already standard in rear locks.

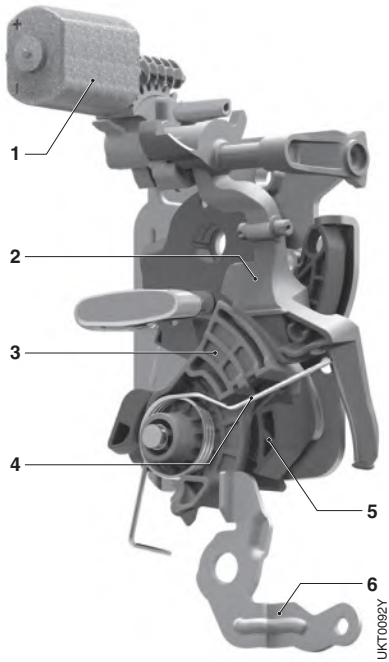
To control entry and exit one or more switchable couplings are required in the

lock which interrupt the opening chain for the outer or inner handle. The door is then locked.

Outer locking
Most of today's vehicles have a central-locking system, which is activated from the outside via the remote key. If the vehicle is without electric power and hence the central-locking system is no longer working, a mechanical lock barrel usually mounted on the driver's door in the outer handle (often under a protective cap) enables the vehicle to be manually locked and unlocked. This is also the case for vehicles with mechanical locks, i.e., without central locking. Vehicles with the passive-entry function as a rule incorporate another pushbutton or a sensor surface in the outer handle which must be actuated to lock the vehicle.

Figure 3: Opening chain for the outer control
1 Outer door handle, 2 Lock barrel,
3 Central-locking motor,
4 Bowden cable for outer handle,
5 Lock holder in the B-pillar (striker),
6 Spagnolet, 7 Locking pawl.

Inner locking
The inner locking, the “knob” in the inside door panel, has already been dropped by some manufacturers. It is replaced in part by an LED in the driver's door in combination with an electric pushbutton in the dashboard or the door and an emergency-locking facility on the lock. This emergency-locking facility enables the vehicle to be locked even when it is without electric power and protected against theft if the battery is flat. The locking action is then performed by means of a lever on the front of the door; this must be opened for operation purposes. Sensor surfaces on the inside of the door or gesture control to activate the central locking from the inside are also conceivable future developments.



Central locking via DC motor
The couplings can be switched either manually by the outer and inner locking or by a DC motor incorporated in the lock (Figure 4). The latter is the case in a central-locking system. In this case all four doors and the rear lock are electrically locked simultaneously. The locking function can be manually canceled by pulling the inside door handle once or twice. The electric central locking is activated via the radio remote control and a passenger-compartment button, for example in the dashboard.

Child-lock function
The child-lock function for the rear doors is a special feature. This function merely disengages the inner handle, preventing rear occupants from being able to open the rear doors from the inside. Depending on the lock used, the door can however be unlocked (but not opened) from the inside, enabling persons outside the locked vehicle to gain entry. The child lock can be activated manually or by a motor in the lock. This is done manually by means of a lever which can be accessed only when the door is open.

Requirements

A side-door lock is subject to an extensive range of requirements. Aside from the legal requirements FMVSS 206 [1] and ECE R11 [2], each manufacturer specifies its own statement of requirements which extends far beyond the statutory provisions. Table 1 provides an overview of the essential requirements relating to a side-door lock as typically apply today.

Figure 4: Typical couplings in the outer and inner opening chain of a side-door lock

Lock layout

The primary concern when it comes to the layout and design of the lock as a safety component is functional robustness. This is followed by criteria such as haptics and acoustics. This involves a pleasant operating feel and a closing and actuator noise that is to impart a high-quality look and feel. Depending on the functional equipment, a side-door lock can consist of 30 to 100 individual parts which interact with each other.

The tensile values or tensile strength of a locking system describe the forces that the locking system must withstand without disengaging. Resilient elements – e.g., elastomer buffers – are required in the lock to prevent door movement and associated noises during vehicle operation. This ensures good closability on the part of the door and the best possible immobilization. The buffers serve to reduce the energy of the swing motion when the door is closed.

During vehicle operation relative movements between the door and the body and consequently also between the lock holder and the lock occur. These can cause noises such as cracking or creaking on account of stick-slip effects particularly in the event of contamination by dust. Material pairings, contact geometries, the rigidity of the lock, and protection against dust accumulation are of crucial importance to the design of the lock.

Market segments, side-door locks

The type of lock that has gained acceptance today has an integrated design in which the mechanical, electromechanical, and electrical components are integrated in a housing – the so-called system lock.

The market for side-door locks is divided into three fundamental segments:

– simple locks with electric central locking (Figure 5a),
– volume locks with electric central locking, theft deterrence, and child lock (Figure 5b),
– premium locks with electric central locking, theft deterrence, electric child lock, electric opening and pulling closed (Figure 5c).

Manufacture
A lock is made up of stampings, injection-molded plastic parts, cold-upsetting parts, springs, sensors, and DC motors. They are manufactured using a variety of production techniques such as riveting, screwing, gluing, and laser welding.

Functional robustness
Functional robustness is verified as standard by means of test catalogs harmonized with the vehicle manufacturer. These are based on the requirements set out in Table 1 and are conducted on test equipment in laboratories. The vehicle manufacturer often conducts its own tests in vehicles as well.

Validation
Real tests cannot take into account all the influencing factors that occur during series production over a number of years and millions of products. These include for example geometric tolerances of individual parts or deviations from material characteristic values. This can only be delivered by simulation calculations since many factors can be taken into account here with justifiable expenditure.
Based on the typical requirements as set out in Table 1 the following are used for the purpose of design and layout:
– virtual strength and structure tests using the finite-element method (FEM, Figure 6),

Table 1: Typical requirements with regard to a side-door lock

Temperature range	– Continuous operation: –40 °C to +80 °C – Refinishing: 120 °C, 1 hour – Extreme load: 300 °C, 2 minutes
Number of door closings	– 100,000 cycles
Number of electric lockings (central locking)	– 60,000 cycles
Tensile forces	– 9 kN in primary detent longitudinal acc. to FMVSS 206 – 8 kN in primary detent transverse acc. to FMVSS 206 – Requirement of the original-equipment manufacturers (OEM) is today double FMVSS 206 and higher
Environmental requirements	– Functional robustness against water, dust and various liquids in all temperature ranges including cyclic repetition with freezing – Corrosion requirements: 144 to 720 h in salt spray
Control forces and control travel at the lock	– As a rule specification of the control forces before and after continuous running for a defined door-seal pressure (100 to 300 N) and control speed at the lock (100 to 300 mm/min); typically 15 to 20 N – Opening capability after an accident up to 5000 N tension
Acoustics	– No rattling or creaking noises – Pleasant closing and actuator noises
Push-in forces	– Force to press the lock holder into the primary-detent position: as a rule under 50 N
Electrical requirements	– Operating voltage 9 to 16 V, start assistance 24 V – Max. permissible current ≈ 5 to 8 A – Control times for central locking, theft deterrence, electric child lock 50 to 500 ms – Actuating forces for central locking with inner-locking knob: 8 N – Cut-off-voltage peaks: –75 V to +150 V – Electromagnetic compatibility as per EMV3 acc. to CISPR 25 [3]
Acceleration resistance	– Centrifuge test with 30 g stationary acceleration – Sled test with acceleration profile
Extreme requirements (misuse)	– Under other drop tests, up to 10 to 15 times increased control forces, up to 1000 mm/s increased control speeds

– virtual functional tests based on multiple-body simulation (MBS),
– statistical tolerance calculations based on the Monte Carlo method.

Simulation calculations are also carried out for the progression of the control forces in order to achieve good lock haptics. The effectiveness of design optimizations can thus be easily verified. In the case depicted in Figure 7 it was possible to reduce the control force from 45.8 N to 36.6 N with the lever ratios and contact points being optimized.

The control-travel figures of the lock with tolerances are crucial to the functionality of the locking system. Here many individual spatial tolerances interact in the control chain and these are superimposed with the aid of statistical calculations, the so-called Monte Carlo method. The result is control-travel figures with the associated tolerances and the probability of their occurrence.

Acoustic simulations are also possible and replace complex measurements at least in part. Optimizations can thus already be defined in the design phase, significantly reducing complex prototypes and measurements. New software tools today also facilitate flow simulations for the assessment and optimization of dust and water robustness.

In spite of the ever-increasing accuracy of simulation methods and material models, real test still cannot be completely replaced. This applies above all to environmental influences such as dust, water, and freezing and also to specific acoustic

Figure 6: Comparison of real and simulated tensile test using the finite-element method

effects such as creaking. Realistic laboratory tests are carried out to avoid costly, complex vehicles tests with test drives.

To obtain meaningful tests in the laboratory, the dust must conform to realistic conditions with regard to composition and particle size. The same applies to the density of the dust and the air flow, which must reproduce the conditions in the door as accurately as possible. A dust-accumulation picture as from real test procedures can then be generated in the laboratory with a dust chamber.

Dust and other environmental influences such as dirt also play a role in the previously mentioned phenomenon of creaking. This arises due to friction between the door and the body in the lock – or more exactly by the lock components which are in contact with the lock holder. The occurrence of a creaking noise can be verified in the laboratory by determining movement profiles and contact forces between the lock and the lock holder and the dirt and dust accumulation in the vehicle. This makes possible design improvements already at a very early stage in the development phase. Figure 8 depicts two design states of a lock. It was possible to eliminate the creaking by introducing furrowing in the contact area of the lock holder with the lock.

Safety functions

Behavior in a crash
The locking system must keep the doors securely closed during vehicle operation. In a crash situation high accelerations, forces, and deformations occur. These must not lead to the failure of the locking-mechanism/lock-holder connection and the unintended opening of the door. After the collision and in a rescue situation, however, the door should be easy to open. To keep the door closed during a crash, in many cases today mass locking mechanisms are installed in the outer door handles. These consist of a weight that is moved during customary accelerations in the crash and then block the outer door handle. This stops the handle from moving outwards and opening the door.

There are additionally tactilely operating systems. In these systems a lever attached to the lock touches the inside of the door outer panel. When this deforms, it blocks the outer control chain, and the door can then permanently not be opened from the outside. This too prevents unintended opening.

Improved systems have speed-based crash freewheels in the side-door lock. If the outer handle is operated too quickly, the movement comes to nothing and the door remains closed. This also covers crash situations in which acceleration-based systems such as mass locking mechanisms do not work. The door can be opened again after the crash.

Theft deterrence
The complete locking system must be protected against electrical, electronic or mechanical tampering. Mechanical and electrical connecting elements which are used to open the doors must not be accessible from the outside or may only be accessible with difficulty from the outside. Certain locks use magnetically operating Hall-effect sensors. These must be fitted in such a way that magnetic fields from the outside cannot cause unlocking or opening.

Many locks have a theft-deterrence system – also called double lock, dead lock or safe function. Depending on the manufacturer, this system is activated always or for instance by pressing the locking button on the remote control twice. Ordinarily this is not possible when there are persons in the vehicle. The theft-deterrence system prevents manual unlocking and opening by the inside door handle, for example after the side window has been smashed. This function is electrically activated in the lock by an additional motor. In the event of a power failure, the theft-deterrence system can be manually deactivated at least on one door via the lock barrel.

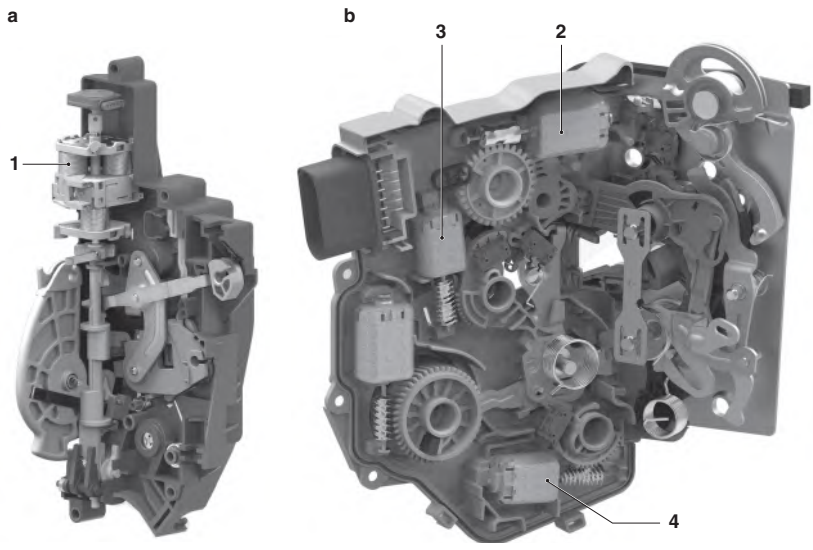
Detection of an opened door
The side-door lock also takes on the important task of signaling an open or closed door to the vehicle. This is done by microswitches in the lock which detect the position of the spagnolet and whether the locking pawl has locked. These signals are evaluated either in the door ECUs or in the car's central electronics. Alternatively, some manufacturers also provide door contact switches outside the lock, but these are less accurate.

This information is used to indicate an opened door or trunk lid in the instrument cluster. These signals are also used for the alarm system, automatic relocking of the doors after a certain period of time in the event of incorrect unlocking, or switching off the cruise control when the door is opened.

Development history

Historical view

The first locks to be used in vehicle doors were based on house locks. These so-called drop-latch locks could not compensate any tolerances, were able to absorb forces only in one direction, and had no preliminary detent. All the components were made of steel, the lever apparatus was not encapsulated, and there were no acoustic damping measures.



From around 1945 onwards this design principle was further developed into the so-called pin lock. This could absorb forces in several directions and had preliminary and primary detents. The locking actions was still performed directly by the drop latch.

In 1955 the first indirectly locking systems were introduced; above all, these reduced the control forces and at the same time improved tensile strength. The first acoustic damping materials reduced rattling noises. From 1960 the indirectly locking systems continued to make inroads into the market. For the most part the spagnolet was on the outside and the lock holder had a more complex design to ensure immobilization with buffer elements. Exclusively mechanical locks were used until the 1970s.

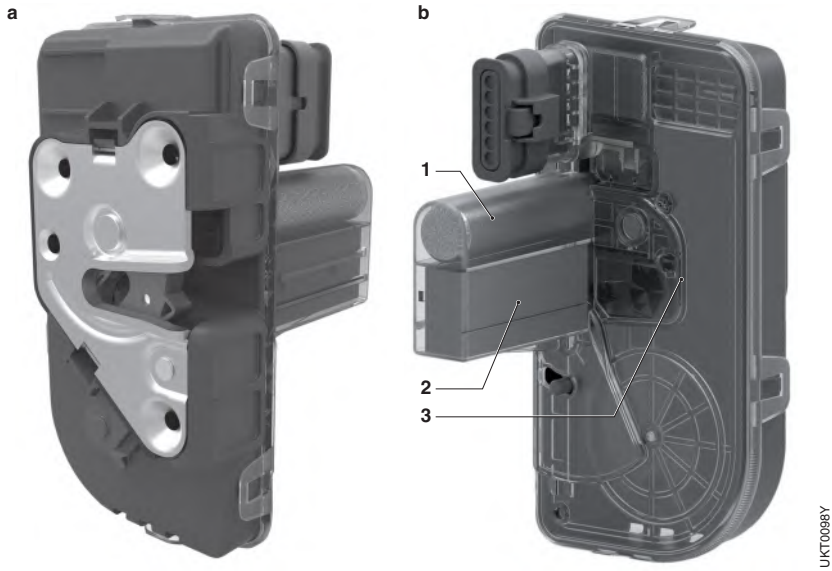
The first locks which locked and unlocked automatically were introduced in the USA in the 1960s. Electromagnets were used to activate them. Pneumatic or electrical control elements (actuators), which were screwed as separate units onto the mechanical basic locks, came later.

The increasing market share of central-locking systems led from the mid-1980s to the actuator being merged with the basic lock, and the so-called system lock was born. Plastic components and sensors were increasingly being used in its design. The indirectly operating locking mechanism with an internal spagnolet became the standard in the ensuing years.

Figure 9: Comparison of a conventional lock with a flex-pole lock
a) Flex-pole lock,
b) Conventional lock.
1 Flex-pole actuator for central locking, theft deterrence and electric child lock,
2 Motor for central locking,
3 Motor for electric theft deterrence,
4 Motor for electric child lock.

The first lock modules which brought together the outer and inner handles and the lock into a preassembled and pretested unit came onto the market in the mid-1990s.

Market trends



The mechanical complexity of locking systems increases with rising functionality. This results in increased weight and a variety of versions, both of which should actually be avoided. Possible solutions are reflected in two market trends: Simplifying the lock body by using a flex-pole actuator and simplifying the locking system by using an electric lock.

Today, a separate DC motor is used as a rule for each electromechanical function in a lock. This means – for a lock with central locking, theft deterrence, and electric child lock – the use of three motors. A flex-pole actuator is an electromechanical control element which can perform these three tasks. This eliminates the need for the motors together with the gear units and the lock becomes lighter, more compact, and more robust. Figure 9 shows a conventional lock and a flex-pole lock in comparison. The interfaces tot he handles and control points remain unchanged.

A further simplification is achieved if the conventional interfaces are also dispensed with, for example in the case of an electric lock. Here the locking pawl is lifted out only by an actuator, manual opening is no longer necessary. Sensors, switches or even smart phones can be used as controls. The lock body is also simplified such that the manual interface is dispensed with. Functions like central locking, theft deterrence, and electric child lock are now only effected by the control software.

Figure 10 shows an electric lock with a cable actuator for lifting out the locking pawl. With an electric lock it must be ensured that after a vehicle-battery failure or a power-supply failure it is still possible to open the door. The can be ensured by integrating a redundant voltage source (battery) into the lock.

Vehicle access by means of digital key

Task and design

In addition to the previously described components of a vehicle-access system these are extended for a system with a digital key. These additional components in the vehicle and the associated technology in the cloud and on the smartphone will be explained in the following.

A secure and digital vehicle-access system extends the described functions of a keyless-entry system by enabling drivers to unlock and lock their vehicle with their smartphone, entirely without the ignition key. The benefit of a digital key becomes apparent above all in fleets, which is why existing commercial-vehicle fleets, for example consisting of trucks, can also be equipment with the key-management system. This increases efficiency and the time available for the dispatchers and also for the drivers.

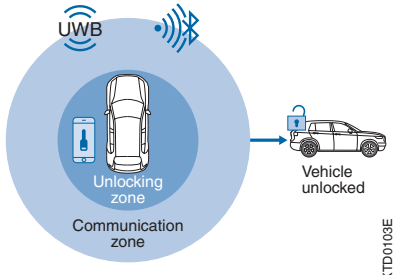
Technology in the vehicle

The hardware of this system ("Perfectly Keyless") consists of different ECUs which combine the technologies "Ultra Wide Band" (UWB), "Bluetooth Low Energy" (BLE), and "Near Field Communication" (NFC). What is new here is primarily the use of UWB technology, a radio-based communication technology for short-range use, which with its frequency band of 6.0 to 8.5 GHz facilitates a pure location accuracy of up to 20 cm. This also permits the implementation of so-called "Passive Entry", i.e., automatic unlocking and locking.

When a smartphone with the right key moves into the vehicle's communication range (communication zone), the smartphone is connected to it via BLE (Figure 11). As soon as the smartphone enters the unlocking zone, the vehicle automatically starts ranging via UWB and determines via the "time-of-flight" measurement (ToF) the distance between the smartphone and the vehicle. When the smartphone is located close enough to the vehicle, the vehicle is unlocked. The locking process works along similar lines.

In the vehicle the information received via UWB, BLE or NFC is managed and evaluated in the ECU which establishes vehicle access. This ECU is also the interface to the vehicle architecture. The received location and key information is made available by the corresponding antennas (Figure 12) via CAN link. Because the antennas are installed in different positions on the vehicle, the current position of the smartphone is determined via the UWB-based ToF measurement and the accompanying triangulation. In addition, the system is supplemented by an NFC

Figure 11: Automatic unlocking
UWB Ultra Wide Band,
BLE Bluetooth Low Energy,
NFC Near Field Communication.



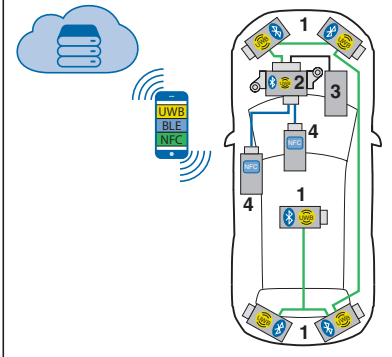


Figure 12: Antenna position in the vehicle
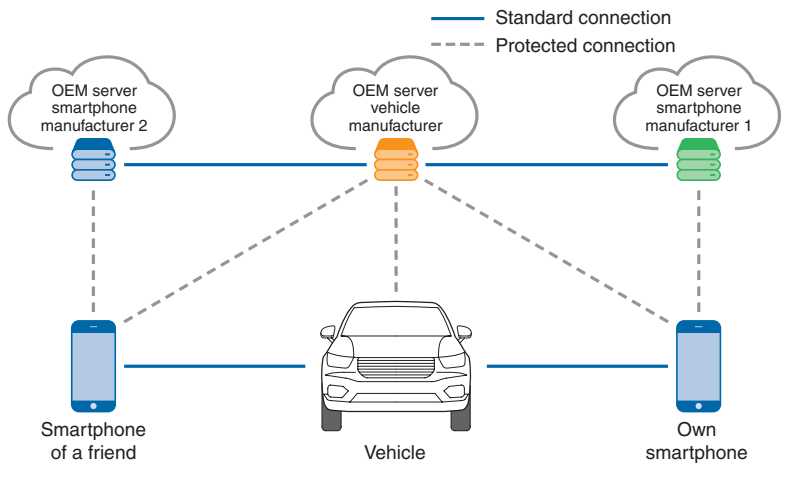
1 BLE and UWB antennas,
2 Master,
3 Body computer,
4 NFC antennas.

reader (Near Field Communication). This functions as a fallback level (back-up) and can even be used for vehicle access when the smartphone battery is flat.



Technology in cloud and app

The digital "Key Sharing Service" is inspired by the Car Connectivity Consortium. The Car Connectivity Consortium (CCC) is a cross-industry organization that defines globally the technologies for smartphone-to-vehicle communication. The CCC is developing the digital key, a new standard which enables electronic devices (smart devices, e.g., smartphones) to interact with the vehicle (see Car Connectivity Consortium Administration, 2021).

The system architecture (Figure 13) shows the main components which are involved in creating a new "friend key", i.e., the key which is created by the owner of the vehicle and sent to an authorized driver. An owner key or a received friend key, i.e., a key already "shared" by the owner of the vehicle, is stored on the respective smartphone in the secure element. The smartphone uses the key app natively implemented by the smartphone OEM to communicate with the vehicle via NFC, BLE or UWB in order for example to unlock or lock the vehicle.

To make the benefit of the digital key available to fleets as well, the system also contains the option of a front end, with which a dispatcher for example can send keys to their drivers. The dispatcher can determine the period of time for which the digital key is valid and also withdraw keys that have already been issued. The back end manages the data for vehicles, drivers, smartphones, and ECUs in the vehicle. It is the interface to the front end. The back end is where the digital keys are created and distributed to the smartphones of the drivers. The digital keys are created in accordance with the CCC (Car Connectivity Consortium). The back-end components run in the Bosch IoT cloud (Internet of Things).

Anti-theft systems

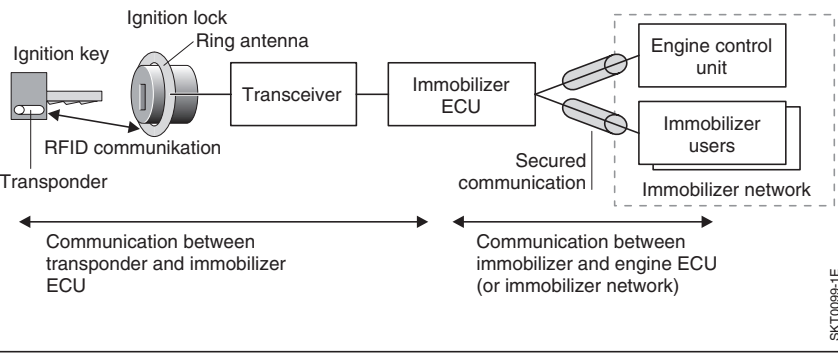
Once the driver has left the vehicle, the vehicle must be protected against unauthorized use. It must be locked and the windows must be closed. This is expressly determined in the German road traffic regulations (StVO) in §14 s. 2 [1].

According to §38a of the German road traffic licensing regulations (StVZO, [2]) motor vehicles must furthermore be equipped with a security device to protect against unauthorized use. Vehicles are for this purpose equipped with a steering lock (steering-wheel lock), which is for the most part connected to the ignition lock. When the ignition key is removed a bolt is enabled which then engages in a hole in the steering column when the steering wheel is moved. This renders the vehicle unsteerable. When the ignition key is inserted again the bolt is pulled out when the steering wheel is turned and the steering is enabled again.

This does not prevent the engine from being started by short-circuiting the ignition. Protection against this is provided by the electronic vehicle immobilizer.

A car alarm is designed to make stealing a vehicle or breaking into the vehicle difficult by issuing an acoustic and optical alarm.

Electronic vehicle immobilizer



The electronic vehicle immobilizer is a theft-deterrence device which is designed to prevent the vehicle from moving under its own power if the associated ignition key is not inserted. Without authentication (checking of an asserted identity) of the transponder integrated in the ignition key, the immobilizer prevents operation of the vehicle by preventing for example engine starting, gear selection, or release of the steering lock.

Since 1998, in accordance with EU Directive 95/56/EU [3], all passenger cars sold in EU countries have been required to be fitted with an electronic immobilizer. Similar regulations apply in many other countries. The electronic immobilizer is not to be confused with automotive alarm systems or with remote-keyless entry systems for remote control of the door locking system.

System design

The electronic immobilizer (Figure 1) is integrated in the vehicle electronics and consists of the following components.

Figure 1: Immobilizer system

Transponder
The transponder is integrated in the ignition key and consists of an antenna, a microprocessor for signal processing and data transfer, a non-volatile memory (EEPROM) for storing a cryptographic key, and a capacitor as an energy accumulator. Passive RFID transponders (Radio-Frequency Identification) in the long-wave range (125 kHz or 134.2 kHz) are typically used in the automotive industry. These do not have their own energy source and their range is limited to a few centimeters [4].

Transceiver
The transceiver (also called the "reader") is connected to a ring antenna which on account of the short range of the radio signal is located near to or directly on the ignition lock. The transmit/receive unit of the transceiver transmits and receives the radio signals via the antenna and relays them to the immobilizer ECU.

Immobilizer ECU
The immobilizer ECU (also called the immobilizer server) contains a microcontroller for performing the immobilizer-function and communicates both with the transceiver and with the engine ECU, and if necessary with further ECUs in the immobilizer network. The immobilizer function can, instead of being integrated in its own immobilizer ECU, also be integrated in another ECU, e.g., in the instrument cluster, in the on-board computer, or in the engine ECU.

The immobilizer function has the task of checking the authenticity of the ignition key and the transponder and enabling the immobilizer.

Engine ECU
The engine ECU receives the signal to enable the immobilizer from the immobilizer ECU via a cryptographically secured connection. Different switch-off paths are disabled without an active immobilizer enable signal, meaning that engine starting is not possible. Typical switch-off paths are starter, fuel pump, and fuel injection.

Immobilizer network
To enhance security the ECUs of further vehicle components are incorporated into the immobilizer network, e.g., the automatic transmission (gear selection or opening of the parking lock can thus be prevented) or the steering.

Users of the immobilizer network must satisfy heightened security requirements, including securing bus communication and measures to increase protection against manipulation ("hardware security").

Functional description
Communication between transponder and immobilizer ECU
Communication between immobilizer ECU with transceiver and transponder is effected via a radio link and is activated as soon as the ignition key is in range or when the ignition is turned on. The transceiver generates with its antenna an electromagnetic field, which is received by the transponder antenna. Through inductive coupling the transponder receives it energy, which is stored in a capacitor.

Data are transferred as a rule in a half-duplex process: Data from the transceiver to the transponder (downlink) and data from the transponder to the transceiver (uplink) are transferred in succession. The received data are processed by the transponder's IC (integrated circuit). To return data to the transceiver, the transponder does not generate its own electromagnetic field, but instead modulates the transceiver signal by means of load modulation. The transceiver registers the fluctuations and decodes them as a transponder data signal [4].

The aim of this communication is to authenticate the transponder in the ignition key. Here the authentication can be unilateral (only the transponder authenticates itself to the immobilizer) or reciprocal (both the transponder and the immobilizer authenticate themselves to each other).

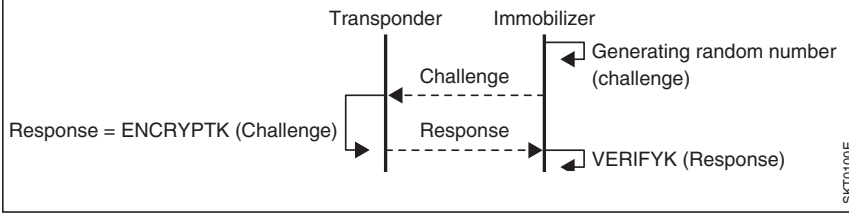
Authentication is performed in modern immobilizer generations according to the challenge-response scheme (see Figure 2). The prerequisite for this scheme is that the transponder and the immobilizer have a common, secret key K. The immobilizer transmits a challenge to the

transponder, which in turn converts and returns this by means of a cryptographic ENCRYPT function and the secret key K. Then the immobilizer performs the same calculation and compares the results (VERIFY). If the results match, the transponder has successfully authenticated itself to the immobilizer, i.e. proven it authenticity. A random number is typically used as the challenge with the aim of preventing attacks by recording and repeating, so-called replay attacks (see section entitled “Security”).

Communication between immobilizer and immobilizer users

The enable signal is transmitted by way of a cryptographically secured communication via the vehicle bus system to the engine ECU and if necessary the other users of the immobilizer network. Once the transponder in the ignition key has been successfully authenticated, the immobilizer is enabled by the immobilizer ECU and normal vehicle operation is possible.

The immobilizer is automatically activated again after the ignition key is removed.



Security considerations

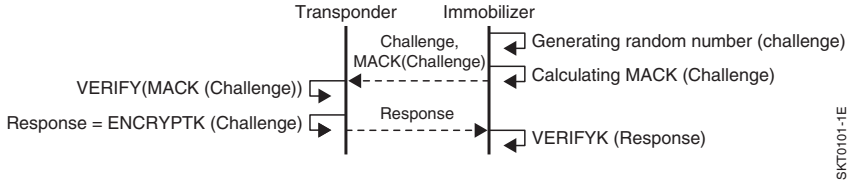
Both older and current generations of immobilizer systems have been successfully attacked in different ways, thereby showing up their weaknesses. Common weaknesses are incorrect implementations, deviations from standardized, cryptographic algorithms and processes, and the use of key lengths that are too short [5], [6], [7].

One requirement that is imposed on an immobilizer system is that the immobilizer even with great criminal application cannot be surmounted or can only be surmounted with great technical effort and financial expense. Attacks should furthermore not be scalable, i.e., knowledge of a successful attack on an individual vehicle should not be reusable for other vehicles. This is achieved among other things by the use of vehicle-individual or component-individual cryptographic keys.

To protect against so-called replay attacks, i.e., eavesdropping on and storing the communication for later use, a new random number (challenge) is generated in the challenge-response scheme for each authentication attempt. A valid authentication message that has been

Figure 2: Challenge-response scheme for transponder authentication
$ENCRYPT_K$: Encryption with the secret key K.
$VERIFY_K$: Comparison with internal calculation with the same key K.
Immobilizer is enabled if authentication successful.

eavesdropped on once is thereby rendered invalid for a later authentication attempt and can no longer be used.



Once limitation of the challenge-response protocol shown in Figure 2 is that the transponder cannot check the authenticity of the immobilizer. Figure 3 shows an extension of the existing protocol. The immobilizer generates a random number (challenge) and then calculates its MAC (Message Authentication Code), a checksum for authenticating the challenge. Both the challenge and its MAC are communicated to the transponder. The transponder checks the MAC and can thus ensure that the challenge comes from a known, authenticated immobilizer ECU. Only if the MAC is valid does the transponder proceed with the protocol as described above; otherwise the communication is aborted at this point. This prevents the transponder from reacting to any challenge and sending back the associated response [8].

Production and infrastructure requirements

The use of symmetrical, cryptographic processes imposes heightened requirements on the overall product life cycle of each component relevant to the immobilizer. In production the cryptographic keys must be generated and programmed in a secure environment. Components relevant to the immobilizer are reciprocally paired via their secret key so that when a part is exchanged the associated key must be programmed again and the new components "taught" again.

Further applications are the provision of replacement ignition keys (e.g., after loss) and the disabling of ignition keys after they are stolen. The actions can be authorized by the manufacturer in each case via a central key administration and a secured infrastructure and the secret keys made available.

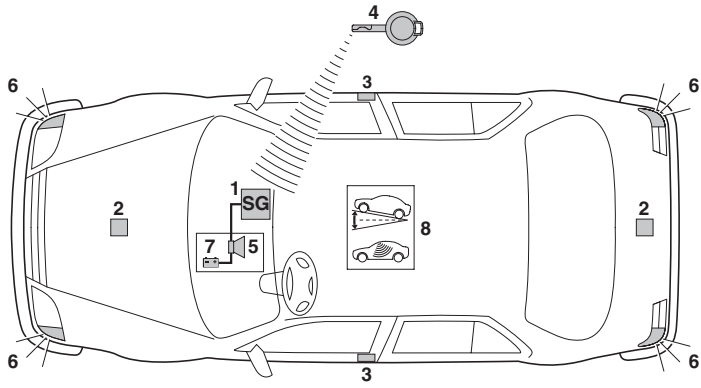
Theft-alarm system

Regulations
Theft-deterrent (alarm) systems must meet the requirements of ECE regulations R18 [9] and R116 [10]. An armed alarm system must be capable of issuing acoustic and visual alarm signals in the event of unauthorized intervention in the vehicle. Extended requirements result from insurance regulations in various countries.

Permissible alarm signals
– Intermittent sound signals
  (25 to 30 s duration, 1,800 to 3,550 Hz;
  min. 105 dB(A),
  max. 118 dB(A) at 2 m distance,
– visual flashing signals
  (max. 5 minutes).

System design
The alarm system comprises a central control unit, sensors that detect intervention, and an alarm siren (Figure 1).

Alarm detectors
– Door and hood contacts,
– interior monitoring,
– tilt sensor,
– self-monitoring of the alarm siren.



Alarm system control unit
Control of the alarm system is assumed by a control unit of the comfort electrical systems in the vehicle. The alarm system is armed or disarmed via the mechanical locks or via the radio remote control. When the command “Arm” is received, monitoring of the alarm detectors is activated. If required, selection buttons can be used to disable individual sensors. This deactivation applies once to the next “Arm” command.

Alongside the sensors, the alarm siren is also armed. Once the siren has assumed the “Armed” status, the control unit starts cyclical communication to monitor the lines. If an alarm is triggered, deactivation of the alarm (e.g. via the radio remote control) must lead to immediate termination of the alarm.

The control unit must ensure that the max. permitted number of alarms per alarm detector is not exceeded. Moreover, overlapping alarms must not lead to prolonged alarm output.

Alarm siren
The alarm siren comprises control-system electronics, a diaphragm as sound source, and a rechargeable battery for redundant power supply. The alarm tone is generated

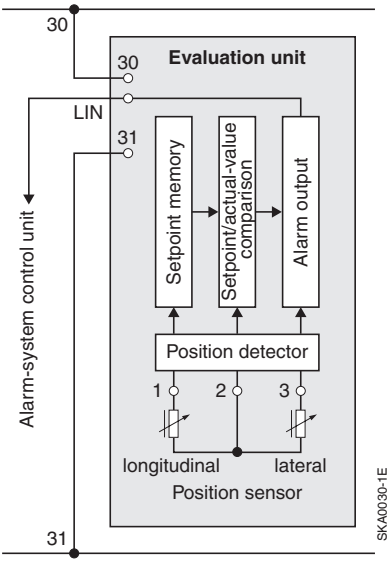


Figure 1: Theft-deterrent system
1 Alarm-system ECU, 2 Hood contact, 3 Door contact, 4 Key with radio remote control, 5 Siren, 6 Turn-signal lamps, 7 Battery, 8 Roof module with tilt sensor and interior monitoring.

by, for example, a piezo-loudspeaker. Communication with the control unit of the alarm system takes place across a serial single-wire bus (e.g. LIN). On the basis of a command from the control unit, the alarm siren can trigger the alarm or autonomously detect a manipulation. Here the following signals are monitored: cyclical communication, line contact to terminal 30 and terminal 31, voltage gradient of the vehicle battery, and overvoltage e.g. due to external supply. The aim is to recognize manipulations reliably and to prevent false alarms.

Tilt sensor
The task of the tilt sensor is to detect changes in the vehicle position caused by jacking up or towing the vehicle. A very sensitive acceleration sensor is deployed here. Its signal depends on the angle in relation to gravity. In order to monitor both the longitudinal and transverse axes of the vehicle, twin-axis micro-mechanical sensors are deployed (Figure 2). Particularly important is the reliable prevention of false alarms, as the vehicle rolling, e.g. due to wind, may not lead to an alarm.

Figure 2: Electronic wheel-theft and tow-away protection

Interior monitoring
The reflections of an ultrasound or a microwave field are analyzed. If the modification exceeds a comparative value, the alarm is triggered. Here, too, reliable prevention of false alarms is an important criterion.

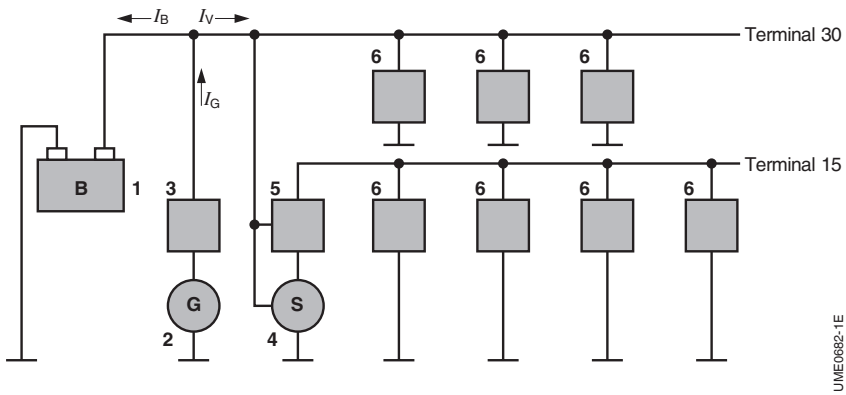
12 V vehicle electrical systems

Function and requirements

The vehicle electrical system of a motor vehicle with drive via an internal-combustion engine (classic drive) comprises the alternator as the energy converter, one or more batteries as the energy accumulators, and the electrical equipment as consumers. Figure 1 shows the schematic diagram of a vehicle electrical system. The nominal voltage of the battery is 12 V; this system is called a 12 V vehicle electrical system accordingly.



The energy from the battery is used to start the vehicle engine, hence the designation starter battery. This is performed via the starter in the classic drive systems. During vehicle operation, the ignition and fuel-injection system, the control units, the safety and comfort and convenience electronics, the lighting, and other equipment have to be supplied with power. An alternator supplies the required electrical power for these components and also to charge the battery.

Heightened comfort and safety requirements resulted and continue to result in a significant increase in the power demand in the vehicle electrical system. Added to this is the continuing trend towards the electrification of ever more vehicle components (e.g., seat adjustment, electric parking-brake system, electric steering servo). Driver-assistance systems and infotainment systems, which are still to be supplied with power even when the engine is stopped, have in the meantime found their way into the subcompact-car segment as well.

Electric and hybrid vehicles also have an electrical system for the electric drive as well as the 12 V vehicle electrical system. Here, however, the 12 V battery is supplied not by an alternator but instead by a DC/DC inverter, which transforms the high voltage from the additional electrical system into the voltage required for the 12 V electrical system (see Electrical systems for hybrid and electric vehicles).

Power of the consumers in the 12 V vehicle electrical system

Consumer classification

The electrical consumers in the 12 V vehicle electrical system have a variety of switch-on durations. Here the operative distinction is between:

– continuous loads, which are always switched on (e.g., electric fuel pump, engine management),
– long-term loads, which are switched on where necessary and then remain on for an extended time (e.g., low-beam headlamps, car radio, electric radiator fan),
– short-term loads, which are only switched on for brief periods (e.g., turn-signal lamps, stop lamps, electrical seat adjustment, power-window units).

Running-time-dependent electrical load requirements

The electrical load requirements encountered during vehicle operation are not constant. The first minutes after startup are generally characterized by high demand (e.g., heated rear window, seat heating, door-mirror heating), followed by a sharp drop in electrical load requirements. These consumers are switched off after a few minutes. The electrical load requirements are then determined predominantly by the continuous loads and the long-term loads. Table 1 shows examples of typical consumers.

No-load-current consumers

Different ECUs and consumers require a power supply even when the vehicle is parked. The no-load current is composed of the sum total of all these switched-on consumers. Most of these consumers switch off shortly after the engine is turned off (e.g., interior lights). Some, however, are always active (e.g., anti-theft alarm system).

An unexpectedly high no-load current can also occur when, for example, shutdown of the ECU interconnection does not work correctly or recurring “Wake-Ups” cause an ECU to frequently reactivate the interconnection when the vehicle is parked. The control unit networking must be configured and validated for this.

The no-load current must be supplied by the battery. The maximum value for the no-load current is defined by the vehicle manufacturers. Battery dimensioning is based among other things on this value. Typical values for the no-load current in a passenger car are approx. 3 to 30 mA.

Table 1: Installed consumers in a 12 V vehicle electrical system taking account of the switch-on duration (examples)

Electrical consumer	Power consumption	Average consumer power
Engine management with electric fuel pump	250 W	250 W
Radio	20 W	20 W
Side-marker lamps	8 W	7 W
Low beam (dipped beam)	110 W	90 W
License-plate lamp, tail lamps	30 W	25 W
Indicator lamps and instruments	22 W	20 W
Heated rear window	200 W	60 W
Fan for interior heating	120 W	50 W
Electrical radiator ventilator	120 W	30 W
Windshield wiper	50 W	10 W
Stop lamps	42 W	11 W
Turn-signal lamps	42 W	5 W
Fog lamps	110 W	20 W
Rear fog warning lamp	21 W	2 W

Design and operating principle

Schematic diagram

The electric system in a motor vehicle can be represented as the interaction of the energy converter (alternator), the energy accumulator (battery) and the consumers (Figure 1).

The alternator is driven via the V-belt by the crankshaft and converts mechanical energy into electrical energy. The alternator regulator limits the output power such that the desired voltage set in the regulator is not exceeded (14.0 to 14.5 V).

When the ignition key is removed, only a few consumers are supplied with voltage (e.g., anti-theft alarm system, car radio, auxiliary heating). The terminal via which these consumers are supplied is called “terminal 30” (continuous plus).

The other consumers are connected to “terminal 15”. When the ignition switch is in the “ignition on” position, the battery voltage is applied to this terminal so that now all the consumers are connected to the power supply.

Charge balance

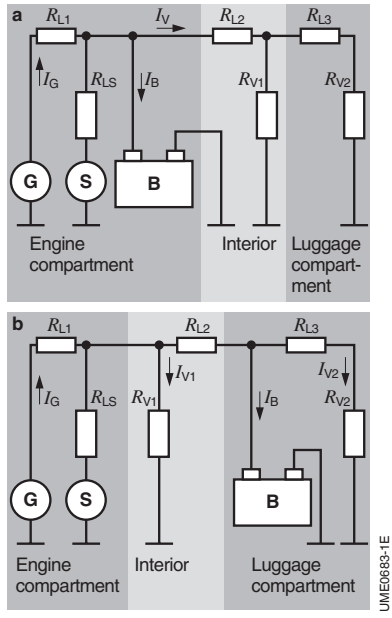
The nominal output of alternators in the 12 V vehicle electrical system ranges from approx. 1 kW in subcompact-size cars to over 3 kW in the upper class. This is less than the consumers need in total. In other words, the battery must also supply power at times during vehicle operation. An equalized battery charge balance must always be guaranteed through the choice and dimensioning of battery, alternator, starter and the other consumers in the electrical system so that the internal-combustion engine can always be started and, when the engine has been switched off, specific electrical consumers can still be operated for an appropriate period of time.

The alternator supplies current (I_G, Figure 1) when the engine is running. To be able to charge the battery, the alternator must increase the vehicle-system voltage above the battery open-circuit voltage. However, the alternator is only able to do this when the cut-in consumers do not demand more current than it can supply. If the equipment current draw I_V in the vehicle electrical system is greater than the alternator current I_G (e.g., when the engine is idling), the battery is discharged. The vehicle system voltage falls to the voltage level of the battery from which current is drawn. If the equipment current draw I_v is less than the alternator current output I_G, a proportion of the current flows to the battery and acts as a battery charging current, I_B. The vehicle system voltage increases to the setpoint value specified by the voltage regulator.

The maximum alternator current is very much dependent on the rotational speed and the alternator temperature. When the engine is idling, the alternator can only supply 55 to 65 % of its nominal output. However, immediately after a cold start at low outside temperatures, the alternator is able from medium engine speed to supply the vehicle electrical system with up to 120 % of its nominal output. When the engine is hot, the engine compartment heats up, depending on the outside temperature and engine load, to 60 to 120 °C. High engine-compartment temperatures cause high winding resistances, which reduce the maximum alternator output.

Battery installation locations

In most cars the battery is located in the engine compartment. However, a large battery (e.g., 100 Ah) takes up a lot of space and sometimes, when the amount of space available in the engine compartment is restricted, may not be able to be installed there. Another argument against installing the battery in the engine compartment is the potentially high ambient temperatures. As an alternative, the battery may be installed in the luggage compartment.



Effect of installation location on charge voltage

The line between a battery installed in the engine compartment and the alternator is shorter than for a battery installed in the luggage compartment. This affects the line resistance and thus directly the voltage drop on the cable. Voltage drops can be minimized by suitable conductor cross-sections and good connections with low contact resistance, even after a long service life.

Figure 2a shows the conditions for installation in the engine compartment. A battery installed in the luggage compartment requires a longer supply line with the additional line resistance R_{L2} (Figure 2b). Because of the higher voltage drop, the charge voltage for a battery installed in the luggage compartment is lower. The additional voltage difference caused by R_{L2} can be balanced by increasing the set-point alternator-voltage value. The power to be provided by the alternator increases as a result.

Effect of installation location on startability
Engine startability is dependent on the voltage applied at the starter. The higher this voltage, the higher the starter speed during the starting sequence. Because of the high starter current, the resistance of the supply line has a crucial effect on this voltage. In the case of the variant with the battery installed in the luggage compartment, the line between the battery and the starter is longer than for the battery installed in the engine compartment; accordingly, the resistance and with it the voltage drop are higher. Better startability is assured when the battery is installed in the engine compartment with short lines to the starter.

R_V Equipment resistances,
I_G Alternator current,
I_V Equipment current draw,
I_B Battery charging current.

Effect of ambient temperature
High temperatures, as can be encountered in the engine compartment, intensify aging effects in the battery (e.g., corrosion of the battery and water loss due to gassing), which have a negative impact on battery service life. High temperatures in the battery can be reduced by shielding.

The charge acceptance of the batteries is restricted at low battery temperatures, i.e., the battery takes in less charge, which can lead to a low state of charge. Low states of charge in turn facilitate aging effects such as sulfating, which lead to reduced usable capacity and therefore shorter service life.

Effect of installation location on voltage stability
Because the battery can only be charged with direct current, the alternating current generated in the alternator must be rectified. This job is performed by a diode rectifier integrated in the alternator (Figure 3). Rectification of the alternating voltage creates a pulsating direct voltage. Furthermore, the switching of the diodes – when the current is commutated from one diode to the next – generates high-frequency voltage oscillations, which are smoothed to the greatest possible extent by the interference-suppression capacitor installed in the alternator.

Electronic consumers (e.g., ECUs) can be disrupted or even damaged by the voltage peaks or the voltage ripple. The battery can use its large capacity to smooth the voltage fluctuations. However, because of the line resistance R_L between the alternator and the battery (Figure 3), they are not completely suppressed at the alternator. When the consumers are connected on

the battery side (Figure 4a) or after the battery (e.g., R_{V1} and R_{V2} in Figure 2a), they are supplied with the extensively smoothed system voltage. When the consumers are connected on the alternator side, i.e., directly to the alternator (Figure 4b), they are exposed to a greater voltage ripple and greater voltage peaks.

Electrical devices (consumers) which feature a high power input and relative insensitivity to overvoltage should therefore be connected close to the alternator, whereas voltage-sensitive loads with a low power input should be connected close to the battery.

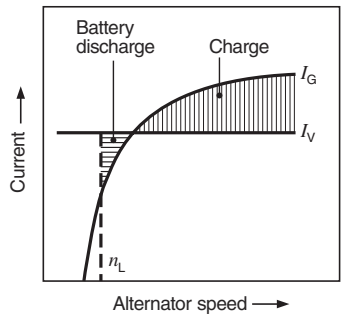
Interaction of the components



Current output of the alternator
Important component parts of the alternator are the stator (Figure 3) and the rotor, which is driven via the V-belt by the crankshaft. An alternating voltage is induced in the three stator windings (see Alternators) when a current flows in the rotor coil (excitation current) and a magnetic field is thereby built up. The excitation current is tapped from the generated alternator current (self-excitation). The induced voltage is dependent on the rotor speed and the level of the excitation current. The generated alternating voltage is rectified by diodes.

The voltage induced in the alternator is dependent on the alternator speed and thus on the engine speed. Therefore the voltage is low at low speeds. For an engine idling speed of n_L, the alternator can only supply some of its rated current if it has a conventional turns ratio (crankshaft speed to alternator speed) ranging from 1:2.5 to 1:3 (values for passenger cars; turns ratio is much higher for commercial vehicles) (Figure 5). The rated current is achieved at full load at an alternator speed of 6,000 rpm. The mean speed attained during vehicle operation must be sufficiently high in order to achieve the nominal alternator output. Driving cycles involving extensive levels of idling are particularly critical, because the available alternator output is so low that the battery is discharged when the electrical load requirements are high.

If the alternator voltage is higher than the battery voltage, a battery charging current flows into and charges the battery. The voltage is limited by the alternator regulator so as to maintain a system voltage of approx. 14 V.

Power generation by the alternator also affects fuel consumption. The increased consumption for 100 W output is in the order of 0.17 l per 100 km driven and is dependent on the efficiency of both the alternator and the internal-combustion engine.

Figure 5: Alternator current output I_G as a function of alternator speed
I_V Equipment current draw,
I_G Alternator current,
n_L Engine idle speed.

Voltage regulation in the vehicle electrical system
Generating the excitation field when starting
A magnetic field is required in the rotor to enable a voltage to be induced in the stator windings of the alternator. Self-excitation is not possible at low speeds after starting. In this phase the battery delivers the excitation current (external excitation).

The torque of an alternator running under load would hinder the starting sequence and idle stabilization of the internal-combustion engine. Alternator regulators therefore correct the excitation current during the starting phase to a low level (controlled pre-excitation). Current generation is delayed until the engine has run up to speed (Load-Response Start, LRS). Until this point the consumers are supplied by the battery.

Voltage regulation during vehicle operation
The excitation current is tapped from the generated alternator current (self-excitation). The alternator regulator adjusts the excitation field by way of a pulse-width-modulated (PWM) current in the rotor winding in such a way that the voltage at B+ (Figure 3) corresponds to the specified setpoint value. The frequency of the PWM signal is 40 to 200 Hz; the pulse duty factor is dependent on how much power is demanded by the consumers. In the case

of a load variation the vehicle system voltage changes, whereupon the alternator regulator adjusts the excitation field by adapting the PWM signal in such a way that the voltage is compensated.

The connection of the excitation winding is known as DF (dynamo field). The alternator regulator outputs the PWM signal as a DFM (DF monitor) to notify other ECUs of the alternator capacity utilization.

The alternator regulator requires the battery-voltage value in order to regulate. It obtains this value via terminal B+. In the case of a long supply line and high currents on the line between alternator and battery, the voltage difference between the battery and the regulator can be high due to the high voltage drop on the line to the extent that power generation by the alternator is too low and the battery is possibly insufficiently charged. This problem can be remedied by the S-terminal, which supplies the regulator with battery voltage via a cable which is separately connected to the battery positive terminal.

The alternator-regulator bus connection (e.g., via LIN bus) allows the system to vary the setpoint value to which the voltage is to be regulated. This makes possible functions such as, for example, recuperation, with which the setpoint value is increased in overrun mode so that the battery can be charged more effectively. The Load-Response Driving (LRF) function effects ramp regulation of the alternator voltage back to the setpoint value during vehicle operation after the connection of a high load and the associated sudden drop in the alternator voltage. This function prevents the alternator from abruptly subjecting the engine to load.

Charge indicator lamp

The charge indicator lamp is activated by the alternator regulator. It comes on with "ignition on" and goes out when the alternator is supplying current. The regulator activates the charge indicator lamp as soon as it detects a fault (e.g., alternator failure due to V-belt break, open circuit or short circuit in the excitation circuit, open circuit in the charging cable between the alternator and the battery).

Charging the battery

Due to the chemical processes that take place in the battery, the ideal battery charge voltage has to be higher at low temperatures and lower at high temperatures. The gassing voltage curve shows the maximum permissible voltage at which the battery does not produce gas significantly. The alternator regulator limits the voltage if the alternator current I_G is greater than the sum of the consumer equipment current draw I_V and the temperature-dependent, maximum permissible battery charging current I_B.

Alternator regulators are normally mounted on the alternator. If there are significant deviations between the temperatures of the voltage regulator and the battery electrolyte, it is better to monitor the voltage-regulation temperature directly at the battery. This is possible in vehicles with a battery sensor. The temperature value is conveyed by means of a communication interface (e.g., LIN bus) (see Battery sensor).

The arrangement of the alternator, battery and consumers influences the voltage drop on the charging cable and thus the charge voltage. The total current $I_G = I_B + I_V$ flows through the charging cable if all electrical equipment is connected to the battery. The charging voltage is accordingly less due to the high voltage drop. If all consumers are connected on the alternator side, the voltage drop is lower and the charging voltage is higher. The alternator regulator can take into account the voltage drop by measuring the actual voltage value directly at the battery via the S-terminal.

Design of the vehicle electrical system

Dynamic system characteristic curve

The dynamic system characteristic curve maps the relationship between battery voltage and battery current during a driving cycle (Figure 6). The envelopes reflect the interrelationships between the battery, alternator, and consumers in conjunction with temperature, engine speed, and speed ratio from engine to alternator. A large area in the envelope means that, with this type of vehicle electrical system, significant voltage fluctuations are occurring in the selected driving cycle and that the battery undergoes more powerful cyclization, i.e., its state of charge experiences powerful temporal changes. The system characteristic curve is specific to every different combination and every set of operating conditions, and is therefore a dynamic curve. Measuring systems can be connected to the battery terminals to plot the dynamic system characteristic curve.

Charge-balance calculation

By means of a computer program, the battery charge level is calculated from the consumer load and the alternator output power at the end of a specified driving cycle. Rush-hour driving (low engine speeds) combined with winter operation (low charging-current input to the battery) is regarded as a normal passenger-car driving cycle. The battery must maintain a stable charge balance even under these very unfavorable conditions for the energy balance of the vehicle electrical system.

The charge-balance calculation is used as the basis for defining the design of the alternator and battery.

Driving profile

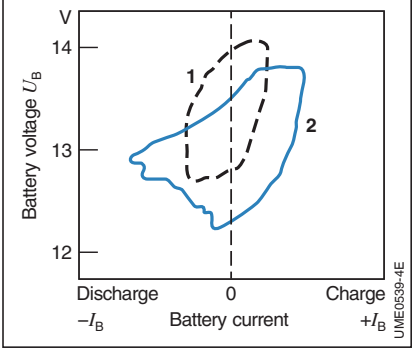
The driving profile as an input variable for the charge-balance calculation is represented by the cumulative-frequency curve of the engine speed (Figure 7). It describes how often a specific engine speed is reached or exceeded.

In urban driving situations in commuter traffic, a car's engine is running at idle speed for a large part of the time due to the frequency of stops at traffic lights and consequently high traffic density.

A city bus running on scheduled routes has a high idle percentage time due to interruptions in driving at bus stops. Another factor that has a negative effect on the battery's charge balance is electrical consumers that are operated when the engine is switched off. Long-distance buses generally spend only a small proportion of the time with the engine at idle speed, but on the other hand may have periods when consumers with a high power input are operated with the engine switched off.

Figure 6: Dynamic system characteristic curves (envelopes for city driving)

1 Characteristic curve with large alternator and small battery,
2 Characteristic curve with small alternator and large battery.



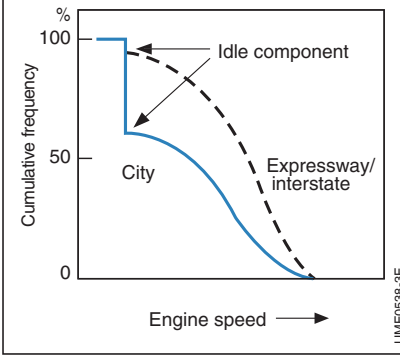


Figure 7: Cumulative frequency of engine speed in city and expressway/interstate driving

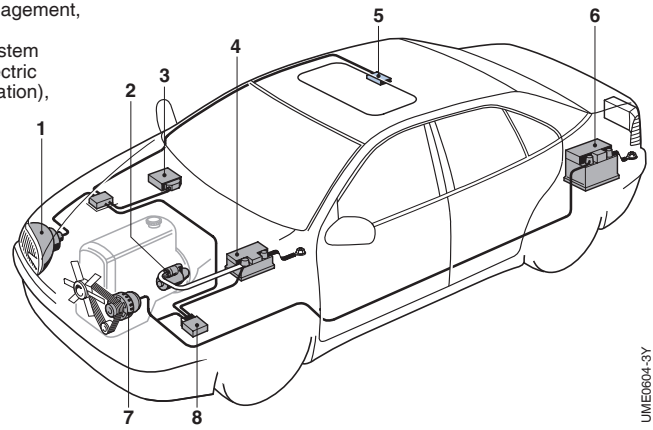
Vehicle-electrical-system simulation
In contrast with this non-analytical approach to charge-balance calculations, the situation in relation to the vehicle-electrical-system energy supply can be calculated at any time during operation using model-based simulations. They can also include electrical system management systems and assess their effectiveness.

In addition to adjusting current levels in the battery, it is possible to record the vehicle-system voltage characteristic curve and the battery cycle at any time during a trip. Calculations performed using vehicle-electrical-system simulations are always useful when it comes to comparing electrical-system topologies and assessing the effectiveness of consumers with a high dynamic response or only brief switch-on durations.



Electrical-system structures

One-battery vehicle electrical system
Figure 1 depicts a one-battery vehicle electrical system, as featured predominantly in passenger-car applications. Working as an energy accumulator is a battery which both supplies the current for the starting sequence and delivers the power supply to the consumers when the engine is stopped and thus there is no alternator output or insufficient alternator output in idling phases. This is the most widely used concept today in that it is the most cost-effective solution for supplying power in motor vehicles.

In the design of a battery for the one-battery electrical system which supplies both the starter and the other consumers in the vehicle electrical system, a compromise has to be found between different requirements. During the engine starting sequence, the battery is subjected to high current loads (300 to 500 A). The associated voltage drop has an adverse effect on certain electrical equipment (e.g., undervoltage reset on units with microcontrollers) and should be as low as possible.

By contrast, only comparatively low currents flow during standard vehicle operation. Battery capacity is the salient factor in providing a reliable current supply. Nei-

8 Electrical-system ECU.

ther properties – output nor capacity – can be optimized simultaneously.

Two-battery vehicle electrical system
In vehicle electrical systems with two batteries – starter battery and general-purpose battery – the "high power for starting" and "general-purpose electrical supply" functions are separated by the vehicle electrical system control unit (Figure 8) to make it possible to avoid the voltage drop during the starting process, while ensuring reliable cold starts, even when the charge level of the general-purpose battery is low.

Starter battery (starting battery)
The starter battery must supply a high amount of current for only a limited period of time (during starting). It is therefore designed for a high power density (high power for low weight). Compact dimensions allow installation in the immediate vicinity of the starter motor with short connecting cables (low voltage drop on the line). The capacity is reduced.

General-purpose battery
This battery only supplies the vehicle electrical system (excluding the starter). It supplies currents to the electrical-system consumers (e.g., approx. 20 A for the engine-management system) and must therefore be able to store and provide large amounts of energy. It also has a high cycle stability. This means it can be charged and discharged very often before the performance criteria of the battery are no longer met. Dimensioning is based essentially on the capacity reserves required for activated consumers, the consumers that operate with the engine switched off (no-load-current consumers, e.g., receiver for central-locking radio remote control, anti-theft alarm system), and the minimum permissible charge level.

Vehicle power supply control unit
The vehicle power supply control unit in a two-battery vehicle electrical system separates the starter battery and the starter from the rest of the vehicle electrical system provided this can be supplied with sufficient power by the general-purpose battery. It therefore prevents the voltage drop that occurs during starting, affecting the performance of the vehicle electrical system. When the vehicle is parked, this prevents the starter battery from becoming discharged by electrical equipment that draws current when switched on and by no-load-current consumers.

The 12 V battery can be charged at higher voltage than the usual alternator voltage in the vehicle. The voltage level is limited by consumers, e.g., the bulbs, whose service life severely deteriorates with the voltage. By separation of the starter battery from the remainder of the vehicle electrical system, there are theoretically no limits for the charge voltage level within the starter battery. It can therefore be raised to the "ideal" value by means of a DC/DC converter (e.g., 15 V). This is dependent on the temperature and on the state of charge. Charging duration is minimized with the increased charge voltage.

If there is no charge in the general-purpose battery, the vehicle power supply control unit is capable of provisionally connecting both vehicle electrical systems. This means that the vehicle electrical system can be sustained using the fully-charged starter battery. In another possible configuration, the vehicle power supply control unit for the starting operation would connect only the start-related consumers to whichever battery was fully charged.

Electrical-system parameters

State of charge
The state of charge of the battery (SOC) is one of the most important parameters in the vehicle electrical system. It can be defined as the ratio of the amount of charge still stored in the battery (actual state of charge) to the maximum amount of charge which the fully charged battery when new can store:

$$\text{SOC} = \frac{Q_{\text{act}}}{Q_{\text{max}}} .$$

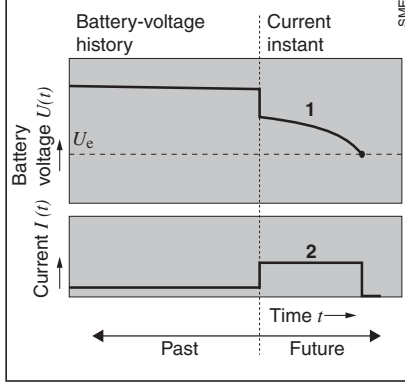
The value Q_{max} is obtained when a fully charged battery is discharged at discharge current I_{20} – corresponding to a twentieth of the nominal capacity in amperes (5 A for a 100 Ah battery) – until the cutoff voltage of 10.5 V is reached. The amount of charge which was drawn during this discharge process corresponds to Q_{max}.

Since in this way Q_{max} is only accessible by means of one measurement (integral of the current over the time, i.e., current and time measurement), the definition can also frequently be provided by the nominal capacity of the battery, which can be found on the label, where: $Q_{\text{max}} = K_{20}$ (nominal).

The currently stored amount of charge Q_{act} is obtained from the difference between Q_{max} and the amount of charge drawn during the discharge of the fully charged battery.

The state of charge of the battery correlates directly with the electrolyte density, where furthermore the steady-state voltage of the battery is proportional to the electrolyte density. The voltage value which is obtained when a stable voltage final value is assumed after the battery charging or discharging process is referred to as steady-state voltage. This can, owing to the slow diffusion and polarization processes in the battery, take several days, especially after long charging phases. The steady-state voltage is measured at the terminals.

The state of charge is defined as follows:



$$\text{SOC} = \frac{(U_{\text{current}} - U_{\text{min}})}{(U_{\text{max}} - U_{\text{min}})}$$

where
U_{current}: Current steady-state voltage.
U_{max}: Steady-state voltage of the fully charged battery (SOC = 100 %).
U_{min}: Steady-state voltage of the battery at SOC = 0 %. Because the dependence of the steady-state voltage on the state of charge is nonlinear for low states of charge (approx. less than 20 %), the value linearly extrapolated to SOC = 0 % must be used here.

In this way, it is possible to infer the state of charge from the measured steady-state voltage.

Functional and performance capability
The capability of the battery to meet a specified functional or performance requirement in its current state – e.g., providing the starting power for the internal-combustion engine – is called the SOF (state of function). The SOF is application-specific and can therefore not be defined generally. For example, the SOF can be used not only as a measure of startability, but also for evaluating the current performance capability of the battery to supply other electrical heavy current consumers, e.g., electrical power steering.

Figure 9: Determination of the SOF value by calculating the voltage curve under load
1 Predicated battery voltage $U(t)$ for the given virtual current profile $I(t)$,
2 Virtual current profile.
U_e Basis for the SOF calculation.

The current performance capability of the battery is evaluated using the SOF by precalculating the voltage drop at battery load with a predefined current profile. If the precalculated (predicted) battery voltage U_e drops below a specified threshold, this means that the battery is no longer delivering the required performance (e.g., for an engine start) (Figure 9).

Moreover, it is also possible to query the current remaining charge or the discharge duration which states how long the battery can continue to deliver the required performance. An application example of this is how long a vehicle can be parked at a known no-load current consumption without losing startability. In this case, the SOF does not provide the voltage drop at high-current load, rather the remaining charge reserve or the discharge duration until the startability threshold is no longer reached (Figure 10).

As already mentioned, the SOF is determined on the basis of the current battery state, i.e., it depends on the current state of charge (SOC), the battery temperature, and the state of health (SOH) of the battery. These variables have to be determined by the battery-status recognition (see Battery sensor) for SOF calculation.

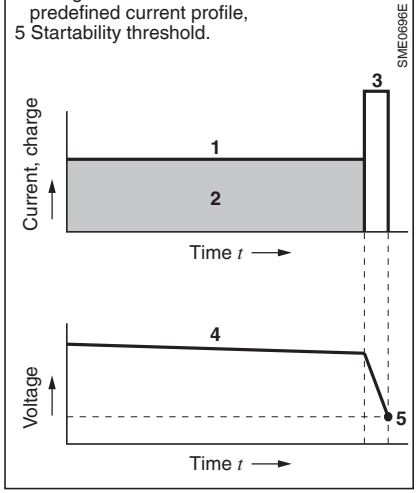
State of health

Depending on the respective operating and ambient conditions, different aging processes take place in the lead battery used in the 12 V vehicle electrical system, which can, for example, lead to an increase in internal resistance (caused by corrosion) or to capacity losses (caused by active mass loss or sulfating) and therefore deteriorate the general performance and storage capability of the battery, i.e. its SOH (state of health) over the service life.

The state of health of the battery with regard to its storage capability can, for example, be expressed by the ratio of current capacity K_{20} to nominal capacity of the battery when new K_{20new}:

$$\text{SOH} = \frac{K_{20}}{K_{20new}} \cdot 100\ \%.$$

Further (application-dependent) SOH quantities can be derived from the corresponding SOF variables by calculating them not for the current battery state, rather with defined values for state of charge (e.g., SOC = 100 %) and battery temperature (e.g., 25 °C) to achieve the desired aim of only factoring the dependence on the state of health into the SOH quantity.



Whereas the SOF states how well a performance requirement can be met in the current state of the battery, the corresponding SOH variable states how well the battery will meet this performance requirement generally in the current state of health. For example, in this way an SOH variable which calculates the battery's remaining minimum performance capability for a start-stop function can be used to permanently deactivate this function when the battery is severely aged, in order to prevent the risk of breakdowns.

Alternator capacity utilization

The current flowing in the alternator excitation winding determines the voltage induced in the stator windings. The alter-

Figure 10: Calculation of the SOF value based on the available charge reserve

This calculation is used to determine the charge reserve or the time duration after which under no-load current the startability threshold will be reached.

5 Startability threshold.

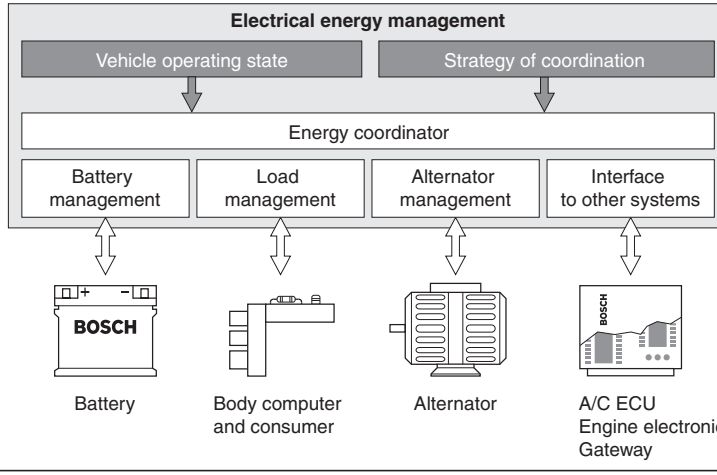
nator regulator regulates the required excitation current by means of a pulse duty factor (PWM signal). DF (dynamo field) is the terminal through which the excitation current is supplied (Figure 4). The pulse duty factor of the PWM signal indicates the alternator capacity utilization, i.e., whether the alternator still has reserves and can supply even more current for additionally connected loads.

The alternator regulator additionally outputs this signal as a DFM signal (DF monitor). Regulators with a bus interface apply this pulse duty factor to the bus (e.g., LIN bus). The excitation current is also output in amperes. Different ECUs evaluate the DFM signal in order, for example, to switch off the seat heating or the windshield heater when the alternator is subject to high capacity utilization.

Electrical energy management

Motivation

Reduced fuel consumption



One of the primary goals of motor-vehicle manufacturers is to reduce fuel consumption and greenhouse gases, in particular CO_2. This is achieved by optimizing the energy flows in motor vehicles. Measures to achieve this goal include:

– Avoiding idling losses by using the start-stop function (automatic engine switch-off and restarting for example when waiting at traffic signals on red).
– Increasing the efficiency of electrical power generation by optimizing the alternator and applying intelligent alternator activation (recuperation).
– Electrically driven accessories to facilitate activation to suit demand by means of isolation from the internal-combustion engine.

Electrical power demand

Additional comfort and convenience functions and electrified accessories give rise to increasing electrical power requirements and at the same time to a reduced range of speed for electrical power generation (e.g., due to start-stop operation). New comfort, convenience and safety functions (e.g., electrical power steering, electric water pump, PTC auxiliary

Figure 11: Electrical energy management (EEM)

heater, electric climate control in vehicles with start-stop function) require additional electrical power, so much so that it is useful to integrate an electrical energy management system (EEM).

Purpose of electrical energy management

Electrical energy management controls the energy flows and at the same time safeguards the electrical power supply in order to maintain vehicle startability and to reduce breakdowns caused by flat (discharged) batteries. Electrical energy management also stabilizes the battery voltage and optimizes the availability of comfort and convenience systems – even when the engine is stopped. This can be achieved by safeguarding a positive or at least equalized charge balance during vehicle operation and by monitoring the power demand when the engine is stopped. Furthermore, peak loads can be reduced by the coordinated switching of electrical consumers. This is coordinated in the electrical energy management system (Figure 11).

The effects of the measures taken sometimes conflict with one another. For example, switching off comfort and convenience consumers results in loss of comfort and convenience, while disabling the start-stop function results in increased fuel consumption. Different vehicle manufacturers prefer different measures, and the possible measures for safeguarding the charge balance are prioritized accordingly.

Functions of electrical energy management

No-load-current management

The no-load-current management implemented in the battery sensor by means of software regularly monitors the battery status and thus startability when the engine is stopped. With the aid of precise battery-status recognition it is possible to optimize the availability of consumers by means of no-load-current management, i.e., the operating time of the comfort and convenience consumers can be maximized. In the event of an imminent loss of startability, electrical energy management can, for example, send a message to the display module in order to notify the user. In addition, when the startability limit is approached, load management will reduce the power consumption (e.g., by reducing the power consumption of the A/C fan) right down to shutting down individual consumers in order to maintain startability for as long as possible. Examples of such comfort and convenience consumers are the auxiliary heater, infotainment, navigation system, and radio.

Energy management during vehicle operation

The function of electrical energy management with the alternator active is, in addition to load management, principally alternator management including a recuperation function and the energy-management interface to other systems such as, for example, engine management.

Switching of consumers

Load management coordinates the activation and deactivation of consumers in order to reduce power peaks. Load management is also involved in controlling the high-performance heating systems (windshield heater and PTC auxiliary heater).

In vehicle operation, too, safeguarding restartability is the primary function of electrical energy management. In critical battery states, load management reduces the electrical power demand in order to recharge battery as quickly as possible. Reservoir-type comfort and convenience consumers (heating systems) are switched back by preference, because intelligent activation can be used to delay for as long as possible perceptible deviations from the nominal performance.

There are limits to deactivating comfort and convenience functions in that this will only be accepted by the user in rare exceptional circumstances. The vehicle electrical system must therefore be configured in such a way that these situations only occur rarely. Noticeable effects must be indicated to the user in order to explain the performance that is deviating from normal operation.

Increasing the alternator output

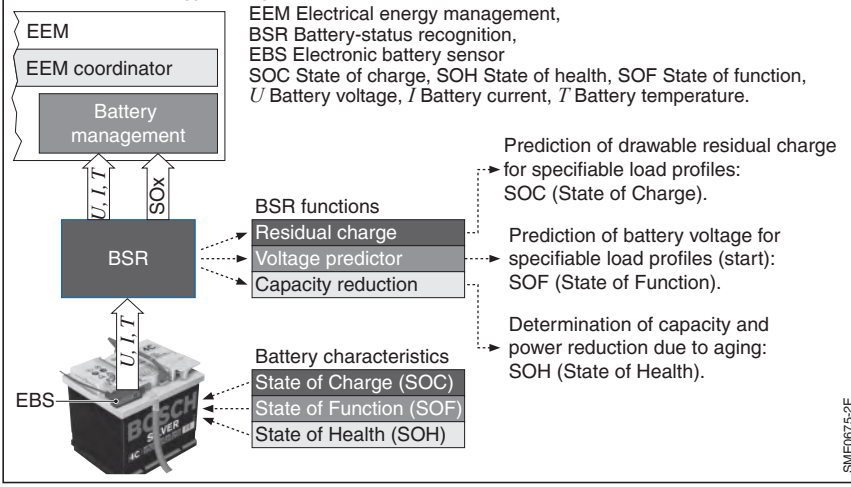
As an alternative or complement to reducing the electrical power demand, it is possible by increasing the engine speed to increase the electrical power generation by

the alternator (e.g., idle-speed increase or disabling of engine stop during start-stop operation). For example, to increase the idle speed, electrical energy management issues a request via the data bus to the engine management. These measures have a direct influence on fuel consumption and noise generation; they must therefore be optimally matched to the individual vehicle.

During a the vehicle's kinetic energy is converted at least partially into electrical energy and delivered to the battery for storage. This function requires an alternator that can be controlled via an interface to input the desired alternator voltage and a battery sensor for recognizing the battery status. The function of the battery sensor itself can be partitioned in the engine electronics, a gateway or a body computer.

Recuperation

During overrun fuel cutoff an increased desired voltage is input for the alternator in order to charge the battery intensively. Electrical power is generated at this operating point without fuel consumption. In driving states with poor efficiency in terms of electrical power generation the alternator voltage is decreased and the battery slowly discharged again in order to minimize the fuel demand for electrical power generation.



A fully charged battery cannot absorb charge. For this reason, recuperation is only possible with a partially charged battery (partial state of charge, PSOC). This is a departure from the conventional charging strategy, the objective of which is to achieve as fully charged a battery as possible. A minimum battery status required for startability must not under any circumstances be undershot, i.e., the current battery status must be known to electrical energy management.

The recuperation function results in an increased cyclical variation of the battery, the influence of which on battery aging must be tested on an application-specific basis. The use of AGM batteries (absorbent glass mat) to increase the possible energy throughput (throughput in Ah over the service life, the throughput critical to service life increases by a factor of 3) is therefore recommended.

The recuperation algorithm must take into account the influence of voltage changes on the consumers, since these can be observable (e.g., change in the speed of the A/C fan or light flickers).

Recuperation provides for fuel savings in the range of 1 to 4 %, depending on the cycle and configuration of the function.

Figure 12: Interaction of battery sensor, battery-status recognition, and electrical energy management

Battery-status recognition and battery management

Function

A crucial element to sound electrical energy management is a battery-status recognition facility (BSR) which reliably calculates the capability of the battery. Algorithms for battery-status recognition normally use as input variables the measured variables of battery current, voltage and temperature. On the basis of these variables the state of charge (SOC), the state of function (SOF) and the state of health (SOH) of the battery are determined and made available to electrical energy management as input variables (Figure 12).

A battery sensor which measures the battery current and voltage directly is used to measure the battery variables. The battery temperature is determined by way of a temperature measurement in the vicinity of the battery, since direct measurement of the battery electrolyte temperature in the vehicle would require an intervention in the battery, which is currently not possible.

Example

An example of a battery-status-recognition function is determining startability on the basis of the SOF. With the SOF the future behavior of the battery when subjected to starting current is predicted. In other words, battery-status recognition determines the battery-voltage dip for a given starting-current profile (Figure 9). Because the minimum voltage level for a successful start is known, the predicted voltage dip provides a measure of current startability. Depending on the interval between the predicted voltage dip and the startability limit, electrical energy management defines measures for maintaining or improving startability.

Battery sensor

The battery measured variables of current, voltage and temperature must be sensed very precisely, dynamically and synchronously. Particularly the measurement of currents in the range of a few mA through to starting currents of more than 1,000 A makes great demands on the sensor system. The electronic battery sensor (EBS) is mounted directly on and combined with the battery terminal. Because the terminal compartment is standardized in accordance with DIN 50342-2 [1], application on different batteries is not necessary.

Current is measured using a special manganin shunt. The core of the battery sensor's electrical wiring is an ASIC which contains among others a powerful microprocessor for recording and processing measured values. The battery-status-recognition algorithms are also processed on this microprocessor. Communication with higher-level ECUs is via the LIN bus.

As well as calculating the battery status for electrical energy management, the battery sensor can also be used for other functions. For example, precise sensing of current and voltage can also be used for prompted troubleshooting in production and workshops (e.g., searching for faulty no-load-current consumers).

Vehicle electrical systems for commercial vehicles

Requirements of truck electrical systems

As in passenger cars, the majority of electrical consumers in trucks and buses are supplied with power via a low-voltage electrical system. It takes a much greater amount of power to start the large diesel engines of trucks (the majority of which are still used as the drive) than it does to start passenger-car engines. The nominal voltage of truck electrical systems in most regions around the world is therefore 24 V. 12 V vehicle electrical systems are sometimes used in light-duty vehicle classes (e.g., 3.5 to 7.5 t) and in heavy-duty vehicles in certain regions, e.g., North America.

Aside from the voltage, which is primarily defined by the vehicle's target market, a range of factors imposes further requirements on truck electrical systems:
– Vehicle-fleet operators: vehicle availability, “total cost of ownership” (TCO).
– Drivers: availability of comfort and convenience consumers.

Figure 1: Schematic diagram of truck electrical systems
a) 24 V electrical system with two series-connected 12 V batteries,
b) 12 V electrical system with several parallel-connected batteries.
1 Batteries, 2 Alternator, 3 Starter, 4 Electrical consumers at terminal 15,
5 Isolating switch (optional), 6 Continuously supplied consumers.

– Variety of vehicle types and use: number and type of consumers, power requirements, vehicle utilization, and driving profiles.
– Statutory requirements for example governing the carriage of dangerous goods (ADR, Accord européen relatif au transport international des marchandises dangereuses par route - European Agreement concerning the International Carriage of Dangerous Goods by Road), tachographs, etc.

The requirements imposed by vehicle operators and drivers differ between trucks and passenger cars in terms of the prioritization. For commercial vehicles, the availability of the vehicle and the costs come first. High requirements for example are very often imposed on the cold-starting performance or on the ability to drive the vehicle to a repair shop independently after initial faults (“limp home”). Further examples are competing requirements relating to fuel consumption, vehicle availability and battery life, which must be taken into account in energy-management functions for trucks. Requirements relating to the availability of comfort and convenience consumers only come second in the order of priorities; these requirements – in contrast to passenger-car requirements – often relate to the power supply when the vehicle is stationary, e.g., running an electrical independent (stationary) air conditioner while sleeping in the vehicle overnight.

The great variety of vehicles gives rise to requirements relating to the scalability and adaptability of the electrical systems to cope with different vehicle equipment, usage profiles, and body structures.

The average power requirement of basic vehicles is typically below that of passenger cars, e.g., for tractor units including semitrailer approx. 500 to 700 W. The reasons for this are the lower number of comfort and convenience consumers and the use of compressed air for many actuators. Body structures can however increase the power requirement.

Schematic design of truck electrical systems

24 V vehicle electrical systems

Similarly to passenger-car electrical systems, the electrical system of a truck consists of one or more energy converters (alternator(s) or in electric vehicles a DC/DC converter of HV (High Voltage) to 24 V), two series-connected 12 V batteries (typically 2 × 100 to 225 Ah capacity), and the electrical consumers (Figure 1a). The functions of the batteries are:
– to supply consumers while the vehicle is stationary (e.g., when sleeping in the vehicle overnight or to cover the no-load current demand),
– to provide power for engine starting in conventional vehicles, and
– to give short-term assistance to the alternator or the DC/DC converter during peak loads when driving.

Installation locations for batteries

Typical installation locations for the batteries are at the sides on the frame or inside the frame at the vehicle rear end (often the case on tractor units), which in conventional vehicles necessitates long cable lengths from battery to starter and alternator.

The positive cable is typically fashioned by way of a main power distributor. Conducting elements of the vehicle, e.g., engine block, clutch or transmission housing, and sometimes the vehicle frame, are used for the ground cable. However, particularly instead of the frame being used, sections are also routed via separate ground cables.

Isolating switches can additionally be fitted to isolate parts of the electrical system; these are sometimes required by law (e.g., for dangerous-goods vehicles).

12 V vehicle electrical systems

The design of 12 V electrical systems for trucks is essentially the same as the design of 24 V electrical systems. On light-duty vehicles (e.g., 3.5 to 7.5 t) a battery is mounted on the frame (e.g., a larger passenger-car battery (100 Ah) or a small truck battery (100 to 140 Ah). On heavy-duty vehicles a number of 12 V batteries are connected in parallel. On vehicles for

the North American market it is customary for example to install up to four batteries behind the engine and transmission under the cab and optionally up to four further batteries at the side on the frame. Figure 1b shows a typical schematic design of 12 V electrical systems for heavy-duty trucks.

24 V/12 VDual-voltage electrical systems

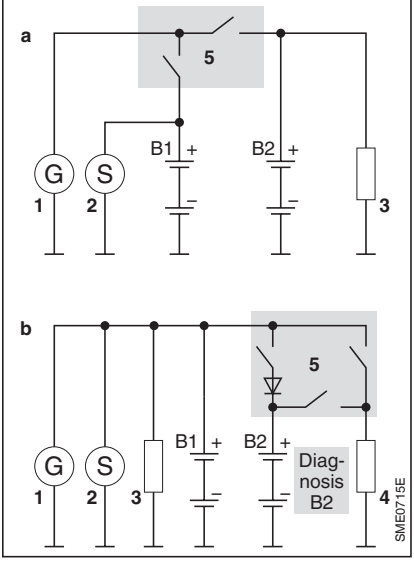
Insular electrical systems for 12 V / 24 V small consumers

Frequently 12 V components for passenger cars are used in European trucks and 24 V components from other regions are used in North American trucks. In such cases insular electrical systems are created via 24 V/12 V or 12 V/24 V DC/DC converters. These insular electrical systems are typically not supported by batteries, i.e., the DC/DC converters must be designed for the peak-power requirements and any return of current from components must be backed up by sufficient input capacities.

Subsystems for 12 V supply in the vehicle and 24 V supply of body structures

In many cases it is necessary to make available a 24 V power supply for body-structure manufacturers in vehicles with 12 V electrical systems. This can be solved by means of a 12 V/24 V DC/DC converter and if necessary an additional 24 V battery. A cheaper solution is to use two series-connected 12 V batteries, replace the 12 V alternator with a 24 V variant, and use a battery equalizer. The 12 V electrical system including starter is supplied via the 12 V mid-tap while the vehicle body is supplied via the 24 V tap.

Dual-battery electrical systems



Separate supply for engine starting and recreational application

In long-distance vehicles in which drivers sleep overnight the batteries are cycled by frequent exhaustive discharging. This cycling causes starter batteries, which are optimized for high power output, to age quickly. In addition, to guarantee cold-starting performance, a charge reserve must always be maintained, meaning that only part of the full battery capacity can be used for the residential phase. A remedy is provided here by dual-battery electrical systems, in which a cold-start-optimized battery (e.g., a wet-cell battery) and a cycle-resistant battery for recreational application (e.g., a gel battery) are used. An energy-management function must control a switch arrangement in such a way that while driving both batteries are charged, when the engine is switched off the consumers are supplied only from the cycle-proof battery, and during an engine-start request the cold-start-optimized battery supplies the starter (Figure 2a).

Redundant supply of safety-relevant consumers

In many vehicles a redundant power supply is required for safety-relevant consumers, e.g., for electric steering. A simple way of achieving this is to install a second, for

Figure 2: Dual-battery electrical systems

the most part much smaller battery with the same nominal voltage (12 V or 2×12 V in series), from which the safety-relevant component can be supplied over a limited period of time if the primary electrical system fails. A circuit in combination with a software function (Figure 2b) ensures that the redundant battery is charged in normal driving operation. The availability of the power reserve must be monitored by means of diagnostic functions and, if the primary electrical system fails, the supply to the safety-relevant component must be switched over by the redundant battery.

Truck-specific implementation of electrical systems

Ground return in truck electrical systems

The return of the negative cable (ground cable) cannot be effected via a consistently conductive chassis in trucks on account of the frame structure with mounted cab. Instead, ground return is effected via a combination of conductive vehicle components such as engine block, clutch or transmission housing, and by a separate ground cable.

Some vehicle manufacturers use the vehicle frame as a ground conductor while other manufacturers lay separate ground cables along the frame. The decision as to the optimal solution depends among other things on the vehicle body and the vehicle manufacture. It is in part technically complex to create a long-lasting low-resistance connection between painted frame parts. Another benefit of using separate ground cables is the monitoring of mass current via current distribution. The connection of conductive vehicle components and ground cables is established by welded-on or pressed-in stud bolts to which ground cables are screwed with cable lugs.

Ground distribution is effected in a star arrangement and the respective ground subsegments are brought together at ground distributors. Such ground distributors can be for example plates with pressed-in stud bolts secure to the engine block or clutch housing.

Connection of body structures and trailers

The power supply to the trailer is provided by the trailer socket, which – protected by one or more fuses – is connected to one of the vehicle power distributors. The connections for vehicle bodies are likewise tapped at vehicle power distributors.

If only small currents are needed for body structures, these can also be supplied via a power sub-distributor or a body-structure-manufacturer interface ECU.

Body structures are typically connected not by the vehicle manufacturer but after the basic vehicle has been completed by a body-structure manufacturer. To ensure the integration of the electrical supply of the body structure in the basic electrical system, it is necessary to take into account typical supply scenarios in the design of the basic electrical system. In addition, the interfaces and specifications to be observed in body-structure-manufacturer guidelines must be described in detail.

Batteries for truck electrical systems

Essentially, the 24 V and 12 V batteries in trucks are subject to similar requirements to those imposed on passenger-car batteries. Truck-specific requirements are derived from the cycle resistance and – as a result of the installation location on the minimally damped frame – from the vibration resistance. At present only lead-acid batteries are used for the 24 V or 12 V electrical system in trucks. Due to the high cost pressure, wet-cell batteries are still frequently used as starter batteries in trucks, but newer technologies such as AGM batteries or gel batteries are also used as optional extras. Typical battery capacities for 24 V electrical systems are 100 to 140 Ah for light-duty trucks and 140 to 225 Ah for heavy-duty trucks.

Energy management for truck electrical systems

The energy management of truck electrical systems also essentially corresponds to that of passenger-car electrical systems. Because in the case of trucks the focus is firmly on vehicle availability and total costs, the design objective of energy management is the optimum between fuel consumption, battery life, and vehi-

cle availability. Truck-specific adaptations of energy-management functions are typically made particularly with regard to load management (e.g., availability of an electric loading ramp, independent air conditioner), intelligent alternator activation (large variety of vehicle weights and thus the distribution of pulling and overrun phases, variety of usage profiles, highly reliable guarantee of battery life and cold-starting performance) or the actuation of isolating switches.

Overview of consumers

As is already known from passenger-car electrical systems, electrical consumers are essentially distinguished on the basis of their switch-on duration (continuous, long-term, and short-term loads). The switch-on durations are very much dependent on for example the time of year and the vehicle's operating mode. In the case of long-distance commercial vehicles there is the additional mode of sleeping in the vehicle overnight (recreational phase). Table 1 summarizes the average electrical-system load in watts of a typical long-distance truck in the various operating modes.

The design-relevant load cases are especially important in the dimensioning of the electrical system. These load cases differ, depending on the design criterion (e.g., charge balance, voltage stability).

In addition to the charge balance, it is also necessary to safeguard the voltage stability and voltage quality in the vehicle electrical system. The voltage limits of the consumers and the different load cases are available in various standards (e.g., LV124 [1], VDA320 [2], SAE J1455 [3], ISO 16750-2 [4]) and differ, depending on the manufacturer, marker or application.

Table 1: Average electrical-system load of a typical long-distance truck

Average electrical-system load [W]	Summer	Winter (0 to 15 min)	Winter (>15 min)	Recreational (>8 h)

Electrical-system concepts for highly and fully automated driving functions

New power-supply requirements

The introduction of automated driving functions and driverless commercial vehicles is accompanied by an increase in the requirements imposed on the vehicle electrical system. At present there are still no certification regulations or binding standards; the state of the art continues to develop rapidly. The power-supply requirements are not yet fixed.

One source of requirements is SAE J3016 [5]. This defines and classifies automation systems for on-road motor vehicles in different levels (SAE levels 1 to 5). In this connection the standard distinguishes on the one hand between driver-assistance functions (SAE level 1 and level 2) in which the driver monitors the driving task and must be available as a fallback level. These driving functions support but do not replace the driver. Therefore there are no higher power-supply requirements here.

The situation is different for higher automation levels (SAE levels 3 to 5). In the case of these automation levels, after a fault in the vehicle – also including faults in the power supply – the automated driving function must be maintained in a fallback mode at least for a limited period of time until either the driver takes over the driving task or the vehicle is automatically placed in a safe state. Derived from this is the requirement that a fault in the power supply must not lead to the total failure of the sensors, control and actuators of the automated driving function.

Another source of requirements relating to the vehicle are the ECE regulations for the type approval of motor vehicles. Even if no concrete provisions concerning the power supply of highly and fully automated motor vehicles are defined in the 2020 version, requirements concerning the supply of power brakes can however be carried over to automated driving functions. The background is the intention of ECE R13 [6] that a single fault must not lead to an unbraked vehicle. If the braking system is designed in such a way that the driver cannot achieve a minimum deceleration of the vehicle with their physical strength, ECE R13 calls for separate monitoring devices and energy accumulators to provide the auxiliary energy needed for deceleration (for example with compressed-air brakes).

This requirement can be similarly carried over to the case of automated driving functions: If no driver is available or the driver does not have the task of being available as an immediate fallback level, two separate energy accumulators and two separate monitoring devices should be available in order also to bring a highly or fully automated vehicle safely to a stop after a fault in the power supply.

Voltage and energy requirements

The required amount of energy in the event of a fault strongly depends on which components in the fallback mode must be supplied over which period of time to guarantee the attainment of a safe state. This is dependent in particular on the configuration of the automated driving function and its area of application (Operational Design Domain, ODD). Thus the amounts of energy to be reserved are much smaller when the vehicle is to be brought to an immediate stop in the event of a fault than when much longer and more complex driving tasks are to be planned and implemented. Especially with regard to the requirement for a “mission completed” it can be much more advantageous also to provide the energy source by way of two channels.

Power supply for safety-relevant consumers

Various safety measures are possible in order to avoid a complete power-supply failure and to guarantee a "secure" power supply to achieve a safe state [7].

Fault avoidance

To avoid failures in the vehicle electrical system, it is necessary to implement for example development processes in accordance with the necessary safety rating (e.g., ASIL level as per ISO 26262 [8]).

Furthermore, it may be necessary to exchange components regularly and preventively, particularly if their typical service life is clearly below the specified vehicle service life, as is often the case with batteries.

Implementation of fault tolerance

Another possible way of maintaining the power supply for safety-relevant components is fault tolerance. The aim is, despite the presence of a fault, to maintain a (possibly degraded) automated driving function.

On the component level this means that for example internal faults such as short circuits must be internally encapsulated before they can significantly influence the voltage in the network. Similarly, energy sources must shut down as soon as they supply under uncontrolled conditions more energy than can be drawn.

The power supply can furthermore be subdivided into subsystems to which functionally redundant components of the automated driving function are distributed. If faults are detected in a subsystem, this can be isolated from other subsystems and thereby prevent fault propagation and safeguard the supply to the remaining components.

In addition, it is important to report detected faults and to react to them through the energy-management system or the safety-relevant driving function.

Fault detection

In the case of redundant systems it is important that in particular non-operating subsystems be checked before the safety-relevant function is activated. It is therefore essential, for example when switching the vehicle on but also on a regular basis during operation, to check the function of the power-supply components and thereby discover latent faults. This applies for example to the above-mentioned electrical isolating switches, which should isolate spontaneously occurring faults from the rest of the vehicle electrical system.

Fault prediction

The prediction of faults can furthermore ensure that an automated driving function is terminated before the onset of an imminent failure. Fault prediction is effected for example through a process of comparing the aging behavior of a component with the previous load cycles or evaluating wear indicators. This is particularly relevant to mechanical or chemical components (alternators, batteries, wiring harness) which exhibit pronounced aging and/or wear behavior.

Solutions, alternatives, challenges

To fulfill the fault-tolerance requirements described above, separate energy accumulators and separate monitoring devices are required to supply safety-relevant consumers. Figure 3 shows a basic Topology. As shown here, the power is provided from the power source. This can be performed simply or redundantly. Depending on the drivetrain configuration, the power source can be, as shown in Figure 4, an alternator on the same voltage level as the consumers or a 48 V system or an HV (high-voltage) system comprising electrical machine, traction battery, and DC/DC converter.

To achieve fault encapsulation, the individual subsystems are connected by

couplers in Figure 3. These couplers can disconnect the subsystems in the event of a power-source overvoltage or a short circuit in base-load consumers. The safety-relevant sensors, actuators and vehicle computers which are required for automated driving or to achieve a safe state can therefore be supplied from energy accumulators B1 and B2.

Couplers too come in different designs, as shown by way of example in Figure 4. These can be designed for example in the form of a DC/DC converter, an electronic semiconductor switch or an electronic power distributor like “Powernet Guardian”. It is also possible to implement in the couplers diagnoses to monitor the wiring harness for supplying the safety-relevant consumers which monitor for example overrange line and connector resistances.

Both lithium-ion and lead batteries are conceivable even for the energy accumulators. Double-layer capacitors (DLCs) as storage devices on the low-voltage side are a possibility only for a few applications with low power requirements on the fallback level.

It is fundamentally important for the power content and the performance of the batteries to be safely and reliably monitored by the electronic battery sensor (EBS) and/or the battery-management system (BMS). Here the voltage limits of the safety-relevant consumers are a significant criterion which must not be violated.

To ensure the absence of interaction between comfort and convenience consumers and safety-relevant components, the introduction also of electronic fuses in the main distribution or sub-distribution

is in development. These can either be integrated in the established power distributors today or be part of the couplers or Powernet Guardian.

As mentioned above, there is the need to implement 12/24 V subsystems if complex passenger-car components like sensors, vehicle control computers or multimedia devices with 12 V voltage requirement must be integrated in the 24 V electrical system. If these fall into the group of safety-relevant consumers, this means that within the safety-relevant subsystems a voltage conversion must take place which further increases the complexity compared with passenger cars.

A second difference from a passenger car is that the supply to the truck trailer must also be taken into account. This contains if necessary safety-relevant consumer such as the ABS ECU, lighting or environment sensors, which depending on the automated driving function and its fallback level are required to attain a safe state. This also results, depending on the safety concept, in potentially the demand for redundancy of these functions.

This example shows that in the field of the power supply of automated driving trucks there are neither established requirements nor solutions and the state of the art will therefore only become established in the coming years.

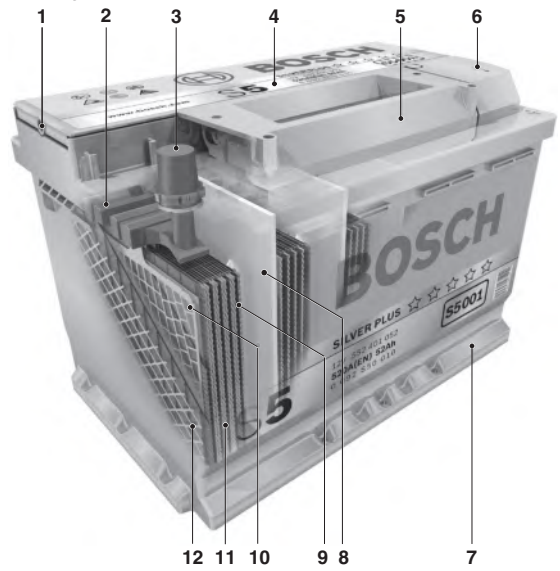
12 V starter batteries

Requirements

The battery is used to start the internal-combustion engine – hence the designation starter battery – and to provide electrical energy for the 12 V vehicle electrical system if the alternator does not provide any energy or enough energy. Because the battery can be charged, it is in the proper sense a rechargeable battery.

The battery in the vehicle electrical system

The performance requirements for starter batteries in motor vehicles are very high. Diesel engines and large-volume gasoline engines have high cold-cranking power requirements with high starting currents, particularly at low temperatures.



When the engine is running, the electric components are usually supplied directly from the alternator. When the engine speed is low, on the other hand, it is supplied partially from the battery.

The battery covers the temporary flow current consumption for ventilators, pumps and electronic components immediately after switching off the internal-combustion engine, as well as for comfort and convenience consumers operated while the vehicle is parked, such as entertainment and communication electronics and for the auxiliary heater, if present. If a vehicle is parked for days or weeks, a peak coil current of typically 3 to 30 milliamperes must be supplied. The battery must still be able to start the vehicle, even after it has been parked for extended periods. For seasonally operated vehicles the starter battery should be removed and connected to a trickle charger. This prevents the battery from suffering damage that can arise as a result of long inoperative periods in the exhaustively discharged state.

In addition to the uniform energy supply, the battery in the vehicle electrical system covers high dynamic current pulses which cannot be delivered by the alternator as quickly (for transient processes, such as for example switch-on processes in the electrical power steering). Furthermore,

12 Negative electrode, with expanded grid and negative active mass.

due to the very high inherent natural capacitance of the double-layer capacitor of a few farad, the battery smooths ripples in the automotive electrical system current, which helps minimize EMC problems (electromagnetic compatibility).

The nominal voltage of the vehicle electrical system is 14 V so that the 12 V battery can be charged with the alternator. With regard to the nominal voltage of the battery the vehicle electrical system is called the 12 V vehicle electrical system.

In commercial vehicles two structurally identical 12 V batteries are connected in series so that a higher starting power can be achieved for the starter with a 24 V vehicle electrical system. To avoid a nonuniform discharge of a battery, no additional 12 V consumers should be connected to a battery. This would lead to this battery "starving" because in the case of charging at constant voltage by the alternator the battery with the higher state of charge determines the charging current.

The battery in innovative vehicle electrical systems

Operating strategies of new vehicles use the battery in an increasingly active manner for reducing fuel consumption and emissions (see also 12 V vehicle electrical system). In vehicles with active alternator control the battery is operated in a partially charged state in order to be able to draw current from recuperation. The alternator output power is reduced in a targeted manner in operating phases (if necessary, all the load is taken off the alternator) in which the engine is working at poor efficiency or engine output is particularly necessary (e.g., during vehicle acceleration, "Passive Boost"). During these phases, the battery supplies the vehicle with electricity. In phases where the motor is highly efficient and when braking, the battery is then recharged in a targeted manner by raising the charge voltage (see Recuperation).

A start/stop system is used to switch off the engine if the vehicle is not moving (e.g., at a red light). The starter battery then covers the vehicle's entire power consumption of approximately 25 to 70 A. The engine is restarted automatically when the driver wants to pull away.

Depending on the operating conditions, using the battery's storage capacity in this way significantly reduces fuel consumption. The increased charging capacity represents an additional load on the battery, which is accommodated by special designs such as AGM and EFB (see Battery designs). Here, charging the battery well and sufficiently is always a requirement for a level charge balance in order to fulfill these tasks in the long term. A battery status detector is used to monitor the battery status. It generally consists of a sensor attached to the negative battery terminal (EBS, electronic battery sensor for measuring current, voltage and temperature) and software that uses the determined measurements to identify the status and capacity of the starter battery. Based on these results, the system can make the necessary intervention into the engine management system based on an operating strategy and, for example, decide whether the engine is to be shut off when the vehicle is stationary, whether it is to be restarted automatically when the vehicle is parked for long periods, or how the alternator voltage must be controlled (see 12 V vehicle electrical systems).

Numerous vehicles are also equipped with two batteries, for example, to guarantee startability even at a high standby current consumption or to prevent inconveniences (e.g., resetting the infotainment systems) due to the short-term voltage drop in vehicles with start-stop function when restarting automatically (see Two-battery vehicle electrical system).

Hybrid and electric vehicles also have a low-voltage vehicle electrical system of 14 V, on which the majority of the electric components work. This is supported by a 12 V battery, in many cases a high-performance starter battery. In some hybrid vehicles, cold cranking is carried out by a starter motor supplied from this battery.

The battery as component
The requirements mentioned define the electrical properties of the energy accumulator such as starting power, capacities and charge-current absorption. Furthermore, depending on operating conditions, thermal requirements (e.g., due to the installation point in the vehicle and the climate zone) and mechanical requirements (e.g., regarding attachments and vibration resistance) must be observed. The battery should also be maintenance-free, safe in use and environmentally friendly in production. The lead battery exhibits very good recyclability and achieves the highest recycling rates of all consumer durables at well over 95 %, where lead and plastic from old batteries are re-used for battery manufacturing.

The battery in operation
The design of the vehicle's components and the electrical operating concept, as well as the usage profile and driver affect the proper function of the battery and, therefore, the vehicle electrical system. Despite the excellent charge acceptance properties of modern starter batteries, a positive battery charge balance sometimes cannot be achieved during regular, short trips through the city in winter (involving high power consumption and low engine speed) and the state of charge decreases. At low states of charge, not only does the amount of energy still available decrease, but the capability of producing currents sufficient to start the engine decreases as well. Low battery charge levels over longer time periods worsen the cold-cranking characteristics and shorten the service life of the battery.

Battery design

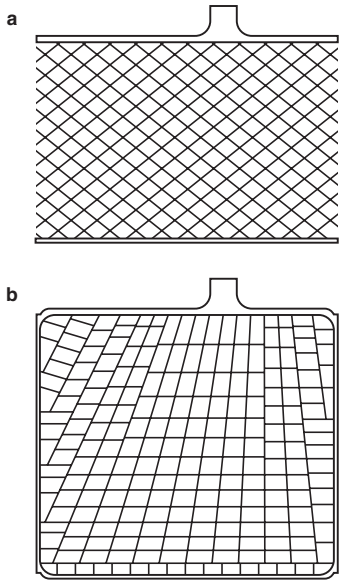
Components
A 12 V starter battery has six electrode blocks which are installed in a polypropylene battery case subdivided by cell partitions (Figure 1, [1]). A cell consists of a stack of positive and negative electrodes arranged in alternation, each designed from a lead grid as a carrier and electrical arrester, filled with porous active mass (lead and lead dioxide, hence the designation lead battery). Microporous separators isolate the electrodes from each other, where they usually enclose the electrodes of one polarity in a pocket-size format. The separators are made from porous polyethylene filled with silica or from a glass-fiber fleece (AGM, Absorbent Glass Mat).

The electrolyte is in the form of diluted sulfuric acid which fills the pores in the electrodes and separators, and the voids in the cells. The electrodes of one polarity are connected in parallel by plate straps and, using cell connectors, are connected and sealed from openings in the partitions to the neighboring cells or the battery terminals. Battery terminals, cell and plate straps are made of lead alloys.

A lead battery develops, particularly during the charging process, a certain amount of oxygen at the positive electrode and hydrogen at the negative electrode. During this electrolysis process, water is consumed from the electrolytes. The charging gases must be released. The one-piece cover welded to the battery case provides the battery's upper seal and contains various ventilation openings depending on design. On conventional batteries, each cell has a plug, which is used for initially filling the battery with electrolyte, maintenance and the release of charging gases. Maintenance-free batteries usually no longer have a plug. Degassing occurs via an advanced labyrinth system, which prevents liquid from escaping, even if the battery is tilted. However, the ventilation openings, often arranged on the side of the cover, must not be sealed on both sides. Porous sintered bodies permeable to gas (called frits) are installed in front of the ventilation opening inside the cover. These sintered

bodies prevent potential flames or sparks outside from backfiring into the inside of the battery.

Conductive grid



Active masses

Because electrochemical reactions in the battery take place very slowly, the electrodes are designed as grids to increase the size of the reaction surfaces. In the manufacturing process, the active masses are coated (pasted) into the conducted grid. The positive active mass contains after the initial charge (forming) porous lead dioxide (PbO_2, dark brown in color). The negative active mass contains porous metallic lead sponge (Pb, metallic gray-green in color).

Manufacturing and geometry

The lead grid is used for the mechanical mount and electric contact of the active masses. Optimizing the grid structure in terms of electrical conductivity improves the utilization of the active masses. The standard grid-manufacturing methods include casting liquid lead into a mold or continuous processes like drawing out (Figure 2a) and punching from a strip (Figure 2b).

Figure 2: Conductive grid
a) Expanded metal grid,
b) Stamped grid.

Alloy materials

Alloying elements are added to the lead used for the grid to optimize the production process and increase the mechanical strength and corrosion resistance. The strong oxidizing electrochemical potential exposes the positive grid to a continuous corrosion attack. As a result, the cross-sectional area of the webs detaches throughout the duration of use, the electrical resistance is increased and alloying elements are in released the electrolytes. Negative grids, on the other hand, do not have corrosive potential and, therefore, are not affected by corrosion (see Corrosion).

Antimony

If, for example, antimony assumes the function of the hardener for the positive grid, it is gradually released by corrosion and travels diagonally through the electrolyte and the separator to the negative electrode. It “poisons” the negative active mass, which greatly increases the spontaneous development of hydrogen there. This increases the self-discharge of the negative electrodes and water consumption if overcharged. Overall, this causes the capacity to be constantly reduced throughout the duration of use. The battery does not achieve the required state of charge, and the electrolyte has to be checked at frequent intervals. This is why, for grids, lead-antimony alloys (PbSb) with a low percentage of antimony by mass are still used only for battery types with plugs for which regular maintenance (replenishment of water) is accepted.

Calcium, tin and silver

Today, calcium, tin and silver are usually standard alloying elements for maintenance-free batteries, because they do not noticeably affect hydrogen development, even when released due to corrosion. To ensure the required strength, the terminals are made from lead alloys with up to around 10 % antimony by mass.

Lead-calcium alloys (PbCa) with around 0.1 % by mass are usually used for negative grids. To ensure the required strength, terminal posts are made from lead alloys with up to around 10 % antimony by mass.

Lead-calcium alloys (PbCa) with around 0.1 % calcium by mass are used for positive grids, which are manufactured in a continuous expanding or rolling and stamping process. Due to the increased percentage of tin (0.5 to 2 %), these alloys feature very high corrosion resistance, which allow lower grid weights.

Casted positive grids are often made from a lead-calcium-silver alloy (PbCaAg). In addition to 0.06 % calcium and tin by mass, this alloy also contains a proportion of silver (Ag). It has a finer grid structure and has proved to be extremely durable even at high temperatures – which have the effect of accelerating corrosion.

Table 1: Electrolyte values of the dilute sulfuric acid in a typical auto starter battery at 20 °C

State of charge	Electrolyte density in kg/*l*	Freezing threshold in °C
Charged	1.28	–68
Semi-charged	1.16…1.20	–17…–27
Discharged	1.04…1.12	–13…–11

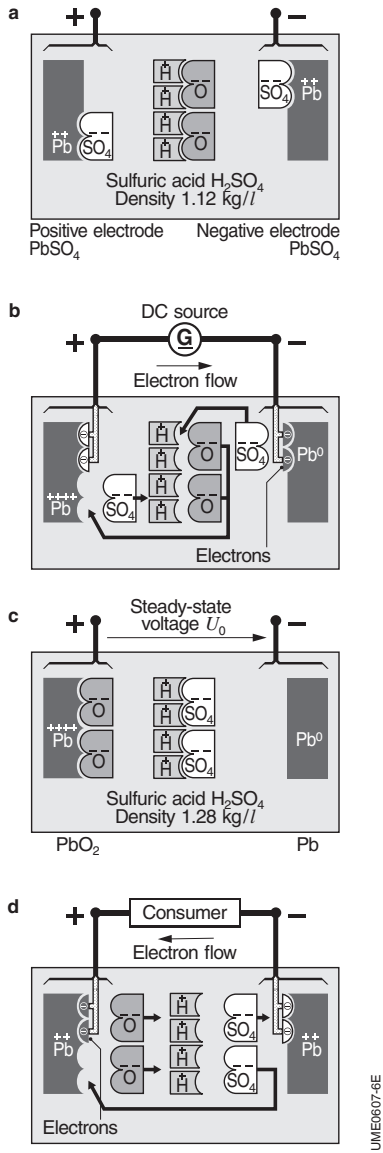
Charging and discharging

Chemical reactions

The active masses of the charged lead battery are the lead dioxide (PbO_2) of the positive electrode, the sponge-like, highly porous lead (Pb) of the negative electrode, and the electrolyte (diluted sulfuric acid, H_2SO_4). The concentration in the charged battery is 37 %, producing an acid density of 1.28 kg/*l*. The electrolyte fills the pores of the active masses and the separator and is simultaneously an ionic conductor for charging and discharging. Compared with the electrolyte, PbO_2 and Pb assume characteristic voltages (individual potentials). Their difference is equal to the cell voltage of approx. 2 V at rest.

Specifically the processes shown in Figure 3 occur.

Discharged cell before charging



Located on both electrodes is $PbSO_4$, which is made up of the ions Pb^{2+} and SO_4^{2-} (Figure 3a). The battery acid has a lower density (approx. 1.12 kg/*l*, Table 1), as it is depleted of sulfate ions (SO_4^{2-}) by the previous current consumption.

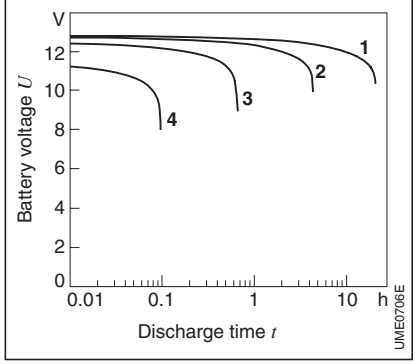
Charging process

Pb^{2+} is converted at the positive electrode into Pb^{4+} due to electron donation (Figure 3b). This combines with oxygen arising from the splitting of H_2O to form PbO_2. On the other hand, elemental lead is formed at the negative electrode. Both these reactions involve the release of sulfate ions SO_4^{2-}, which with H^+ ions form sulfuric acid again and thereby increase the acid density.

The specific gravity of electrolyte can be used to indicate the state of charge of the battery (see Table 1). The accuracy of this relationship depends on battery design, electrolyte stratification, and battery wear with a certain degree of irreversible sulfating or a high degree of shedding of plate material. The electrolyte densities specified in Table 1 apply at a temperature of 20 °C; the electrolyte density drops by approximately 0.01 kg/*l* for every 14 K that the temperature rises and vice-versa when the temperature drops. The low value specified in Table 1 applies to high electrolyte utilization, the high value to low electrolyte utilization.

Figure 3: Charging and discharging processes in a lead battery
a) Discharged cell before charging,
b) Charging process,
c) Charged cell,
d) Discharging process.

Charged cell
$PbSO_4$ on the positive electrode is converted into PbO_2 and $PbSO_4$ on the negative electrode is converted into Pb (Figure 3c). There is no further increase in electrolyte density.



If the charge voltage continues to be applied after the cell has reached a state of full charge, only the electrolytic decomposition of water occurs. This produces oxyhydrogen gas (oxygen at the positive electrode, hydrogen at the negative electrode).

Discharging process
The direction of current flow and the electrochemical processes during discharging are reversed in relation to charging, which results in the Pb^{2+} and SO_4^{2-} ions on both electrodes being combined to form the discharge product $PbSO_4$ (Figure 3d).

When the cell discharges, PbO_2 and Pb combine with H_2SO_4 to form $PbSO_4$ (lead sulfate). This conversion causes the electrolyte to lose SO_4^{2-} ions (sulfate ions), and its electrolyte density decreases.

When a discharge current is applied to the battery, this reduces the battery voltage depending on the magnitude of current and the duration of discharge (Figure 4). Therefore, the charge quantity that

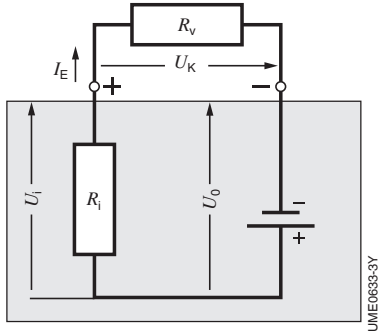


Figure 4: Battery-voltage curves as a function of the discharge duration for various discharge currents
1 I=0.05 A per Ah,
2 I=0.2 A per Ah,
3 I=1.0 A per Ah,
4 I=4.0 A per Ah.

can be drawn from the battery decreases when the current level increases.

Behavior at low temperatures
The chemical reactions in a battery always take place more slowly at lower temperatures and when internal resistance is increasing. The voltage at the specified discharge current and, therefore, the starting power of a battery even when fully charged decreases as the temperature drops and the internal resistance increases (Figure 5). The further the discharge progresses, the more the concentration of acid drops, up to the freezing point of the electrolyte. A discharged battery can only supply a low current which is not sufficient to start the vehicle.

Battery characteristics

In addition to mechanical parameters, such as physical dimensions, attachment, and terminal design, characteristic electrical ratings are defined in testing standards (e.g., DIN EN 50342, [2], [3], [4]). General terminology on batteries is described in DIN 40729 [5].

For the cross-manufacturer marking of starter batteries, a nine-digit ETN (European Type Number) was described in the appendix of the revised EN 50342-1:2001 to compile the most important properties of a starter battery (including voltage, nominal capacity, cold cranking performance, terminal details, etc.). However, this representation cannot map expanded differences regarding construction characteristics, design and areas of application, which are described additionally in requirements outside of EN 50342-1. Therefore, starting with the version from 2006, the ETN nomenclature was withdrawn as a standard in coordination with battery manufacturers and users. Since then, the ETN only continues to be used occasionally.

Capacity
Capacitance is the charge quantity in ampere hours (A h) which can be drawn from the battery under specified conditions. It decreases as discharge current increases and temperature decreases.

Nominal capacity
EN 50342-1 defines the nominal capacity K_{20} as the charge the battery is able to deliver within 20 h up to a cutoff voltage of 10.5 V (1.75 V per cell) at a specified, constant discharge current $I_{20} = K_{20}/20$ at 25 °C. Nominal capacity is calculated from the quantities of active masses used (positive mass, negative mass, acid) and is not dependent on the number of electrodes.

Low-temperature test current
The low-temperature test current I_{CC} indicates the battery's current output capability at low temperatures. According to EN 50342-1, the battery terminal voltage with I_{CC} at –18 °C must be at least 7.5 V (1.25 V per cell) up to 10 seconds after discharging has started. Further details relating to the discharge period are specified in EN 50342. The short-term response of the battery when discharged at I_{CC} is largely determined by the number, geometric surface area of electrodes, the gap between electrodes, and the separator thickness and material.

The battery internal resistance R_i and other resistances in the starter circuit determine the cranking speed of the engine and also identify the starting response. For a charged battery (with 12 V), R_i at –18 °C is in the order of magnitude of $R_i \leq 4{,}000/I_{CC}$ (in mΩ), where I_{CC} must be applied in amps.

Water consumption
Lead batteries lose water from the electrolyte through electrolysis, particularly when charging. EN 50342-1 defines the test conditions for quantification. A limit value of water consumption of 1 g/A h, for example, means that, under test conditions, a battery with a 50 A h nominal capacity may lose up to 50 g of water. By comparison, the electrolyte of this kind of battery in new condition, depending on type, contains approximately 1.8 to 2.7 kg of water.

Cycle stability
Lead batteries undergo a certain amount of aging during repeated charging and discharging. Cycle stability means the capacity to be able to carry out a certain number of charging and discharging cycles under test conditions until the criteria at the end of service life are reached. EN 50342-1 defines the test conditions for quantification.

Battery types

Low-maintenance and maintenance-free batteries according to EN
Whether batteries require maintenance by refilling with water depends primarily on the grid alloy used. Batteries with lead antimony alloy (conventional and low-maintenance batteries) are very durable in cyclical charging and discharging operations, but require frequent maintenance because of the high degree of water loss and, therefore, are only used in some commercial vehicles.

Longer maintenance intervals result from low-maintenance batteries with negative grids made from a lead-calcium alloy (PbCa) and positive grids from an antimony alloy (PbSb). However, due to the antimony content in the positive grid, these hybrid batteries also seldom meet the high demand for very low water consumption (in accordance with EN 50342-1, less than 1 g/A h). Batteries with a water consumption under 4 g/A h in accordance with EN 50342-1 are considered maintenance-free in accordance with the EN standard.

Completely maintenance-free battery
Both grids in completely maintenance-free batteries are made from the lead-calcium alloy. When the vehicle electrical system is operating normally, this water decomposition is reduced to such an extent (in accordance with EN 50342-1, less than 1 g/A h) that the electrolyte reserves will last for the entire service life of the battery. Therefore, completely maintenance-free batteries do not require electrolyte level monitoring and do not usually provide a facility for doing this. They have a safety labyrinth cover that prevents electrolyte from escaping even when the battery is at a strong slope and are tightly sealed with the exception of two ventilation openings.

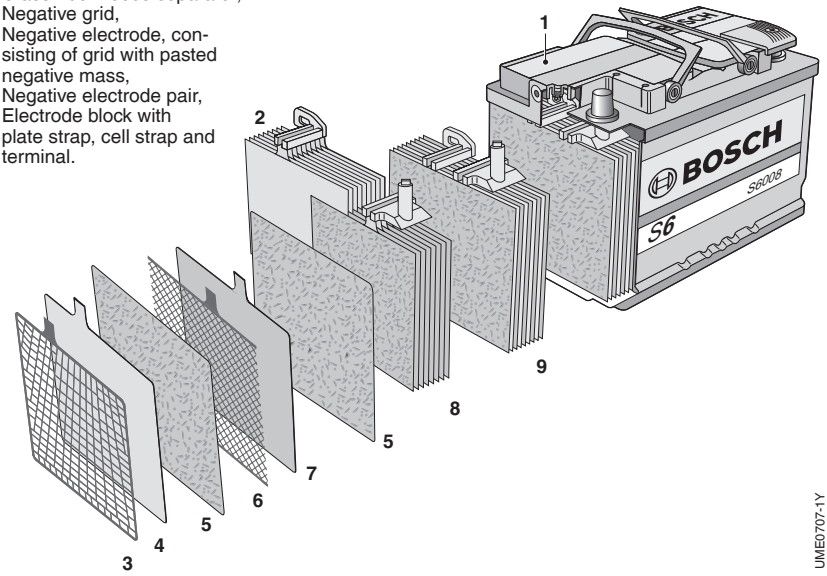
Completely maintenance-free batteries are already filled with electrolyte in the manufacturer's plant and can be stored in a fully charged state for up to 18 months after delivery due to the very low self-discharge.

A "dry" storage without electrolyte occurs only for very few designs (particularly for motorcycles). The electrolyte is

first poured in from a delivered acid pack when commissioning in workshops or at dealers' locations.

AGM battery

AGM (Absorbent Glass Mat) batteries are often used for applications with high charging capacities. In these batteries, the electrolyte is bound in a microporous glass-fiber fleece, which, instead of the conventional separators, is located between the positive and negative electrodes (Figure 6).



"Fixing" the electrolyte prevents, for example, the sulfuric acid of high concentration and density released during the charge from sinking and accumulating in the lower area of the cell. This "acid layer" with excess H_2SO_4 in the lower cell area and a shortage in the upper cell area occurs gradually during repetitive charging and discharging in conventional lead storage batteries with freely moving electrolyte. This impairs the charging behavior, accelerates the coarsening of the $PbSO_4$ discharge product's crystalline structure (sulfating), reduces the storage capacity, and accelerates the overall aging process of the battery.

In AGM batteries, these effects are reliably prevented. The elastic fleece also slightly pressurizes the electrode pair. This reduces the shedding and separation effect of the active mass considerably. Overall, this enables charging capacities more than three times higher than in comparable starter batteries with free electrolyte by charging and discharging throughout the entire service life. This makes it particularly well-suited for vehicles with a start/stop system that require the consumer to be supplied when the engine is stopped and then restarted reliably.

Other typical cases of application for AGM batteries include vehicles with many electrical consumers that are also used when the vehicle is stationary (e.g., auxiliary heater, consumer electronics), taxis, special vehicles and logistics vehicles.

Figure 6: AGM battery

7 Negative electrode, consisting of grid with pasted negative mass,
8 Negative electrode pair,
9 Electrode block with plate strap, cell strap and terminal.

In the AGM battery, the oxygen that occurs at the positive electrode in an internal circuit is used up again, the amount of hydrogen that is produced there is suppressed and the amount of water loss is therefore minimized further. This circuit is enabled by small gas channels in the separator fleece, through which the oxygen is transported. The individual cells are separated from the environment by valves that open only if the operation causes the internal pressure to exceed a value of approximately 100 to 200 mbar. Under normal operating conditions, the valves are closed, which reduces water consumption even further. Lead batteries with sealed valves, such as the AGM battery, are called VRLA batteries (Valve-Regulated Lead-Acid Battery) and are completely maintenance-free.

The inner resistance is particularly low and high cold start currents are achieved because of the high porosity of the glass-fiber fleece. Therefore, AGM batteries are also often used in diesel vehicles.

Even if the battery housing is destroyed (e.g., in case of an accident), the electrolyte bound in the glass-fiber fleece (diluted sulfuric acid) does not generally leak. This and the improved gassing characteristics make the AGM battery particularly well-suited for installation points in the passenger cell.

Gel battery

In an AGM battery the electrolyte is fixed by an absorbent glass mat. Another method for fixing the electrolyte is to add silicic acid to the liquid. The gel battery therefore has in principle the same design as a lead battery with liquid electrolyte, which is immobilized in a gel by the addition of silicic acid. This delivers a leakproof, maintenance-free battery which is sealed to the outside by a valve (VRLA, Valve-Regulated Lead-Acid).

The benefit of this method lies in the simple design, which through support of the active masses results in increased cycle stability. The drawback is that ionic migration is hindered by the gel, which results in increased internal resistance. This type is therefore generally not used as a starter battery in passenger-car applications; it shows off its strengths when used as a general-purpose battery in two-battery vehicle electrical systems or in solar or camping applications.

It is important to ensure that an adapted charger that takes into account the slower power consumption is used.

EFB battery

The EFB battery (Enhanced Flooded Battery) is a battery with free electrolyte optimized for use in vehicles with a start/stop system. Although an acid layer is also formed when cyclic charging batteries without fixed electrolyte, such as the AGM battery. However, the positive plates coated with polyester scrim, which provide additional support of the active mass, and further design features produce a more robust design and a greater deep-cycle resistance in comparison with standard batteries.

EFB batteries are generally used in vehicles with a start/stop system and low consumer loads.

Commercial vehicle battery

Bosch also provides completely maintenance-free batteries for commercial vehicles. Specifically in commercial vehicle applications, these batteries offer a substantial cost advantage. These battery types have a special labyrinth cover, which guarantees leakproof performance and features central venting. Porous frits integrated into the outlet opening prevent flames or sparks outside from backfiring into the inside of the battery. There are special design variations for applications with extreme cycle or vibration stress.

The housing dimensions of commercial vehicle batteries are described in the standard EN 50342-4.

Deep-cycle resistant battery

Due to their design (relatively thin electrodes, lightweight separator material), starter batteries are less suitable for applications which involve repeated exhaustive discharging, as this results in heavy wear on the positive electrodes (mainly caused by a loosening and shedding of active mass). A deep-cycle resistant starter battery has separators with glass mats that support relatively thick plates containing positive mass and therefore prevent pre-

mature shedding. Service life measured in charge and discharge cycles is nearly twice as long as a standard battery.

Vibration-proof battery
In a vibration-proof battery, the electrode blocks are fixed to the battery case by means of cast resin or plastic to prevent any relative movement between the two components. In accordance with DIN EN 50342-1, this battery type must pass a 20-hour sinusoidal vibration test (at a frequency of 30 Hz) and be capable of withstanding a maximum acceleration of 6 g. Requirements are therefore about 10 times greater than for standard batteries.

Vibration-proof batteries are mainly used, for example, in commercial vehicles, construction machines or tractor vehicles.

Heavy-duty battery
A heavy-duty battery combines the attributes of the deep-cycle resistant and vibration-proof types. It is used in commercial vehicles which are subjected to extreme vibrations, and where cyclic discharge patterns are commonplace.

Battery for extended current output
This battery type shares the basic design of a deep-cycle resistant unit, but has thicker and fewer electrodes. Although no low-temperature test current is specified, the starting power lies well below (35 to 40 %) starter batteries of the same size. This battery type is used during extreme cyclic charges, sometimes for driving purposes as well.

Motorcycle battery
Batteries for use in two-wheelers are used in the same way as in passenger cars. A battery with a much lower capacity than its passenger-car counterpart is sufficient for motorcycle use. These batteries accordingly have smaller dimensions.

One advantage of gel and AGM batteries is that they can be used in any location on account of the fixed electrolyte.

These battery types are often delivered “dry and precharged”. Prior to use, these batteries must be filled with the acid provided. The manufacturer's instructions and precautionary measures for handling sulfuric acid must be observed!

Because motorcycles are often only operated in the summer months, it is recommended to connect the batteries to a trickle charger while they are out of service in order to avoid exhaustive discharge caused by standby-current consumers, which will shorten the battery service life.

There are in the meantime also motorcycle applications that use a lithium-ion-battery.

Lithium-ion starter battery
It stands to reason to make use of the features of lithium-ion technology such as energy and power density, service life and cycle stability for starter batteries as well. Such batteries already appear occasionally on the market. Above all the LiFePO4 system is used for safety reasons.

The battery system must contain the necessary control and monitoring electronics so that in can be used as a spare battery for conventional vehicle electrical systems. Details about the features and function of the electrochemical system are provided elsewhere (see Traction batteries).

Using the battery

Charging

In vehicle electric systems, the alternator regulator specifies the voltage. In terms of the battery, this corresponds to the IU charging method, where the battery charge current I is initially limited by the output of the alternator and then reduces automatically if the battery voltage reached the control value (Figure 7). Since the current consumption capacity of the battery decreases at low temperatures, the charge voltage in the vehicle is usually regulated depending on the temperature (Figure 8). At battery temperatures well under 0 °C, current is consumed only very slowly.

The IU charging method prevents damage due to overcharging, and makes sure that the battery has a long service life. Modern battery chargers operate according to similarly defined characteristic curves.

Older devices, on the other hand, still operate using constant current or a W-characteristic curve. In both cases, once the full state of charge has been reached, charging continues with only a slightly reduced current, or possibly a constant current. This leads to high water consumption and to subsequent corrosion of the positive grid. In particular, maintenance-free batteries can be damaged by this in the long term.

Discharging

Shortly after discharging at a continuous current begins, the voltage in the battery drops to a value which only changes relatively slowly if discharging continues. Only shortly before the end of the discharging process will the voltage collapse sharply due to exhaustion (d.h. complete electrochemical implementation) of one or more of the active components (positive or negative mass, electrolyte).

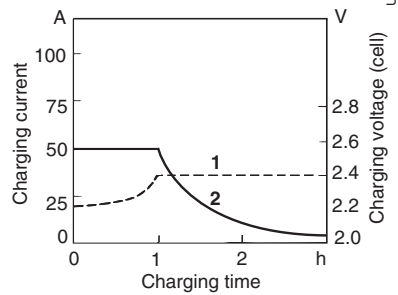
Self-discharge

Batteries discharge over a period of time if no electrical equipment is connected. Causes include the spontaneous development of oxygen at the positive electrode and hydrogen at the negative one, as well as the continuous slow corrosion of the positive grid. Batteries should therefore always be stored in well ventilated rooms and sparking and naked flames must be avoided in the proximity of batteries.

Completely maintenance-free batteries with lead calcium grids have a self-discharge of approximately 3 % per month at 25 °C, which remains roughly constant over the entire service life and nearly doubles for each temperature increase of 10 degrees.

Batteries using the lead-antimony alloy lose approximately 4 to 8 % of their charge every month when new. As battery ages, this value can increase by up to 1 % or

Figure 7: Charging according to the IU characteristic
1 AGM battery,
2 Low-maintenance standard battery.



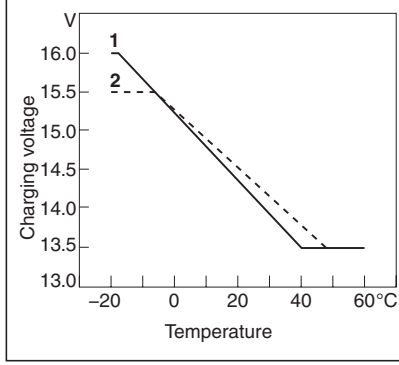


Figure 8: Temperature-dependent charging characteristic
1 Charge voltage,
2 Charging current.

more each day due to the migration of antimony to the negative electrode until a point is reached when the battery finally stops functioning.

Battery maintenance

On low-maintenance batteries, the electrolyte level should be inspected in accordance with the manufacturer's operating instructions; when required, it should be replenished to the MAX mark with distilled or demineralized water. This is generally not required for maintenance-free batteries in accordance with EN standard. This step is omitted entirely for completely maintenance-free batteries.

All batteries should be kept clean and dry to minimize self-discharge. Terminal posts, terminal clamps for connection with the vehicle electrical system, and fixing parts should be coated with acid-protection grease.

Before the onset of winter, it is recommend to check the battery status with a modern battery tester. If this tester recommends recharging, the battery should be recharged at a maximum voltage of approximately 14.4 to 14.8 V with a suitable charger with a regulated charging characteristic curve (IU charging characteristic curve or similar to prevent overcharging). Here, note the information in the user manual for the vehicle, battery and charging device. The charging area should be well ventilated (risk of explosion due to oxyhydrogen gas, risk of explosion, no naked flames or sparks). The electrolyte is corrosive. Therefore, gloves and protective eyewear must be worn when handling.

If no battery tester is available, a measurement of the electrolyte density or – if not possible – the steady-state voltage as a replacement. The battery should be recharged as described above if the electrolyte density is under approximately 1.24 g/m*l* or the steady-state voltage is under approximately 12.5 V.

Batteries temporarily removed from service should be stored in a cool, dry place. If the above-mentioned criteria exist, recharging is also required. Long inoperative periods at a low state of charge increase grid corrosion and reinforce sulfating. During this, the finely crystalline lead sulphate transforms into roughly crystalline, which makes the battery more difficult to recharge. These effects gradually damage the battery and can lead to their failure in the long term.

Battery malfunctions

Functional disturbances due to damage inside the battery cannot be remedied through repair. The battery has to be replaced.

A battery failure usually does not happen abruptly; instead, steadily decreasing starting power can provide an indication of the problem. Causes usually include a combination of consumed or sulfated active masses, grid corrosion and short-circuits due to separator wear. Modern battery testers can be used to evaluate whether a weak battery needs to be replaced or can simply be recharged.

If no battery defects are determined and the battery's charge is still always low, there may be a fault in the vehicle electrical system (defective alternator, electrical consumers remain switched on when the motor is not running, etc.). The battery can also be insufficiently charged as a result of using the vehicle primarily for short-distance driving. This can be balanced by occasionally driving longer distances or, alternatively, by occasionally recharging with an external charging device.

Battery testers

The starter battery is a wearing part. The service life is heavily dependent on the type and use of the vehicle and the climatic conditions. Aging becomes noticeable due to an increase in the internal resistance R_i (which impedes the start performance) and a reduction of the storage capacity by loosening of the active masses or sulfating. A low state of charge, on the other hand, is not a characteristic of aging, but a consequence of a usage with insufficient charge balance.

Often, a quick evaluation of the state of an older starter battery is desired, for example, to decide whether recharging is sufficient or a replacement is required. To do so, battery testing devices are available that can be connected to the powered-down battery and make a statement after a test duration of generally less than a minute.

Usually, these testing devices imprint a certain current charge profile onto the battery and deduce the battery state from the voltage response. To do so, they use partially simplified electrochemical impedance spectroscopy approaches (EIS, see electrochemical impedance spectroscopy). In general, the battery's correlation to the steady-state voltage is used to estimate the state of charge. Therefore, the battery must not be charged with other currents during the test.

Either a very rough evaluation (e.g., "ok", "charge", "replace", "test again") or a quantifying specification (e.g."state of charge 82 %", "startability 87 %") is given, depending on the design of the tester. Different manufacturers use a wide variety of methods.

Often, nominal values of the battery (capacities, cold cranking performance) must be specified and relative evaluations are made. The battery design (free electrolyte or AGM) and the battery temperature are also often requested or measured directly to also take into account this important influencing factor.

Battery testers cannot replace a complete test according to the applicable standards (e.g., EN 50342-1), but instead quickly give guideline for additional actions for batteries that have been in use for an extended amount of time. This test is not valid for new or like-new batteries because the structure of the active masses is often not yet balanced immediately after manufacturing.

Replacing the battery

Specifications in the vehicle's operating instructions must be taken into account when replacing batteries. These operating instructions often describe the specified or permissible sizes and design. The replacement battery should at least provide the specified capacity and cold cranking values to ensure functional and operational reliability. If a special battery design, such as AGM or EFB, is specified, such as in vehicles with a start/stop system, a replacement battery of the same design must be used.

Important: If the voltage in the vehicle electrical system drops to 0 V, consumers like the automotive sound system (car radio) may have to be restarted by entering a PIN. To avoid this situation, it is advisable when replacing the battery to connect a backup battery.

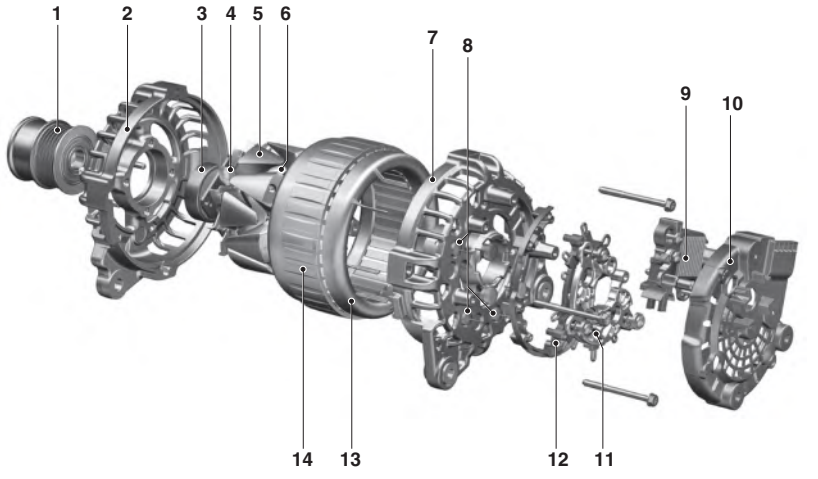
Alternators

Electric power generation



Motor vehicles need an alternator to charge the battery and to supply the electrical equipment such as ignition and fuel-injection systems, ECUs, lights, etc. with power. To charge the battery, it is necessary for the alternator to generate more current than is required by the electrical equipment when switched on. The alternator output, the battery capacity and the power demand of the electrical equipment must be matched to each other to ensure that under all operating conditions enough current is supplied to the vehicle electrical system and the battery is always sufficiently charged. This results in a consistent charge balance.
Because the battery and many items of electrical equipment have to be supplied with direct current, the alternating current generated by the alternator is rectified. The alternator is equipped with a voltage regulator so that it can supply the battery and the electrical equipment with a constant voltage.

Figure 1 shows an exploded view of an alternator. These alternators are designed for charge voltages of 14 V (in the 12 V vehicle electrical system) in passenger cars and of 28 V (in the 24 V vehicle electrical system) in many commercial vehicles.

Requirements

The essential alternator requirements are:
– maintenance of a direct-voltage supply to all electrical equipment in the system,
– charging reserves for (re)charging the battery, even at a constant load from electrical devices in continuous operation,
– maintenance of a constant alternator voltage throughout the entire ranges of engine speed and load conditions,

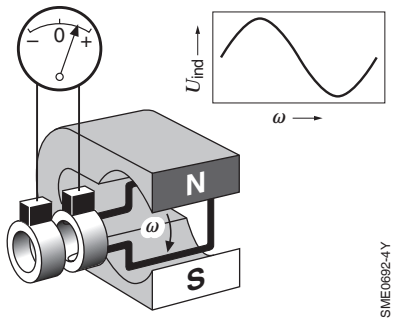
– high level of efficiency,
– low operating noise,
– robust design capable of withstanding external stresses (such as vibration, high ambient temperatures, temperature cycles, dirt, moisture),
– long service life, comparable with that of the vehicle itself (for passenger cars)
– low weight,
– compact dimensions.

Principle of electromagnetic induction
To generate an alternating current a conductor loop is rotated between the north and south poles of a permanent magnet (Figure 2). If, as a result of the rotation of the conductor loop, the magnetic field in this conductor loop changes, a voltage is induced in it. According to Faraday's law of induction, the induced voltage U_{ind} increases as the speed v of the conductor-loop motion vertical to the magnetic-field lines increases and as the magnetic flux Φ passing through the conductor cross-section increases. The following applies:

$$U_{ind} \sim \frac{d\Phi}{dt} .$$

If the conductor loop consists not only of one turn but of n turns, this produces the n-fold induced voltage.



If the conductor loop rotates uniformly at the angular velocity ω the shape of the induced voltage is sinusoidal. The induced voltage can be tapped at the ends of the conductor loop via collector rings and carbon brushes. An alternating current flows when the circuit is completed.

The magnetic field for generating the induced voltage (excitation field) can be generated by permanent magnets. The advantage of these is that, thanks to the simplicity of their design, they do not have to be technically sophisticated. This solution is used in small alternators (e.g., bicycle dynamos). The disadvantage of excitation using permanent magnets is that it cannot be regulated.

A excitation field capable of being regulated can be generated with an electromagnet. An electromagnet consists of an iron core and a winding (excitation winding), through which an excitation current is passed. The number w of its windings determines together with the magnitude of the excitation current I_E the magnetomotive force θ ($\theta = w\, I_E$). The magnetomotive force of the excitation winding drives in the alternator's magnetic circuit – similarly to the voltage in an electric circuit – a magnetic flux Φ. The flux is directed in the closed magnetic circuit through highly magnetizable iron components and via air gaps as small as possible between the stator and the rotor. By altering the excitation current, it is possible to adjust the magnetic flux and with it the magnitude of the induced voltage.

When an external power source (e.g., a battery) supplies the excitation current, this is referred to as external excitation. When the excitation current is tapped directly from the generated alternator current inside the alternator, this is referred to as self-excitation.

ω Angular velocity.

Alternator design

Claw-pole principle

The essential components of an alternator are the three- or multi-phase armature windings and the excitation system (Figures 1 and 3). Because the design of the armature-winding system is more complex than that of the excitation system and the currents generated in the armature winding are much greater than the excitation current, the armature windings are accommodated in the stationary stator – also called the frame (stator winding). The magnet poles with the excitation winding (rotor winding) are located on the rotating part, the rotor (inductor). The rotor's magnetic field is generated as soon as an excitation current passes through this winding. The alternator must feature a high number of pole pairs so that it can generate a high induced voltage already at low speeds. A high number of poles generates a high response per rotation and thus a high induced voltage. This is the prerequisite for a high alternator output.

By applying the claw-pole principle, the magnetic field of a single field coil can be split in such a way that the required 12 to 16 poles or 6 to 8 pole pairs are created (Figures 3 and 4). The number of poles than can be realized is limited. A low number of poles results in low machine utilization, while a high number of poles greatly increases the magnetic dispersion losses. For automotive alternators there is a good compromise from these two operative connections between 12 and 16 poles, depending on the output of the machines. Small alternators have smaller numbers of poles because the leakage fluxes increase with small pole pitches.

In the alternator, the armature contains three of more identical windings (phases) which are spatially offset in relation to one another (Figure 3). Because of the spatial offset of the windings, the sinusoidal alternating voltages generated in them are likewise out of phase with one another (temporally offset, Figure 5). The resulting alternating current is called three-phase alternating current or three-phase current.

Alternator circuits

In three-phase alternators, six current leads would be needed to transmit electrical energy in the case of non-connected windings. This number can be reduced to three by linking the three circuits. The circuits are linked in a star connection (Figure 6a) or in a delta connection (Figure 6b). The winding starts are usually designated u, v, w and the winding ends x, y, z.

In the case of a star connection, the ends of the three winding phases are interconnected at a single point, the star point. Without a neutral conductor the sum total of the three currents to the star point is zero at every moment.

Rectification of alternating voltage
The alternating voltage generated by the alternator must be rectified, since direct current is required to supply the battery and the electronics in the vehicle electrical system.

Two power diodes are connected to each phase – one diode on the positive side which is usually connected via the positive heat sink of the rectifier to the B+ stud and one diode on the negative side which is connected via the negative heat sink of the rectifier to the alternator casing (B– terminal) (Figure 3). The alternator casing is also electrically connected to vehicle ground via the alternator mounting points. The positive half-waves are conducted by the diodes on the positive side (B+ stud), the negative half-waves by the diodes on the negative side (vehicle ground). This principle is called full-wave rectification (Figure 5).

Full-wave rectification of the three phases with the so-called B6 bridge circuit brings about the addition of the positive and negative envelope curves of these half-waves to a rectified, slightly rippled alternator voltage.

The direct current which the alternator delivers under electrical load via terminals B+ and B– to the vehicle electrical system is not smooth, but slightly rippled. This ripple is further smoothed by the battery in parallel with the alternator and, if necessary, by capacitors in the vehicle electrical system.

In the case of alternators where the stator winding is star-connected (Figure 6a), two additional diodes (therefore also called "supplementary diodes") rectify the positive and negative half-wave of the star point. By rectifying the third harmonic in the phase voltages, these supplementary diodes can increase the alternator output current at 6000 rpm by up to 10 %. Alternator effi-

ciency is thus significantly improved in the upper speed range. In the lower speed range, the amplitude of the third harmonic is below the vehicle system voltage such that the supplementary diodes cannot deliver any current. Supplementary diodes are rarely used in modern-day alternators.

Instead of high-blocking-capability power diodes, modern-day motor-vehicle alternators use Zener diodes to rectify the alternating voltage. Zener diodes limit voltage peaks that occur and thereby protect the alternator regulator and sensitive electrical-system consumers against overvoltages which can be caused for example by the deactivation of consumers (load-dump protection). When using a 14 V alternator, the response voltage of a rectifier fitted with Zener diodes ranges from 25 to 30 V.

Reverse-current block

The rectifier diodes in the alternator serve not only to rectify the alternator voltage, but also to prevent the battery from discharging via the stator windings. If the engine is stopped or if the engine revs are so low (e.g., starting speed) that the alternator is not yet excited, without diodes a battery current would flow through the stator winding. The diodes are polarized with regard to the battery voltage in the reverse direction so as to prevent the flow of any significant battery discharge current. Current can therefore only flow from the alternator to the battery.

Generally, alternators are not provided with polarity-reversal protection. Reversal of battery polarity (e.g., mixing up the battery poles when using an external battery to start the vehicle) can lead to destruction of the alternator diodes and poses a threat to the semiconductor components of other devices.

Alternator electric circuits

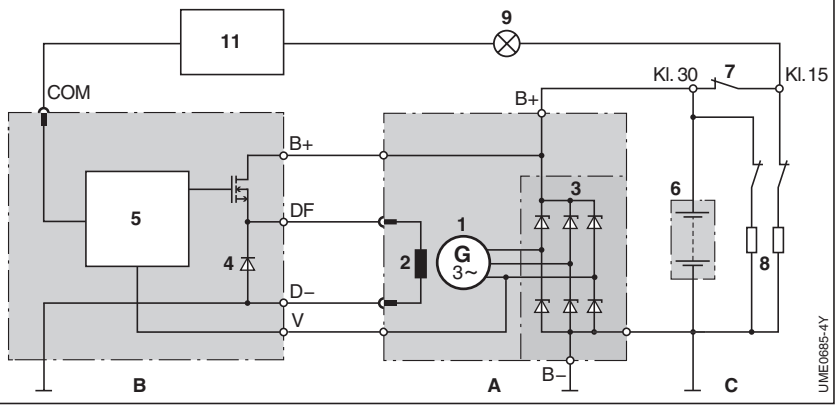
The standard version of an alternator has three electric circuits:

– pre-excitation circuit (external excitation by battery current),
– excitation circuit (self-excitation),
– main circuit.

Pre-excitation circuit

Before self-excitation of the alternator can start, a voltage must be induced in the stator which can drive the excitation current. The rotor does also have a low residual magnetism (remanence) in the unenergized state, but this is not sufficient for self-excited operation. The alternator must therefore be externally excited at the start of operation. This is done via the pre-excitation circuit, which is supplied by the battery.

Previously the pre-excitation current was directed via the charge-indicator lamp and if necessary to a resistor connected in parallel to the charge-indicator lamp. As soon as the voltage at the stator winding was high enough for the excitation diodes to have switched through, the excitation winding was supplied by the current generated in the alternator (self-excitation). Because the old regulators were switched through with the alternator stationary, the excitation circuit had to be disconnected from the main circuit so that the battery was not discharged by the excitation circuit with the vehicle at a standstill. Thanks to the "intelligent" multifunction regulators and interface regulators which have come to be used in the meantime, it has been possible to dispense with these excitation diodes because the new regulators deactivate the excitation current automatically with the vehicle at a standstill. When the multifunction regulator (see Voltage regulation) receives the information "ignition on" via the communication interface or connection L (Figure 7), it switches on the pre-excitation current with the permanently set on/off ratio (approximately 20 %, "controlled pre-excitation"). As soon as the rotor is turning, the regulator detects a voltage signal at its phase connection V, and from its frequency it can derive the alternator speed. When the switch-on speed set in the regulator is reached, the regulator switches through the output stage completely (on/off ratio 100 %) so that the alternator starts to supply current to the vehicle electrical system.



Excitation circuit
The purpose of the excitation current I_{err} is to generate a magnetic field in the rotor's excitation winding during the alternator's entire operating period and thereby induced in the stator windings the required alternator voltage. Since alternators are self-excited generators, the excitation current is branched from the stator winding. Alternators with multifunction regulators draw the excitation current directly from terminal B+ (Figure 7). The excitation current flows through the rectifier's power-plus diodes via the multifunction regulator, the carbon brushes, collector rings, and the rotor winding to ground (B–).

Main circuit
The alternating voltage induced in the alternator's phases must be rectified by the bridge circuit fitted with power diodes and directed to the battery and the electrical loads/consumers.

The alternator current I_G flows from the stator windings via the power diodes to the battery and to the consumers in the vehicle electrical system. The alternator current is divided into the battery charging current and into the consumer current.

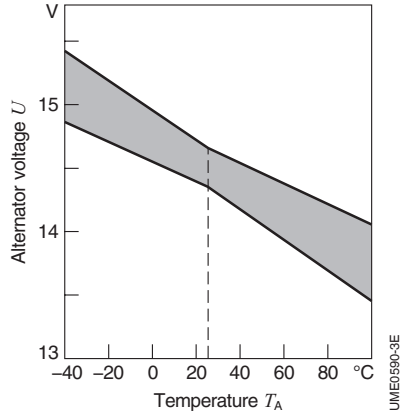
DFM (DF monitoring), S Sensing (battery-voltage supply lead),
L Lamp connection (activation of alternator indicator lamp).

Voltage regulation



Function of voltage regulation

At constant excitation current, the alternator voltage is dependent on the alternator speed and load. The function of voltage regulation is to keep the alternator voltage – and thus also the vehicle system voltage – constant over the full speed range of the vehicle engine, irrespective of electrical load. To this end, the voltage regulator regulates the extent of the excitation current and consequently the magnitude of the magnetic field in the rotor depending on the voltage generated in the alternator. In this way, the regulator keeps the vehicle system voltage constant and prevents the battery from being overcharged or discharged during vehicle operation (see also Voltage regulation, 12 V vehicle electrical systems).

Vehicle electrical systems with 12 V battery voltage are regulated in the 14 V tolerance zone, those with 24 V battery voltage (commercial-vehicle sector) in the 28 V tolerance zone. As long as the voltage generated by the alternator is below the control voltage, the voltage regulator does not switch and the regulator output stage is switched on (on/off ratio 100 %).

The regulator characteristic curve (alternator voltage as a function of temperature) is adapted to the chemical properties of the battery. At low temperatures the alternator voltage is slightly higher to improve the battery charge in winter. The input voltages of the electronic devices are taken into consideration here. At higher temperatures the alternator voltage is lower so as to avoid battery overcharging and gassing in summer. An example of a characteristic curve is shown in Figure 8. The voltage level is 14.5 V with a gradient of –10 mV/K (temperature compensation).

Figure 8: Regulator characteristic curve
Permissible tolerance band of the alternator voltage (14 V) as a function of the alternator intake-air temperature T_A.

Principle of voltage regulation

If the voltage exceeds the upper setpoint value, the regulator switches off the output stage for activating the rotor winding. Driven by the inductance of the field coil, the excitation current initially flows on via the free-wheeling diode connected in parallel to the rotor winding; excitation becomes weaker and as a result the alternator voltage decreases. If now the alternator voltage drops below the lower setpoint value, the regulator switches on the excitation current again. Excitation increases and with it also the alternator voltage. If the voltage exceeds the upper setpoint value again, the regulation cycle begins afresh. Since the regulation cycles are in the range of milliseconds, the mean alternator-voltage value is well regulated to the specified characteristic curve (Figure 8).

The ratio of the respective on- and off-times is decisive for the magnitude of the mean excitation current. Because the performance of the alternator is lesser at low than at high rotational speeds, the excitation current must be adapted with changes in rotational speed. At low rotational speeds the on-time of the regulator output stage (power transistor) is relatively long and the off-time short. The excitation current is only interrupted by the regulator for a short time and consequently its mean value is high. Conversely, at high rotational speeds the on-time is short and the off-time long. A low excitation current flows.

If the excitation current were to be interrupted by the regulator output stage, a voltage peak would be created by the inductance of the excitation winding. A free-wheeling diode is connected in the regulator in parallel to the rotor winding to prevent the creation of such voltage peaks, which would destroy the regulator. It takes

over the excitation current at the point when the regulator output stage is switched off and ensures that the excitation current decays slowly until the regulator output stage is switched on again.

Regulators

Voltage regulators were formerly produced using discrete components. Today they incorporate hybrid or monolithic circuits (Figure 7). When monolithic technology is applied, the control and regulator IC, the power transistor, and the freewheeling diode are all accommodated on a single chip.

Multifunction regulators and interface regulators

Multifunction regulators and interface regulators perform special functions in addition to the task of voltage regulation described above. These regulators are today fitted in all new compact alternators. They draw the excitation current directly from B+ so that no excitation diodes are required.

The following additional functions can be integrated in these regulators:

– controlled pre-excitation,
– recognition of "alternator turning" through evaluation of the phase signal at connection V,
– emergency regulation in the event of interruption of the line at connection L or of the interface line (communication interface),
– overtemperature protection by limiting the excitation current when the limit temperature is exceeded,
– load-response functions.
– In the case of interface regulators, the control voltage can be adjusted via the communication interface.

For the "load-response function" (LR) a distinction is made between LR Driving and LR Start. LR Driving brings about a slow correction of the excitation current after an electrical-system load has been cut in so that the engine has sufficient time at idle to compensate the alternator's rising drive torque. LR Start means that the alternator is inactive for a specific period after starting so that the engine can settle to a stable idle.

The power loss of the alternator indicator lamp in the instrument panel is frequently too great and disruptive. It can be reduced for example by transferring to an LED display. Multifunction regulators permit the activation of both bulbs and LEDs as display elements.

Intelligent alternator regulation

Voltage regulators with digital interfaces (interface regulators) are the response to increased demands for greater mutual compatibility between engine-management and alternator-regulation systems. Various interfaces (e.g., bit-synchronous interface or LIN interface) are used here depending on the vehicle manufacturer. These interfaces are the means used to communicate information which in older regulators was output via individual connector pins.

The control voltage can be adjusted via the regulator interface. If a low control voltage is set, this results in low or no alternator power output because the voltage generated by the alternator is at the battery-voltage or lower. The power input and the torque input at the alternator shaft decrease to low levels. On the other hand, the alternator voltage can be stepped up via the interface so that the alternator charges the battery and supplies the electrical equipment in the vehicle electrical system.

Because the alternator converts mechanical energy into electrical energy, the power input at the alternator shaft increases as the electrical power output increases. The internal-combustion engine needs more fuel to cover the alternator's power requirement. However, if the alternator voltage is stepped up in overrun phases, the energy tapped by the alternator at the crankshaft does not cost any additional fuel, because overrun fuel cutoff stops the fuel supply. When the driver presses the accelerator pedal, the engine ECU steps down the alternator voltage again with the aid of the communication interface to the regulator in order to relieve the strain on the engine by the alternator torque. This process is also known as intelligent alternator regulation and recuperation.

Interface regulators allow a fine-tuning of load-response functions to engine operating state, optimization of torque patterns to reduce fuel consumption, and adjustment of charging voltage to improve the battery charge state.

Characteristic alternator values

Alternator performance

Automotive alternators function through the constant transmission ratio to the engine in a large rotational-speed range (1,600 to 20,000 rpm). Characteristic curves reflect the characteristic performance of an alternator. The alternator full-load characteristic refers here to a constant alternator voltage and to a defined ambient temperature.

Figure 9: Typical characteristic curve of an alternator

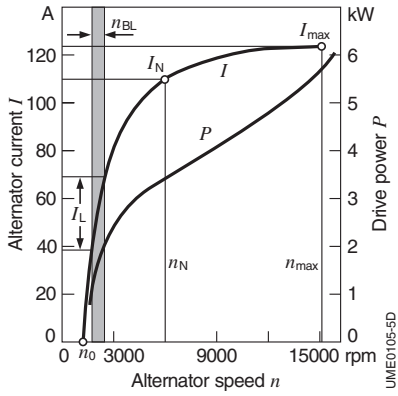
I_N Rated current.



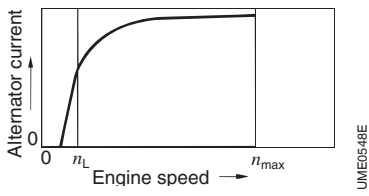


Figure 10: Characteristic curve of maximum alternator current at constant voltage

n_L Idle speed,
n_{max} Maximum speed.

Current characteristic

Defined rotational-speed points of the alternator are considered to describe the current characteristic (Figure 9).

Zero-ampere speed

The alternator can only deliver current to the vehicle electrical system when the induced voltage U_{ind} in the stator windings is greater than the sum total of the two diode forward voltages and the vehicle system voltage applied between B+ and B– (from approx. 1,000 rpm). The induced voltage increases with the frequency of the change in flux, i.e., with the speed of the rotor:

$$U_{ind} \sim \frac{d\Phi}{dt}.$$

There is a speed range between zero and the "zero-ampere speed", in which the alternator does not output any current (Figures 9 and 10) because the induced voltage in this range is too low.

Rotational speed and current at engine idle

The alternator speed at engine idle depends on the alternator's transmission ratio in relation to the engine. For compact-diode alternators this is typically in the range of n_L = 1,500 rpm, for compact alternators according to the usually higher transmission ratio typically in the range of n_L = 1,800 rpm.

The current generated by the alternator at engine idle speed (idle current) must at least be enough to supply the permanently switched-on loads/consumers.

Rated speed and rated current

The full-load current which the alternator outputs at the rated speed n_N = 6,000 rpm, at the alternator voltage U_G = 13.5 V, and at ambient temperature T_U = 23 °C is referred to as rated current.

Maximum speed and maximum current

The alternator current rises sharply under full-load conditions as the speed increases. The maximum current I_{max} is the highest current that can be generated by the alternator.

At higher speeds the voltage drop at the magnetizing reactance X_h (Figure 11) and the leakage reactance X_σ becomes so great that, in spite of an increasing

induced voltage, the current fails to rise significantly. The magnetizing reactance is obtained from that part of the coil inductance which generates the profitable induced voltage and whose flux takes the envisaged paths in the rotor and the stator. The leakage reactance forms that part of the flux which is not linked to the rotor – i.e., leakage fields which short, for example, in the end winding or directly via the groove.

The alternator's speed is first and foremost limited by its design (see Conditions of service).

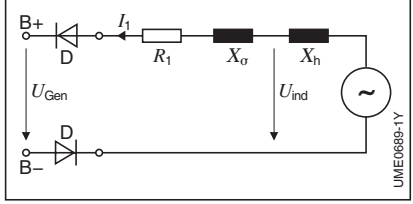
Characteristic of drive power

The characteristic of drive power is used to design the drive belt. The characteristic shows by way of the engine speed range what power (maximum) is transmitted by the engine to the alternator. It is also possible to determine the alternator's efficiency from its drive power and power output. The characteristic of driver power exhibits a flat shape in the middle speed range and rises sharply at higher speeds.

Operating conditions

Rotational speed

The utilization of an alternator (generable energy per kilogram of mass) increases as the speed increases. It is therefore necessary to aim for as high a transmission ratio as possible between the crankshaft and the alternator. The alternator already outputs at least a third of its rated power when the engine is at idle speed. However, it is important to ensure that at maximum engine speed the maximum permissible alternator speed is not exceeded. Widening of the claw poles and the service life of the ball bearings used determine the maximum permissible speed of motor-vehicle alternators.



Typical values for the maximum speed are for compact alternators in the range of 18,000 to 22,000 rpm, for compact-diode alternators in the range of 15,000 to 18,000 rpm, and for alternators for commercial vehicles between 6,000 and 12,000 rpm. The transmission ratio for passenger cars is between 1:2.2 and 1:3, and for commercial vehicles up to 1:5.

Cooling

The losses arising during conversion from mechanical to electrical energy results in the alternator components being heated. The surrounding air in the engine compartment is used to cool the majority of the motor-vehicle alternators used today.

Figure 11: Simplified diagram of a phase with rectification

B+ Battery positive terminal,

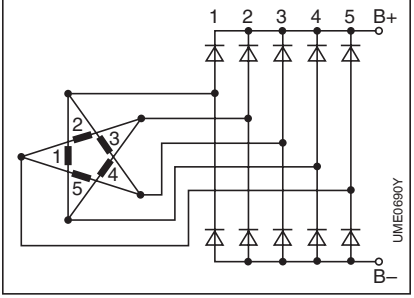
D Rectifier diodes,
I_1 Alternator current,
R_1 Ohmic resistance,
X_σ Leakage reactance,
X_h Magnetizing reactance,
U_{ind} Induced voltage,
U_{Gen} Alternator voltage.

If the surrounding air is not sufficient to cool the alternator, fresh-air induction from cooler areas or liquid cooling are suitable measures for cooling the components adequately.



Engine vibrations
The alternator can, depending on the mounting conditions and the vibration characteristic of the engine, be exposed to vibration accelerations of 500 to 800 m/s^2. The mountings and the components of the alternator are thereby subjected to high forces. Critical natural frequencies in the alternator assembly must therefore be avoided at all costs.

Engine-compartment climate
The alternator is exposed to splash water, dirt, oil and fuel mist, and where necessary road salt (grit). To protect the alternator against corrosion, it is imperative to observe minimum distances between components with different electric potentials or to insulate the live components.

Acoustic behavior
The stringent demands placed on the noise emissions of modern-day vehicles and the superior smooth running of modern-day internal-combustion engines require quiet alternators. As well as chamfers on the claw-pole fingers which reduce the hard chopping of the magnetic flux at finger edges, there are other possibilities for reducing the noise magnetically generated by motor-vehicle alternators. The following may be used: firstly, five phases in a pentagram connection (Figure 12), and secondly, two three-phase systems which electrically offset by 30°.

Interference-suppression measures
The alternator and also other electrical loads/consumers of a motor vehicle can interfere with other electrical and electronic devices through their electromagnetic fields. Intensified interference suppression of alternators is then necessary if for example a radio installation, a car phone, or a car radio is operated in the immediate vicinity of or in the vehicle itself. Alternators are for this reason equipped with an suppression capacitor. On older compact-diode alternators a suppression capacitor can be subsequently mounted to the outside of the collector-ring end shield. On compact alternators it is already integrated in the rectifier or in the regulator housing.

Figure 12: Pentagram-connected five-phase stator winding with connected bridge rectifier as measure for improved acoustic behavior
B+ Battery positive terminal,
B– Battery negative terminal.

Efficiency

The ratio between the power which is supplied to the unit and the actual power output is known as the efficiency. Losses are an unavoidable byproduct of all processes in which mechanical or kinetic energy is converted into electrical energy. The losses in the claw-pole alternator are categorized as follows (Figure 13).

Losses in the claw-pole alternator

Copper losses in the stator and rotor windings

The ohmic losses in the stator windings and the rotor winding are called copper losses. They are proportional to the square of the current.

Iron losses in the laminated stator core

Iron losses result from hysteresis and eddy currents produced by alternating magnetic fields in the iron of the stator.

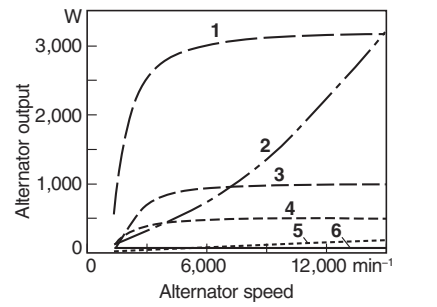
Eddy-current losses on the claw-pole surface

Eddy-current losses on the claw-pole surface are caused by fluctuations in flux brought about by the stator slotting.

Rectifier losses

Rectifier losses are caused by the voltage drop at the diodes. Standard diodes have a voltage drop of around 1 V. Rectifier losses can be reduced and thus efficiency improved by using semiconductors with a lower voltage drop, such as for example high-efficiency diodes with a voltage drop between 550 mV and 700 mV or active rectification diodes (ARDs), which with the aid of activated MOSFETs exhibit only a few millivolts of voltage drop.

Mechanical losses



Mechanical losses include friction loss in the rolling bearings and at the sliding contacts, air resistance encountered by the rotor and, above all, fan resistance which rises dramatically as speed increases (aerodynamic losses).

Efficiency optimization

In regular automotive operation, the alternator operates in the part-load range. Efficiency at medium speeds is then 70 to 80 %. The use of a larger (and heavier) alternator allows it to operate in a more favorable part-load efficiency band for the same electrical load. The efficiency gains provided by the larger alternator more than compensate for losses in fuel economy associated with greater weight. However, the higher mass moment of inertia in the belt-drive system must be taken into consideration.

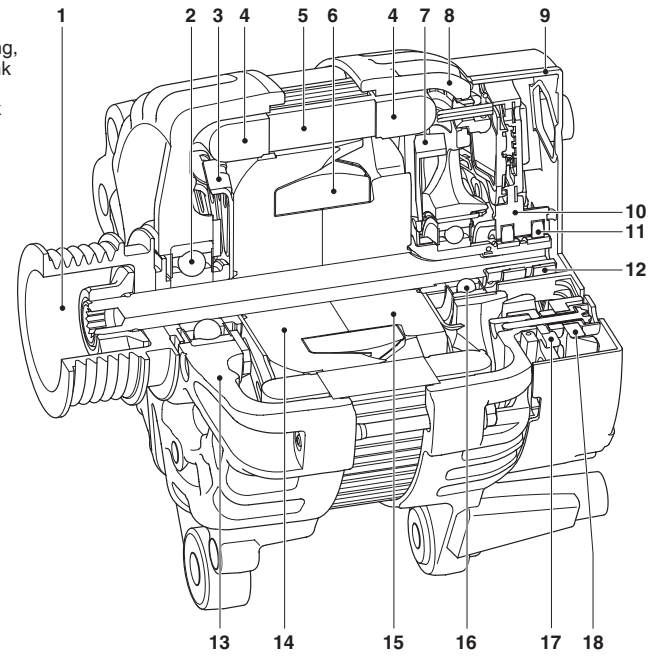
Alternator versions



Claw-pole alternators have completely replaced the direct-current generators previously used as standard in motor vehicles. Based on equal outputs for both concepts, a claw-pole alternator weighs 50 % less, and is also less expensive to manufacture. Large-scale application (at the beginning of the 1960s) only became feasible with the availability of compact, powerful, inexpensive, and reliable silicone diodes.

Design criteria
Different basic designs have been developed for the various conditions of service and performance ranges of the respective vehicle types and their driving engines. The following criteria are crucial to the choice of alternators:

- vehicle type,
- operating conditions,
- rpm range of the respective internal-combustion engine,
- battery voltage of the vehicle electrical system,
- power demand of the loads/consumers,
- strain of the alternator by environmental influences (e.g., heat, dirt),
- installation conditions and dimensions.

Derived from these criteria is the required electrical dimensioning of the alternator, i.e.,
- alternator voltage (14 V or 28 V),
- maximum power output (voltage × current intensity),
- maximum current.

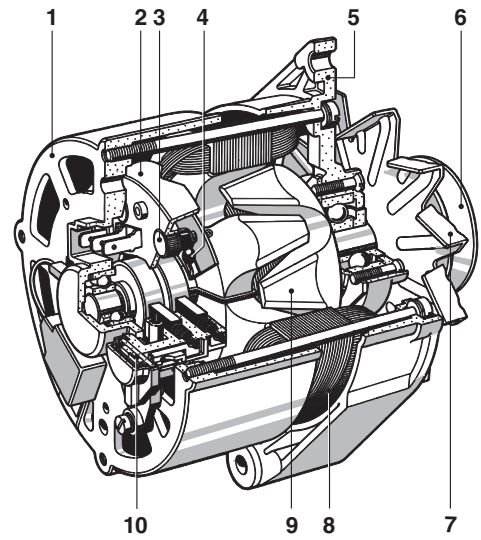
Design of an alternator for use in vehicles

The alternator casing consists of the drive end shield and the collector-ring end shield (Figure 14, see also Figure 1), between which the stator is mounted. The rotor shaft is mounted in the two bearing halves. The alternator stator consists of laminations provided with slots which are stacked and welded into a fixed laminated core. The slots contain the coils of the stator windings.

The rotor gives the claw-pole alternator its name. It consists of two opposingly polarized pole-wheel halves whose claw-like pole fingers mesh alternately as south and north poles (see Figures 3 and 4).

The two pole-wheel halves enclose the ring-coil-shaped excitation winding (see Figure 4). The excitation winding is supplied with current via the carbon-brush/collector-ring system (see Figure 3). Because the regulator adjusts the excitation current as a function of alternator voltage and set control voltage (nominal voltage), the brush holder with the carbon brushes is often integrated in the regulator housing. The regulator housing is mounted on the collector-ring end shield. Springs press the brushes against the collector rings so that, even under raw ambient conditions, they establish an engine a secure electrical contact with the collector rings on the rotor shaft.

The magnetic working flux passes through the pole core, the left pole half and its fingers, across the air gap to the fixed laminated stator core with the stator winding, and returns through the right pole-wheel half back to the pole core to complete the circuit.



The electronic voltage regulator forms together with the brush holder a single unit if it is intended for mounting directly on the alternator. In some cases the electronic voltage regulator is mounted separately from the alternator in a protected place on the vehicle body or is integrated in a control unit (e.g., in the engine management). The external regulator can then be connected via electrical plug-in connections to the brush holder.

Compact alternator

The compact alternator is characterized by two internal fans which are mounted on the rotor at the drive and collector-ring ends. The fans draw in air in each case axially and discharge the heated air radially (double-flow ventilation). The two small

Figure 15: Compact-diode alternator

6 Belt pulley,
7 External fan,
8 Stator,
9 Claw-pole rotor,
10 Transistor regulator.

fans produce substantially less aerodynamic noise than the large external fan of a compact-diode alternator. They are also suitable for higher rotational speeds (maximum speed: 18,000 to 22,000 rpm). These two properties provide for a higher transmission ratio between the crankshaft and the alternator so that compact alternators can output up to 25 % more power for the same engine speed and size.

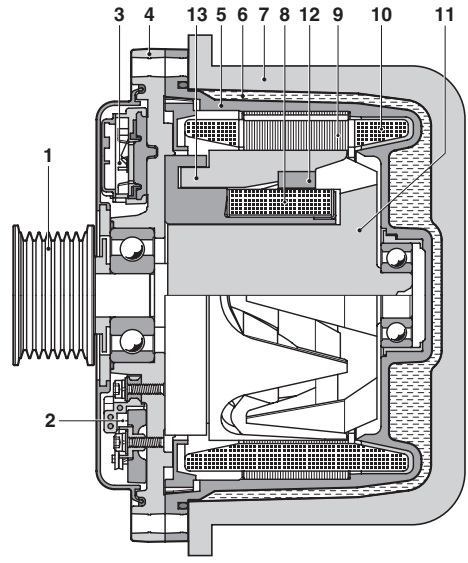
The compact alternator is today used across the board in the passenger-car and commercial-vehicle sectors. The EL Series (Efficiency Line), the BL Series (Base Line) or the PL Series (Power Density Line) is used to suit the individual requirements. The service life of the alternator is a decisive factor in the commercial-vehicle sector. For this reason, larger ball bearings at the drive end and a brush/collector-ring system optimized for longer service life are used in the Classic Line (CL) and Heavy Duty (HD) Series and in the HDS (Heavy Duty Second Generation) Series.

The maximum permissible speed of commercial-vehicle alternators ranges between 6,000 rpm and 12,000 rpm.

Compact-diode alternator

The compact-diode claw-pole alternator (Figure 15) differs from the compact alternator first and foremost in the form of the large fan which is located between the belt pulley and the pot-shaped alternator casing. The external fan with a maximum speed of 12,000 to 18,000 rpm draws the cooling air axially through the casing (single-flow ventilation).

Because the rectifier, regulator, and brush/collector-ring system are arranged inside the end shield, the shaft inside the collector rings must be relatively thick to be able to transmit the belt-drive forces to the external ball bearing. The collector rings therefore have a large diameter, only permitting a limited brush service life.



Compact-diode alternators can still be found in older vehicles.

Alternators with windingless rotors

The windingless-rotor alternator is a special design variant of the claw-pole alternator where only the claw poles rotate, while the rotor winding remains stationary. With this design, the regulator supplies directly to the rotor winding; sliding contacts are not required (Figure 16).

Figure 16: Liquid-cooled alternator with windingless rotor

2 Rectifier
3 Regulator,
4 Drive end shield,
5 Alternator casing,
6 Coolant jacket,
7 Jacket casing for engine mounting,
8 Stationary rotor winding,
9 Stator core,
10 Stator winding,
11 Windingless rotor,
12 Non-magnetic intermediate ring,
13 Conductive element.

The rotating parts consists merely of the rotor with pole wheel and conductive element. The conductive element consists as a rule of a magnetically highly permeable material (e.g., soft iron), which boosts the magnetic flux of a magnetic field acting on the conductive element or forwards it (e.g., to the stator core). Six pole fingers of the same polarity in each case form a pole-finger crown as north and south poles. Only one of the two pole-finger crowns is connected directly to the rotor shaft. A non-magnetic retaining ring, which is located below the meshing pole fingers, holds the two crowns together as claw-pole halves.

The magnetic flux passes from the pole core of the rotating rotor via the fixed internal pole to the conductive element, then across its pole finger to the fixed stator core. The magnetic circuit is completed in the rotor pole core via the opposingly polarized claw half. The magnetic flux must when compared with the collector-ring rotor overcome two additional air gaps between the rotating pole wheel and the fixed internal pole.

Thanks to the omission of the wear component collector-ring/carbon system, these alternators are particularly suitable for applications which require a long service life combined with heavy alternator load, e.g., for construction machinery or traction generators. The units weigh somewhat more than claw-pole alternators with collector rings due to the fact that additional iron and copper is required to conduct the magnetic flux through two additional air gaps.

Liquid-cooled alternator

The windingless rotor is also used in liquid-cooled alternators, among other applications. In the case of this alternator, engine coolant flows around the complete jacket and rear of the alternator casing. This significantly reduces noise when compared with air-cooled alternators in that the alternator is completely encapsulated and no fan produces aerodynamic noise. The electronic components are mounted on the drive end shield.

Current alternator series

Efficiency Line

Efficiency Line (EL) Series alternators are suitable for vehicle electrical systems with medium to high power demand. The Efficiency Line covers the rated-current range of 150 A through 250 A. As the name already intimates, Efficiency Line alternators convert energy with high efficiency. Five phases are used from a rated current of 180 A to improve acoustic behavior and reduce the voltage ripple. A winding with a high copper space factor (44 to 50 %) is pulled into the stator core.

Base Line

Base Line (BL) Series alternators were developed for vehicle electrical systems with low to medium power demand. Their rated current extends to 150 A. Owing to their compact design they can also be installed in the confined engine compartments of small vehicles. The stator core carries a three-phase pull-in winding with a copper space factor of between 40 % and 50 %.

Power Density Line

Power Density Line (PL) Series alternators were developed for vehicle electrical systems with medium to high power demand. The Power Density Line covers the rated-current range of 150 A through 250 A. The stator winding is inserted into a flat iron core. The flat core with winding is bent round and the ends are welded. The flat core delivers a copper space factor of over 60 %, which is crucial to the high power density of PL alternators.

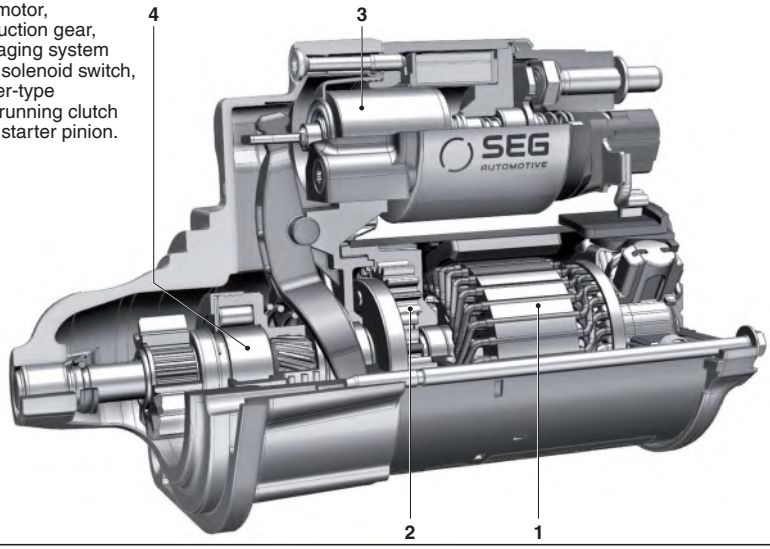
All PL alternators are of five-phase design to keep noise emissions and voltage ripple as low as possible. The optimized cooling and high efficiency enable them to be operated at high ambient temperatures.

Starters for passenger cars and light commercial vehicles

Application

Overview
Internal-combustion engines require start assistance to start. They must be cranked by a starter at a minimum speed before they can supply sufficient power in sustained operation. A starter consists of the following assemblies (Figure 1):
– starter motor (electric motor, DC motor),
– reduction gear,
– engaging system with solenoid switch,
– overrunning clutch with starter pinion.

The starter torque is transmitted via the starter pinion and the engine-flywheel ring gear to the engine (see Figure 6). The starter pinion engages the ring gear during the starting operation. The ring gear with around 130 teeth is located on the engine flywheel or on the housing of the hydrodynamic torque converter. The starter pinion with around 13 teeth is situated a few millimeters in front of the ring gear in its rest position.



Requirements

Because of the high step-down ratio between the starter pinion and the ring gear, the starter may be designed for high speeds and low torque. This allows the dimensions and the weight of the starter to be kept small. The transmission ratio is in the range of around 1:10, enabling the speeds required for sustained internal-combustion engine operation to be achieved.

Compression and decompression in the cylinders means that the torque required to turn the internal-combustion engine over fluctuates considerably, as a result of which the engine speed also fluctuates considerably. Figure 2 shows a typical graph for engine speed and starter-motor current on cold start.

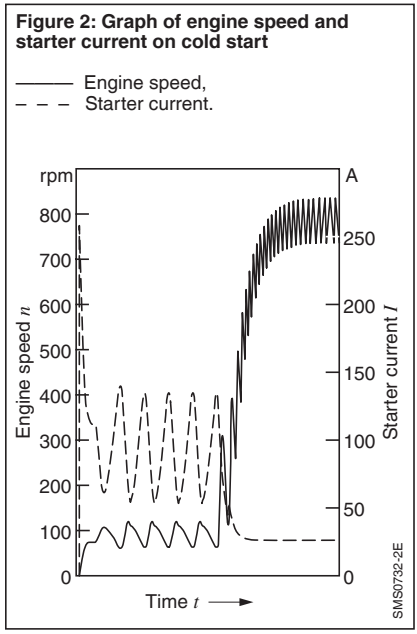
The starter itself must satisfy the following technical requirements:
– readiness to function at any time,
– sufficient starting power,
– long service life,

Figure 1: Starter for passenger cars and light commercial vehicles
1 DC motor,
2 Reduction gear,
3 Engaging system with solenoid switch,
4 Roller-type overrunning clutch with starter pinion.

– robust design,
– low weight and small installation space,
– maintenance-free operation.

Influencing factors
The starter must crank the internal-combustion engine at a minimum speed (starting speed) in order to achieve the thermodynamic and mechanical conditions for sustained operation. The cranking speed largely depends on the characteristics and properties of the internal-combustion engine (engine type, engine swept volume, number of cylinders, compression, bearing friction, engine oil, fuel-management system, additional loads driven by the engine), and the ambient temperature. In general, starting torque and starting rotational speed require a gradual increase in starting power as temperatures decline. However, the power supplied by a starter battery falls as temperatures drop because its internal resistance increases. This opposing relationship of electrical load requirements and available power means that the cold start constitutes an unfavorable operating scenario. This must be taken into consideration in the design of the starting system.

Classification
Passenger-car starting systems are designed for a rated power of up to 3 kW and a rated voltage of 12 V. These can start gasoline engines with up to approximately 7 liters engine displacement and diesel engines with up to approximately 4 liters.



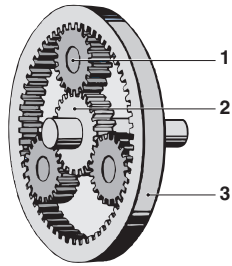
Use of lithium-ion batteries
The use of lithium-ion batteries imposes particular demands on a starter. These batteries are used because they are lower in weight, require less space for installation, and are more suitable for recuperation. Higher voltages and currents are involved compared with lead-acid batteries, meaning that the starter is subject to increased electrical and mechanical load.

Starter design and operation

A starter essentially consists of the electric motor and the engaging system with solenoid switch, engagement lever, overrunning clutch, meshing spring, and starter pinion. The engaging system ensures that the starter pinion meshes (engages temporarily) with the ring gear. In addition, the starter incorporates a reduction gear, which increases the electric-motor torque at the starter pinion.

During the start, the starter pinion engages with the ring gear by means of the solenoid switch with the assistance of the helical spline when the driving switch is operated. The starter pinion drives the internal-combustion engine via the ring gear until the engine can run at sustained operation. After a successful start the starter pinion is returned to the rest position (demeshing) by spring force and with the assistance of the helical spring while the internal-combustion engine accelerates quickly to high revs.

Figure 2: Graph of engine speed and starter current on cold start

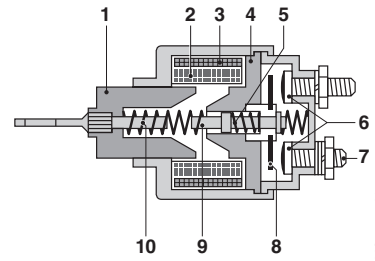


Starter motor
The starter motor is a permanent-field or electrically excited DC motor.

Reduction gear
The objective of starter development is to minimize the weight and dimensions of the starter by reducing the volume of the electric motor etc. In order to achieve the same starting power at the same time, a higher armature speed is required to compensate for the existing lower armature torque. In order nevertheless to achieve unchanged starting power, it is necessary for the now smaller armature torque of the electric motor to be compensated by a higher armature speed. The speed is matched to the engine crankshaft speed by increasing the overall step-down ratio from starter-motor armature to crankshaft with the aid of a reduction gear integrated in the starter. This reduction gear usually takes the form of a planetary gear (Figure 3). It comprises a sun gear mounted on the armature shaft, a planetary-gear carrier normally with three planet gears, and a fixed internal ring gear.

The planetary gear transmits the armature torque via the coupled planetary-gear carrier to the starter drive shaft and to the starter pinion. The high armature speed here (up to 25,000 rpm) is stepped down at a ratio of $i \approx 3$ to 5. The further reduction ratio from starter pinion to ring gear produces an engine speed of around 300 rpm.

Figure 3: Planetary gear
1 Planetary gear (planetary gears are coupled to each other via a planetary-gear carrier not pictured here),
2 Sun gear,
3 Internal ring gear.

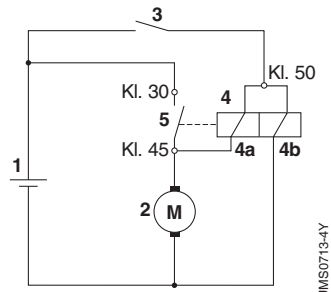


Solenoid switch
The starter current is up to 1500 A for passenger cars. Since contacts for such high currents are subjected to high loads, it is essential to use a power relay. The solenoid switch is actuated by a relatively low control current (relay current, approx. 30 A for passenger cars). For switching it is sufficient to have a mechanical switch (driving switch, start button) or a simple minirelay which is actuated by the engine ECU.

The solenoid switch used in the starter (Figure 4) consists of switch armature, pull-in winding, hold-in winding, magnetic core, contact system (contact spring, contact stud, contact bridge), switch cover with integrated connections, split switch shaft, and return spring. The solenoid switch has to fulfill two functions:
– advancing the starter pinion over the engagement lever into the ring gear and
– switching the main starter current by closing and opening the contact bridge.

The winding is divided into a pull-in winding and a hold-in winding in order to limit heating of the switch winding. Both windings are connected in parallel when the solenoid switch is activated (Figure 5). The magnetic forces of the two windings are added up. The start of the two windings are both applied to terminal 50 of the solenoid switch. The winding end of the pull-in winding is connected via the starter-motor

Figure 4: Solenoid switch
1 Switch armature, 2 Pull-in winding,
3 Hold-in winding, 4 Magnetic core,
5 Contact spring, 6 Contacts,
7 Electrical connection, 8 Contact bridge,
9 Armature shaft (divided), 10 Return spring.



armature, that of the hold-in winding is connected directly to the ground potential. When the battery positive terminal is connected to terminal 50 of the solenoid switch (driving switch in start position), the switch armature is pulled axially into the housing by the magnetic force generated by the pull-in winding and hold-in winding. This movement pushes the starter pinion forwards via the engagement lever towards the ring gear (Figure 6). Only once the switch armature is almost completely pulled in is the contact bridge closed and the main starter current switched on. This prevents the starter motor beginning to rotate before the starter pinion has engaged in the ring gear.

As the two winding ends for the pull-in winding are now connected to positive, current flows only in the hold-in winding. The lower magnetic force of the hold-in winding is sufficient to hold the switch armature securely until the driving switch is opened.

The pull-in and hold-in windings must have the same number of turns. Otherwise the solenoid switch may lock during the deactivation process because the two windings now connected in series are supplied in reverse via terminal 45. The same numbers of turns ensure that the magnetic fields of the coils now passed through in opposite directions compensate each other and the solenoid switch switches off reliably.

Meshing of the pre-engaged-drive starter

The pre-engaged-drive starter has become a worldwide standard for the passenger car, as reliable operation over the entire operating range is guaranteed with this engagement principle. On pre-engaged-drive starters, the engagement travel is made up of a lever-travel phase and a helical-travel phase. When the driv-

11 Helical spline, 12 Meshing spring,
13 Engine-flywheel ring gear.

ing switch is closed terminal 50 of the solenoid switch is connected to the battery positive terminal. The solenoid-switch armature attracts the engagement lever, which in turn pushes the overrunning clutch with the starter pinion via the helical spline against the internal-combustion engine's ring gear (lever travel). The starter-motor armature still does not rotate in this phase as the main current for the armature and excitation windings is not yet switched on (Figure 6a).

If a pinion tooth meshes directly with a tooth gap on the ring gear (tooth-gap positioning) when the starter pinion meets the ring gear, the starter pinion engages as far as the movement of the solenoid switch allows (Figure 6b). If the starter-pinion tooth strikes a tooth on the ring gear (tooth-tooth positioning, Figure 6c) when the starter pinion meets the ring gear – this occurs approximately 80 % of the time – the switch armature tensions the meshing spring via the engagement lever, as the starter pinion can travel no further axially. Once the pinion travel limit generated by the solenoid switch has been reached, the contact bridge of the switch armature closes and the starter-motor armature begins to rotate. In the case of tooth-gap positioning, the rotating starter motor screws the starter pinion fully into the ring gear via the helical spline (helical travel). Starting from a tooth-tooth position, the starter motor turns the starter pinion in contact with the ring gear until a pinion tooth finds a tooth gap in the ring gear and the pretensioned meshing spring pushes the starter pinion and overrunning clutch forward.

The sloping teeth provided at the front of the starter pinion permits an earlier start of the axial engagement movement and consequently produces a greater alignment of pinion tooth and ring-gear tooth at the moment of the first power transmission. This reduces wear.

When the driving switch is opened, the return spring pushes the switch armature – and the starter pinion and overrunning clutch via the engagement lever – back into the rest position. The overrunning torque caused by the friction of the overrunning clutch generates an axial force in conjunction with the helical spline, which supports the starter-pinion's demeshing process.

Overrunning clutch

In all starter designs, the drive torque is transmitted by an overrunning clutch (overriding clutch). It is located between the starter motor and the starter pinion and has the following functions:

– Transmitting the torque from the starter motor to the pinion as long as the starter motor cranks the internal-combustion engine.
– Disengaging the connection between starter pinion and drive shaft as soon as the internal-combustion engine by its own efforts accelerates to higher revs than the starter motor.

Roller-type overrunning clutch

Overrunning clutches for starters are usually frictional in design (roller-type overrunning clutch, Figure 7). The assembly essentially consists of

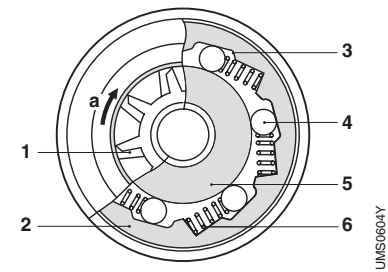
– the driver with the roller race,
– the cylindrical rollers,
– the springs, and
– the starter pinion with the inner race.

The driver is connected via the helical spline to the drive shaft. The cylindrical rollers can move on the roller race and establish the frictional connection between the inner race of the starter pinion and the outer-rotating clutch shell of the driver. The springs press the cylindrical rollers into the narrowing part between the driver's roller race and the inner race. When the starter motor starts, the inner race is also move by the frictional forces acting on the cylindrical rollers. The greater the torque, the further the cylindrical rollers are moved into the narrowing part of the roller race, and as a result the transmissible frictional forces increase proportionally to the torque.

When the overrunning operation is initiated, the cylindrical rollers are moved into the widening part of the roller race, whereby with relatively small force they are in contact with the slipping inner race and the roller race. The overrunning torque that develops is dependent on the spring force and relatively small compared with the torques acting in the drive

direction. However, it does impact on the idle speed of the starter-motor armature that is obtained.

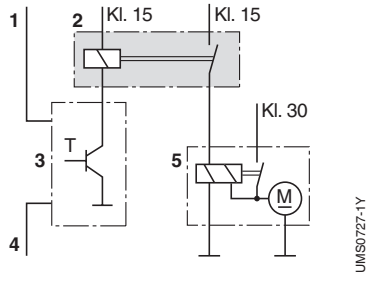
Usually the overrunning clutch is moved together with the pinion during engagement axially in the direction of the ring gear. However, there are starter versions in which only the pinion is moved and the overrunning clutch is axially fixed ("stationary overrunning clutch").



Demeshing
When the driving switch is released, the voltage at the solenoid-switch windings returns to zero. The magnetic force abates and the return spring presses the switch armature back, as a result of which initially the primary-current contact (contact bridge) opens and the starter current is interrupted. The return spring completes the retraction of the starter pinion, disengaging it from the ring gear. The demeshing process is supported by the axial forces acting in the helical spline. The starter freewheels to a standstill and the entire engagement mechanism returns to the rest position.

Switch-off function
The switch armature is connected to the engagement lever in such a way that there is a certain amount of free travel or "play". If the internal-combustion engine fails to achieve sustained operation, the start must be aborted. At this point, the starter pinion and the ring gear are under full load and the starter pinion is fully engaged. When the switch current is switched off, there must be sufficient switch-armature free travel to allow it to open the primary-current contacts. If this is not the case, the engagement lever holds the switch armature in place. The primary-current contact remains closed and it is not be possible to abort the start.

Configuration of a starter



The most important boundary conditions which must be taken into consideration in the configuration of a starter are:
- The minimum starting temperature, i.e., the lowest engine temperature at which a start must still be possible.
- The resistance to rotation of the engine, i.e., the required torque at the crankshaft including all supplementary loads.
- The requirement minimum engine speed at the minimum starting temperature.
- The transmission ration between the starter and the crankshaft.
- The nominal voltage of the starting system.
- The properties of the starter battery.
- The resistance of the supply leads between the battery and the starter and the contact resistances of terminals and switching elements (isolating switches, etc.).
- The starter's speed/torque characteristic.
- The maximum permissible voltage dip in the vehicle electrical system at which the operating capability of the vehicle electronics is still guaranteed.

Figure 7: Roller-type overrunning clutch
1 Starter pinion,
2 Clutch shell,
3 Driver with roller race,
4 Cylindrical roller,
5 Pinion shaft (inner race),
6 Spring.
a Direction of rotation.

In view of these boundary conditions, the starter cannot be considered in isolation. As an integral part of the overall system of internal-combustion engine including its ancillaries, the vehicle electrical system with battery and cabling as well as the starter itself, the starter must be matched to the other components.

Figure 8: Automatic starting system (circuit diagram)
1 Starting signal from driver,
2 Ballast relay,
3 ECU,
4 Park-Neutral position or clutch signal,
5 Starter.

Triggering the starter

Conventional control
During conventional starts, the driver connects the battery voltage (driving switch in starting position) to the starter solenoid switch. The switch current generates in the solenoid switch the switch force which on the one hand moves the starter pinion towards the ring gear and on the other hand switches on the starter's primary current. The starter is switched off by means of the driving switch, which opens and disconnects the voltage from the solenoid switch.

Automatic starting systems
The high demands on vehicles with regard to convenience, safety, quality, and low noise levels have resulted in an increase in the use of automatic starting systems. An automatic starting system differs from a conventional one by virtue of additional components: one or more ballast relays, as well as hardware and software components (e.g., an ECU) to control the starting sequence.

The driver then no longer directly controls the starter relays current; instead the ignition key is used to send a request signal to the control unit, which then performs a series of checks before initiating the starting sequence. The safety check comprises a wide range of options and can verify any of the following:
– Is the driver authorized to start the vehicle (theft-deterrence feature)?
– Is the internal-combustion engine stationary (prevents the pinion from meshing with the moving ring gear)?
– Is the state of charge (in relation to engine temperature) sufficient to carry out the start?
– For automatic transmissions, is the selector lever in the Park position or, for on manually shifted transmissions, is the clutch disengaged?

When the check has been completed successfully, the control unit initiates the start. During the start the starting system compares the engine speed with a desired speed for the internal-combustion engine. Once the engine reaches the desired speed, the ECU switches the starter off. This achieves the shortest possible starting time, reduces the noise levels, and lessens starter wear.

Start/stop system

An automatic starting system can also be used as the basis to implement start/stop operation. Here, the internal-combustion engine is switched off when the vehicle is not in motion taking into account defined temperature inputs and the state of charge of the battery, e.g., at traffic lights on red, and restarts automatically when required.

The operation of a start/stop system – consisting of start/stop starter motor, ECU with start/stop function, electronic battery sensor, deep-cycle-resistant battery, pedals with sensors – presupposes a higher-level activation by means of which the switch-off and restart strategy is implemented.

A start/stop system requires an electrical energy management system that incorporates battery-charge detection. Measures may also be required to stabilize the vehicle electrical system during the starting phase to avoid unacceptable voltage drops. The control equipment and starting system must therefore be matched. The control units have to fulfill their function at a significantly lowered supply voltage.

Demands imposed on start/stop starters

Driven by the efforts of the automotive industry to reduce CO_2 emissions, the global market share of vehicles with start/stop functionality has risen. This is accompanied by demands imposed on starting comfort (start duration and starting noise), on starter service life, and on availability. One technical challenge with regard to start/stop starters is to optimize the rapid-starting performance of the respective internal-combustion engine (repeatable rapid starting). To be able to satisfy the demands with regard to service life and more rapid starting to reduce noise generation, the deep-cycle resistance of start/stop starters is increased significantly compared with conventional starters. Such starters exhibit features like optimized pinion geometry and pinion resilience, load damping, and long-life carbon-brush systems. Starters for start/stop operation achieve in conjunction with a high-quality ring gear more than 330,000 starting cycles.

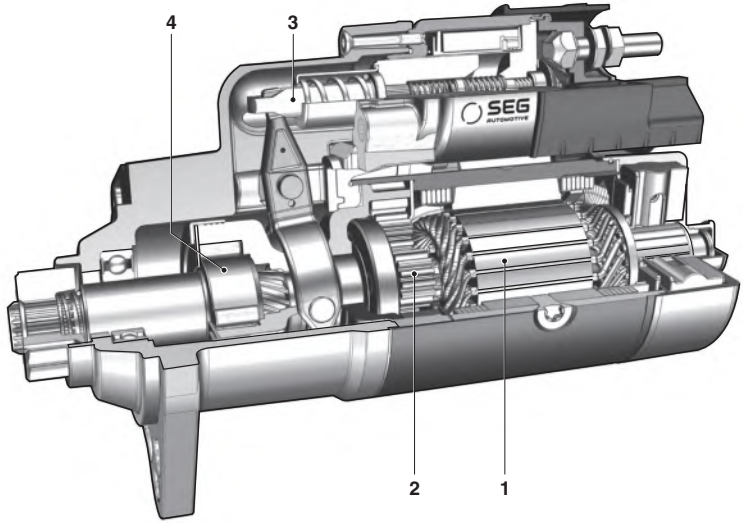
If in a start/stop system the engine stop is immediately followed by a start request (e.g., because the traffic lights turn green at the very moment of the engine stop) this is referred to as “Change of Mind” (CoM). In such a situation the length of time until the engine restart is reduced whereby with the restart the system does not wait for the engine to be at a standstill but instead a start occurs while the engine is still moving. This results in further demands imposed on the starter, particularly with regard to its capacity to mesh with a moving ring gear. Above all meshing with a return-swinging ring gear generates high loads in the drivetrain and wear at the interface between starter pinion and ring gear. In a positive CoM situation (engine turns in the drive direction) additional component load and wear is also accompanied by increased noise emissions. Knowledge of the rundown behavior of the internal-combustion engine and with it the loads to be expected during CoM starts is of vital importance when it comes to designing CoM-capable start/stop systems.

Starters for heavy commercial vehicles

Application

Starters for heavy commercial vehicles are used in trucks as well as in construction machinery, agricultural machinery, locomotives, and stationary engines. These starters have a similar basic design to passenger-car starters (see Starters for passenger cars and light commercial vehicles), sharing among others the following common components (Figure 1):
– DC motor,
– reduction gear,
– engaging system with solenoid switch,
– roller-type overrunning clutch and starter pinion.

Commercially-vehicle starters are typically based on four-pole electrically excited direct-current machines. Starters for large engines (HEF and TB/TF sizes) are designed as six-pole electrically excited machines.



Power requirements

Typical commercial vehicles are equipped with diesel or gasoline engines (sometimes even gaseous-fuel engines) with a displacement of approx. 3 l through 16 l, and for special applications even up to approx. 150 l. The starter types developed for these requirements cover a power range (specified maximum power output) of approx. 2.3 kW through approx. 10 kW in 12 V and 24 V vehicle electrical systems. Furthermore, even starters with up to 25 kW and 110 V are available for special applications.

For large engines up to 150 l displacement HEF and TB/TF size starters (no longer used for new applications) can also be used in parallel starting systems, in which up to three starters supply their power to a common ring gear (Figure 2).

Figures 3 and 4 provide an overview of the starter types used in the commercial-vehicle sector.

Figure 1: Starter for heavy utility vehicles with four-pole electrically excited direct-current machines
1 DC motor, 2 Reduction gear, 3 Engaging system with solenoid switch, 4 Roller-type overrunning clutch and starter pinion.

Operating principle

Torque is transmitted via roller-type overrunning clutches which, depending on the starter size, are moved along with the pinion or are designed to be stationary. To satisfy special requirements, commercial-vehicle starters have special features which are described in the following.

Two-stage meshing

The starter pinion meshes with the ring gear prior to the actual starting operation. The starter torque can be transmitted only when the pinion has become sufficiently aligned with the ring gear.

To guarantee this function with minimal wear even with high starter torque over the entire service life, commercial-vehicle starters are equipped from a rated power of approx. 5 kW with a two-stage meshing system. Here, after the switching relay has been activated (Figure 5), the starter pinion is already turned slowly during the meshing operation to be able to mesh with a gap before the primary current is switched, and then the full starter torque is available. The torque of the first meshing stage is for this purpose reduced by a winding in the solenoid switch (pull-in winding), which is connected as a series resistor to the electric motor (Figure 5a). On successful meshing the switch shaft switches off the pull-in winding shortly before the end point is reached via the NC contact. Shortly after the primary current is switched on via the main contact (Figure 5b).

In some starter types the synchronization between pinion movement and main

Figure 2: Parallel starting system

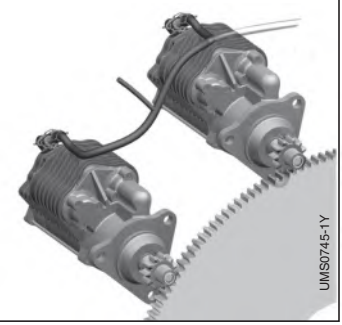


Figure 4: Starter types for commercial vehicles (12 V)

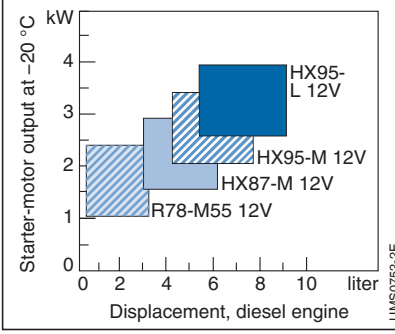

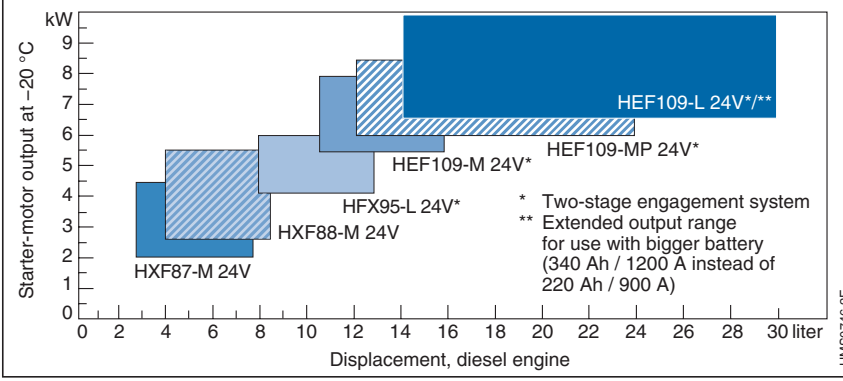

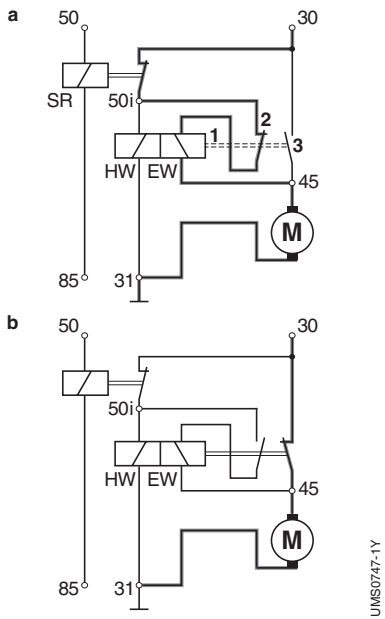

Figure 3: Starter types for commercial vehicles (24 V)

contacts is configured in such a way that the required meshing depth is not only dynamically achieved but also geometrically predefined. These starter types perform in the event of a “corner to corner” connection between pinion and ring gear a “blind connection”, in which the second stage is not switched. The starting operation must then be interrupted by the operator (or the ECU) and repeated.

Figure 5: Current flow for two-stage meshing system

Switching relay

The relay activation currents required for starter activation are up to 60 A for one-stage meshing systems and up to 200 A for two-stage meshing systems. To be able to switch these currents, an additional switching relay (“IMR”, integrated mechanical relay, Figure 6), which is actuated with an activation current of approx. 2 A, is used in all two-stage systems. This relay is mounted on the starter (see Figure 7). It is a compact power relay consisting of a magnetic circuit with simple winding and a contact system with angled contact plate and two contact screws. For contact making the armature draws into the excited magnetic circuit and with the contact plate completes the circuit between the two contact screws. After the excitation current has been switched off, the return spring lifts the contact plate back off the contact screws and pushes the armature back to the rest position.

The switching relay is optionally also available for one-stage systems to reduce the activation current at the system end.

Special requirements for commercial-vehicle starters

Ambient conditions
The engine compartments of commercial vehicles are subjected to heavy dirt, dust and water bombardment both in agricultural- and construction-machinery applications and in on-highway applications. To ensure robust operation under these boundary conditions, commercial-vehicle starters are increasingly being equipped with a free-ejecting meshing drive. The starter is sealed here by a shaft seal between pinion shaft and starter housing against the engine compartment.

Free-ejecting commercial-vehicle starters can optionally also be completely sealed against water ingress; they are then suitable for use in forded conditions or with a flooded engine compartment. A pressure-equalization element is used here to reduce air-pressure fluctuations inside the starter caused by ambient and temperature conditions.

Protection against misuse
Because of the varied conditions of use and the prerequisite of maximum availability, some applications necessitate a feature that provides protection against misuse, preventing the starter from incurring damage due to excessive activation.

For this purpose, starters are available for mid-size and heavy diesel engines with the option of a built-in thermostatic switch (Figure 7) in the electric motor which interrupts an excessively long cranking operation before the starter can incur damage due to overheating.

This safety feature is self-resetting and reversible, i.e., a new starting operation can be initiated after the starter has cooled down.

In TB/TF Series starters thermostatic switches are optionally available in the carbon brushes and in the relay winding as well to provide further safeguarding in other operating conditions.

Potential-free housing
In commercial vehicles and also in passenger cars the engine block or the vehicle chassis is usually used as frame potential for the electrical connection between the battery and the starter. However, some special applications (e.g., in ships, locomotives, and special vehicles with readily flammable cargos) require the vehicle chassis to be isolated (potential-free). For this purpose commercial-vehicle starters are optionally equipped with an “isolated return line” (Figure 8), in which all the connections are insulated against the starter housing.

The negative-side connection to the vehicle electrical system is then established via a special terminal 31 with a separate supply line to the negative battery terminal.

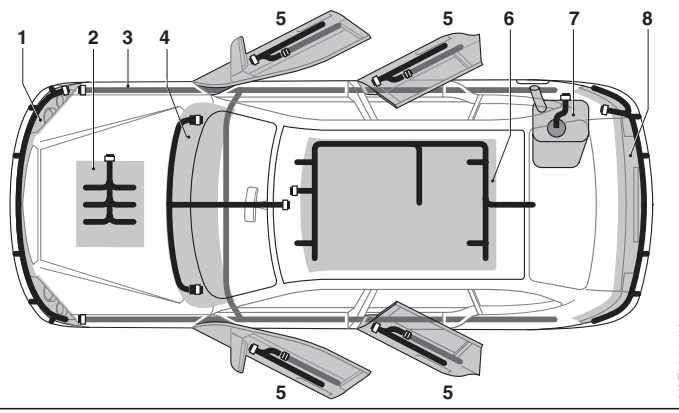
Wiring harnesses and plug-in connections

Wiring harnesses

Requirements
The purpose of the wiring harness is to distribute power and signals within a motor vehicle. A wiring harness in the present-day, mid-class passenger car with average equipment has approximately 750 different lines, their length totaling around 1500 meters (Table 1). In recent years, the number of contact points has practically doubled due to the continuous rise in functions in the motor vehicle. A distinction is made between engine-compartment wiring harnesses and between body, front-end, rear-end, cockpit, roof, door, and tank wiring harnesses (Figure 1, Table 2). Above all, engine-compartment wiring harnesses are subject to high temperature, vibration, and media loads.



Wiring harnesses have considerable influence on the costs and quality of a vehicle. The following points must be taken into consideration in wiring-harness development:
– imperviousness to dust and media,
– electromagnetic compatibility,
– temperatures,
– protection of the wires against damage,
– wire routing,
– ventilation of the wiring harness.

It is therefore necessary to involve wiring harness experts as early as in the system definition stage. Figure 2 shows a wiring harness that was developed as a special intake-module wiring harness. Thanks to the optimization of routing and security in conjunction with engine and wiring-harness development, it was possible to achieve an advancement of quality as well as to yield cost and weight advantages.

Dimensioning and selection of materials
The most important tasks for the wiring harness developer are:
– dimensioning of line cross-sections,
– material selection,
– selection of suitable plug-in connections,
– routing of lines under consideration of ambient temperature, engine vibrations, acceleration and EMC,
– consideration of the environment in which the wiring harness is routed (topology, assembly stages in vehicle manufacture and equipment on the assembly line).

Line cross-sections
Line cross-sections are defined based on permissible voltage drops. The lower

3 Body,
4 Cockpit,
5 Doors,
6 Roof,
7 Tank,
8 Rear end.

cross-section limit is determined by the line strength. Convention has it that no lines with a cross-section of less than 0.5 mm^2 are used. With additional measures (e.g. supports, protective tubes, tension relief), even a cross-section of 0.35 mm^2 may be permissible.

Table 1: Complexity of wiring harnesses (typical values for complete wiring harness)

	Small vehicle	Medium class	Luxury class
Number of plug connectors	70	120	250
Number of contact points	700	1500	3000
Number of wires	350	750	1500
Total length of wires in meters	700	1500	3200

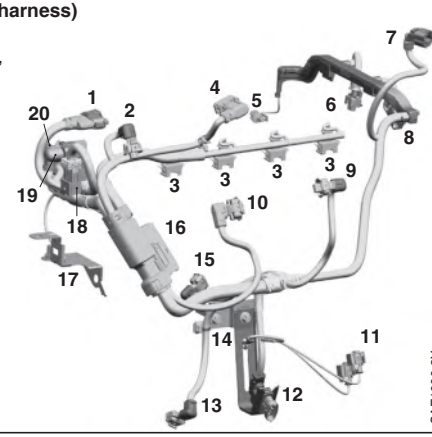
– Twisted wires	24	24
– Total length (in meters)	1370	226
– Different contact parts	72	17
– Assorted components (e.g. plug housings, cable ducts, coverings)	227	63



Materials

Copper is usually used as the conductive material on account of its high conductivity. Recent trends have involved the increased use of aluminum on account of its weight and cost advantages above all for line cross-sections greater than 2.5 mm^2. The insulation materials for the lines are defined by the temperature to which they are exposed. It is necessary to use materials that are suitable for the high temperatures of continuous operation. Here, the ambient temperature must be taken into consideration as much as the heating caused by the flow of current. The materials used are thermoplastics (e.g. PE, PA, PVC), fluoropolymers (e.g. ETFE, FEP), and elastomers (e.g. CSM, SIR).

If the lines are not routed past particularly hot parts (e.g. exhaust pipe, exhaust-gas recirculation) in the engine topology, one of the criteria for the selection of the insulation material and the cable cross-section could be the derating curve of the contact with its associated line. The derating curve represents the relationship between current, the temperature increase that it causes, and the ambient temperature of the plug-in connection. It can be taken from the relevant technical customer documentation for the contact. Normally, the heat generated in the contacts can only be carried away along the lines themselves. What is also to be noted is that at high usage tempera-

tures (>100 °C) the contact materials can give way to the applied mechanical stresses (metal relaxation). It is possible to influence the relationships described by means of larger line cross-sections and the use of suitable contact types and more noble surfaces (e.g. gold, silver) and thus higher limit temperatures. For highly fluctuating current intensities, it is often useful to measure the contact temperature on an application-specific basis.

Line routing and EMC measures
Lines should be routed in such a way as to prevent damage and line breaks. This is achieved by means of fasteners and supports for the wiring-harness branches. Vibration loads on contacts and plug-in connections are reduced by fastening the wiring harness as close to the plug as possible and at the same level as the vibration where possible. The line routing must be determined in close cooperation with the engine or the vehicle developer.

To avoid EMC problems, it is recommended to route sensitive lines and lines with steep current flanks separately, making maximum use of the available space. Shielded lines are not straightforward to produce and are therefore expensive. They also need to be grounded. The twisting in pairs of signal lines is a more cost-favorable and effective measure.

Line protection
Lines need to be protected against chafing and against making contact with sharp edges and hot surfaces. Adhesive tapes are used for this purpose. The level of protection is determined by the interval and winding density. Corrugated tubing (material savings from corrugation) with the necessary connecting pieces is often used as line protection. However, tape fixing is still an essential means of preventing movement of individual lines inside the corrugated tube. Optimal protection is offered by cable ducts.

Wiring harnesses are at risk from rodents. A remedy may be provided by rodent-resistant, extruded plastic tubing.

Plug-in connections

Function and requirements
Electrical plug-in connections must establish a reliable connection between different system components and thereby ensure the safe functioning of the systems under all operating conditions. They must be designed in such a way as to withstand the multitude of loads to which they are exposed over the entire service life of the motor vehicle. Examples of such loads are
– vibration loads,
– temperature fluctuations,
– high and low temperatures,
– humidity and moisture loads and splash water,
– aggressive liquids and corrosive gases, and
– micro-movement of the contacts with resulting fretting corrosion.

These loads can increase the contact resistances of the contacts up to the point of total interruption.

Even the insulation resistances can decrease and result in the short-circuiting of neighboring lines. Electrical plug-in connections must therefore exhibit the following properties:
– low contact resistances of the current-carrying parts,
– high insulation resistance between the current-carrying parts of different voltage potential,
– high imperviousness to water, moisture, and salt spray.

Aside from the physical properties, plug-in connections must satisfy further requirements for the area of application, such as
– easy, error-free handling in automotive assembly,
– safe reverse-polarity protection,
– secure and noticeable locking and easy unlocking,
– robustness and compatibility with automatic machine handling in wiring-harness production and transportation.

The high integration density of electronics in the motor vehicle places high demands on a car's plug-in connections. Not only do they carry high currents (e.g. activation of ignition coils), they also carry analog

signal currents with low voltage and current intensity (e.g. signal voltage of the engine-temperature sensor). Throughout the service life of the vehicle, the plug-in connections must ensure the reliable transmission of signals between ECUs and to the sensors and actuators.

The increasing demands of emission-control legislation and active vehicle safety are forcing the ever more precise transmission of signals through the contacts of the plug-in connections. Many parameters must be taken into account in the conception, design, and testing of a plug-in connection (e.g. environmental influences, imperviousness, contact forces, contact form, surface quality).

The most common cause of failure of a plug-in connection is wearing of the contact caused by vibrations or temperature change. The wear promotes oxidation. This results in an increase in ohmic resistance - the contact may, for example, be subjected to thermal overload. The contact part may be heated beyond the melting point of the copper alloy. In the case of highly resistant signal contacts, the vehicle controller often detects a plausibility error by comparison with other signals; the controller then enters fault mode. These problem areas in the plug-in connection are diagnosed by the on-board diagnostics (OBD) required by emission-control legislation. However, it is difficult to diagnose the error in the service workshops because this defect is displayed as being a component failure. It is only possible to diagnose the faulty contact indirectly.

For the assembly of the plug-in connection, there are various functional elements on the plug housing intended to ensure that the cables with their crimped contacts can be joined to the plug-in connection reliably and defect-free. Modern plug-in connections have a joining force of less than 100 N so that the assembly operative is able to reliably join the plug to the component or ECU interface. The risk of plug-in connections being connected to the interface incorrectly increases with higher connecting forces. The plug would come loose during vehicle operation.

Table 3: Uses of plug-in connections

	No. of pins	Special features	Application
Low-pin-count	1 to 10	No joining-force support	Sensors and actuators (many different requirements)
High-pin-count	10 to 300	Joining-force support by slide, lever, module construction	ECUs (several, similar requirements)
Special plugs	any	e.g. integrated electronics	Special applications (individual, matched requirements)

Design and types

Plug-in connections have different areas of application (Table 3). These are characterized by the number of pins and ambient conditions. There are four different classes of plug-in connection: direct engine attachment, attachment close to the engine, transmission attachment, and body attachment. Another difference is the temperature class of the installation location.

High-pin-count plug-in connections

High-pin-count plug-in connections are used for all ECUs in the vehicle. They differ in their number of pins and the geometry of the pins (Table 4). Figure 3 shows a typical design of a high-pin-count plug-in connection. An example of the mating component of the plug is pictured in Figure 4. The high-pin-count male connectors are usually soldered in or stitched in on the ECU board.

The complete plug-in connection is sealed against the plug connector of the associated ECU by a circumferential radial seal in the plug housing. This, together with three sealing lips, ensures a reliable seal against the ECU sealing collar.

The contacts are protected against the ingress of humidity along the cable by a flat seal, through which the contacts are inserted and the line crimped to them. A silica-gel mat or silica mat is used for this

purpose. Larger contacts and lines may also be sealed using a single-core seal (see Low-pin-count plug-in connections).

When the plug is assembled, the contact with the line attached is inserted through the flat seal that is already in the plug. The contact slides home into its position in the contact carrier. The contact latches on its own by a locking spring that engages in an undercut in the plastic housing of the plug. Once all contacts are in their final position, a slide pin is inserted to provide a second contact safeguard, or secondary lock. This is an additional security measure and increases the retaining force of the contact in the plug-in connection. In addition, the sliding movement is a means of checking that the contacts are in the correct position.

The operating force of the plug-in connection is reduced by a lever and a slider mechanism. For this purpose the studs provided on the side of the plug shroud in Figure 4 are engaged by the slider links (Figure 3) when the plug is connected to the interface. When the lever mounted in the plug housing is repositioned, the slide is pushed via toothing transversely to the plug-in direction into the plug housing and uses the links on both sides to draw the plug into the interface by the studs.

Low-pin-count plug-in connections

Low-pin-count plug-in connections (Figure 5) are used for actuators (e.g. fuel injectors) and sensors. Their design is similar in principle to that of a high-pin-count plug-in connection. The operating

force of the plug-in connection is not usually supported.

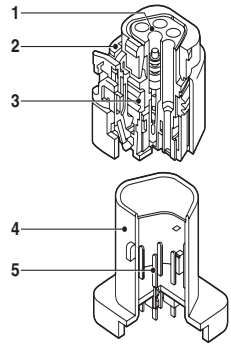
The connection between a low-pin-count plug contact system and the interface is sealed with a radial seal. Inside the plastic housing, however, the lines are sealed with single-core seals secured to the contact.

Contact systems

The electrical contact system inside a plug-in connection is formed as a rule by a jack (on the plug side) and a contact pin, or a flat blade, or a pin (on the component side).

Figure 5: Low-pin-count plug-in connection

1 Contact carrier, 2 Housing,
3 Radial seal, 4 Interface, 5 Flat blade.



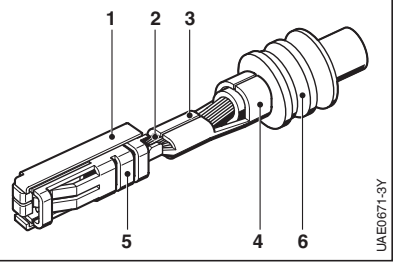


Figure 6: Contact

1 Steel overspring, 2 Single core,
3 Conductor crimp, 4 Insulation crimp,
5 Meander, 6 Single-core seal.

There are different type series for the various fields of use for Bosch plug-in connections. Depending on the conditions of use, the specially suited contacts are used in these. Figure 6 shows by way of example a two-part contact which is used in motor vehicles in components which are subject to particular vibration loads.

The inner part – the live part – is pressed from a high-quality copper alloy. It is protected by a steel overspring, which at the same time increases the contact forces of the contact by means of an inwardly acting spring element. A catch arm pressed out from the steel overspring engages the contact in the plastic housing part.

Contacts are coated with tin, silver or gold, depending on requirements. To improve the wear characteristics of the contact point, not only are different contact coatings used but also different structural shapes. Different decoupling mechanisms are integrated into the contact part to decouple cable vibrations from the contact point (e.g. meandering routing of the supply lead).

The cables are crimped onto the contact. The crimp geometry on the contact must be adapted to the cable concerned. Pliers or fully automatic, process-monitored crimping presses with contact-specific tools are available for the crimping process.

Electromagnetic compatibility

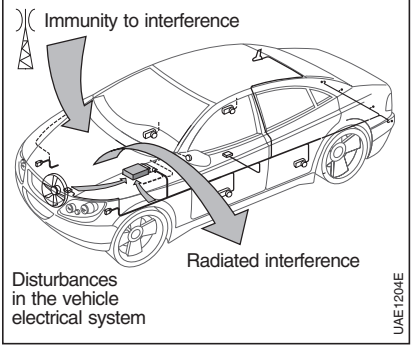
Requirements

Electromagnetic compatibility (EMC) is the general term for the target state in which electrotechnical devices and state-of-the-art technologies (e.g. wireless systems) do not have unintended mutual interference from electrical, magnetic or electromagnetic effects.

Particularly in vehicle electronics, the importance of electromagnetic compatibility is increasing due to the higher amount of electrical equipment and the use of new technologies, such as electric and hybrid drives with new energy accumulators (e.g. high-performance batteries and fuel cells) on the one hand and mobile communication systems (e.g. phone, navigation and Internet) on the other. This leads to a rising level of complexity in today's automobiles (Figure 1).

Electronic power train systems installed in the vehicle (e.g. engine and transmission control, electric drive), safety systems (e.g. antilock braking system, driving-dynamics control system, and airbag), comfort and convenience electronics (e.g. climate control, electrical adjusting devices) and mobile communication systems (e.g. radio, navigation, Internet) are arranged next to each other in close proximity. The associated high density and number of fast-switching, high-performance electronic components on the one hand and the requirements of today's communication on the other pose a great and, in part, new challenge to electromagnetic compatibility (Figure 2).

Figure 2: Electromagnetic compatibility in motor vehicles



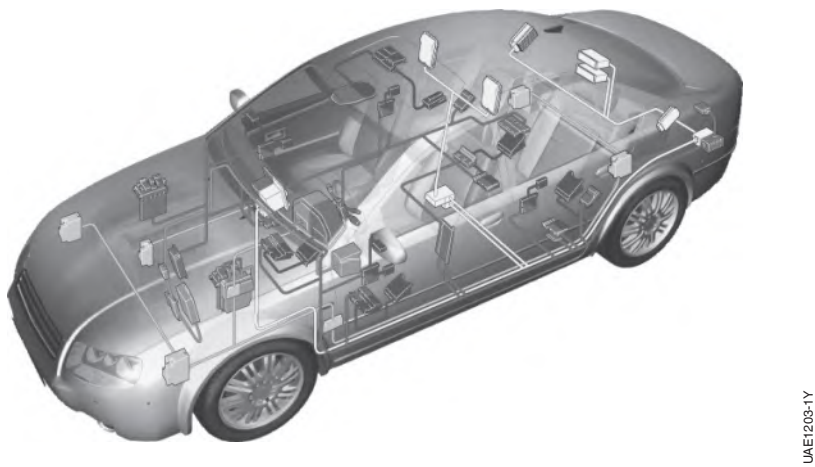


Figure 1: Electronic systems and wiring harness in a modern motor vehicle

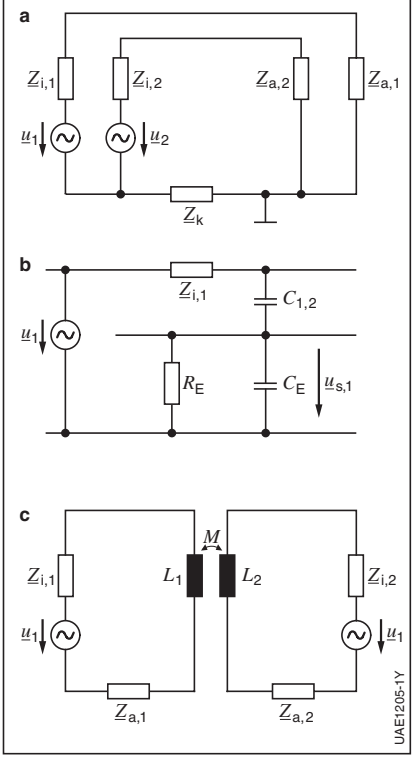
Interference emission and interference immunity

Sources of interference in the DC vehicle electrical system

Ripple in vehicle electrical system

In a conventional vehicle with combustion engine, the alternator supplies the vehicle electrical system with rectified three-phase current. Although the current is smoothed by the vehicle battery, a residual ripple remains. In addition, the energy requirements of the electrical and electronic systems influence the DC voltage supply.

The amplitude of the ripple in the vehicle electrical system depends on the load on the vehicle electrical system and the wiring. Its frequency changes according to alternator speed and the consumer behavior. The fundamental oscillation is in the kilohertz range. It can penetrate the vehicle sound systems – either directly (conductive) or inductive – where the ripple is heard as a howl in the loudspeaker system.



Pulses in the vehicle electrical system

Voltage pulses are generated on the supply lines when electrical equipment is switched on and off. They are routed to adjacent systems directly through the power supply (through conductive coupling, Figure 3a) and indirectly by coupling from connecting lines (through inductive and capacitive coupling, Figure 3b and Figure 3c). These unwanted interference pulses can cause anything from malfunction to total destruction of the adjacent systems. The signal shapes and amplitudes acting as disturbance values depend on the configuration of the vehicle electrical system, such as the ground concept, the position of the wiring harnesses and the individual lines in the wiring harness.

The wide variety of pulses that occur in the vehicle are classified into typical pulse shapes. Major parameters are pulse amplitude, signal rise and fall times as well as internal resistance of the pulse source. A suitable selection of permitted values for interference emission from the sources of interference and the required values for interference immunity ensures that there is no unintended behavior of the electronic systems without unnecessarily high effort for interference suppression. This can be done using various concepts. For example, a higher interference emission for the electric actuators and motors can be allowed than for typical pulse sources if the electronic components, such as control units and sensors, are designed with corresponding interference resistance.

Potentially susceptible devices
Electronic control units and sensors are potentially susceptible devices for interference signals that enter the vehicle electrical system from the outside (Figure 2). These interference signals come from the neighboring systems in the vehicle. Malfunctions occur when the system loses the ability to distinguish between interference signals and useful signals. The possibility of taking effective measures depends on the characteristics of useful and interference signals.

The control unit is unable to distinguish between useful and interference signals if the characteristic of an interference signal is similar to that of a useful signal – for instance, when a pulse-shaped interference signal is at the same frequency as the signal from a wheel-speed sensor. Critical frequencies are those in the range of useful signal frequencies ($f_S \approx f_N$) and a low multiple of a signal frequency.

Special feature in vehicle electrical systems with high voltages
High voltage and currents in motor vehicles with hybrid and electric drives pose new challenges. In addition to the contact protection required due to the high voltages, EMC is particularly important. In the components of the power electronics (e.g. inverter and DC/DC converter) and in the electrical machine, large interference signals can arise. Only by using shielding concepts along with suitable filter circuits can these interference signals be reduced enough to allow compliance with the required limit values for mobile communication in the vehicle.

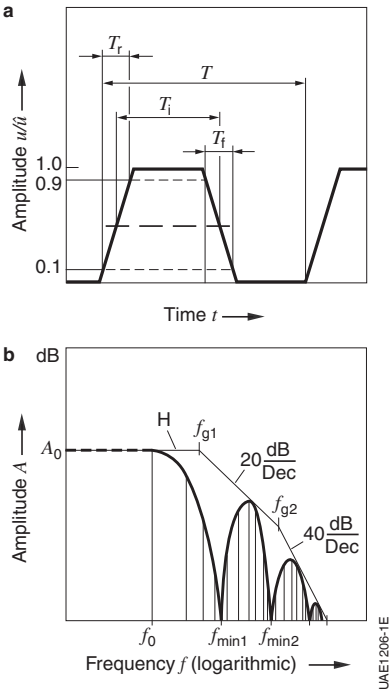
Another special feature is the charging devices with their connections to the public power supply network. This interface, and the resulting requirements with regard to permitted interference emission into the public power grid and the necessary interference protection, must be taken into consideration in the overall design of vehicle electrical systems with high voltages.

High-frequency vibrations and oscillations in the vehicle electrical system
In addition to the low-frequency ripple in vehicle electrical systems and the pulses in these systems, high-frequency vibrations and oscillations are caused in many electromechanical and electronic components by switching operations. Examples include commutation operations in brush motors or in electronically commutated electric motors, activation of output stages or circuits in digital electronics (such as the CPU core of an electronic control unit). These oscillations can spread – more or less attenuated – into the vehicle electrical system via the connected lines, particularly the power supply lines, and can get into the systems for communications electronics via the power supply lines or the capacitive and inductive coupling in the wiring harness.

Depending on whether the measured spectrum of radio interference voltage has a more or less continuous curve or consists of discrete lines, we refer to it as broad-band interference or narrow-band interference. Broad-band interference is caused, for example, by electric motors in wiper drives, control systems, fans, fuel pumps or alternators, but also by certain electronic components. Narrow-band interference is caused, for example, by electronic control units with microprocessors. This allocation depends on the used bandwidth of the radio service under consideration or the bandwidth used during the measurement compared to the characteristics of the interference signal. The various interference signals also have various effects on analog and digital radio systems.

Disturbances can travel through the electric lines in the wiring harness to the supply and signal connections and into the connecting cables of the antennas. They can also be received by the antennas directly and, just like the desired useful signals, they can get into the receiver circuits of the mobile communication devices. These high-frequency disturbances can interfere with vehicle communication systems, because they are often found in the frequency and amplitude range of the useful signal. Narrow-band interference is

Figure 4: Time signal and spectrum for a trapezoidal pulse



a) Dependency on time,
b) Dependency on frequency.
T Period duration,
T_r Rise time (from 10 % to 90 %),
T_f Release time (from 90 % to 10 %),
T_i Pulse duration,
A_0 Amplitude,
$\hat{u}$ Pulse amplitude,
f_0 Basic frequency of the time signal,
f_{n-1} Harmonics,
f_{min} Periodic minimums,
f_g Fundamental frequencies,
k Pulse duty factor,
n Number of the nth harmonic,
m Number of lines between minimums,
H Envelope,
Dec Decade.

$$f_0 = \frac{1}{T}, \qquad k = \frac{T}{T_i},$$

$$f_{n-1} = \frac{n}{T} = n f_0, \qquad f_{min} = \frac{n}{T_i},$$

$$f_{g1} = \frac{1}{\pi T_i}, \qquad f_{g2} = \frac{1}{\pi T_r},$$

$$m = \frac{T}{T_i}, \qquad A_0 = 2\hat{u}\,T_i.$$

particularly critical, because it has signal characteristics that are very similar to the spectrum of transmitters (Figure 4).

Electrostatic discharge

The subject of potential danger to components and electronic circuits from electrostatic discharge (ESD) also belongs to the field of EMC. The task here is to protect components and equipment from interference or damage by static discharge from humans or from machinery (exposed components) during operation, production and maintenance. This involves both adopting appropriate methods for handling equipment and designing equipment in such a way that the voltages (up to several thousand volts) produced by electrostatic discharges are reduced to acceptable levels.

Immunity to interference from electromagnetic fields

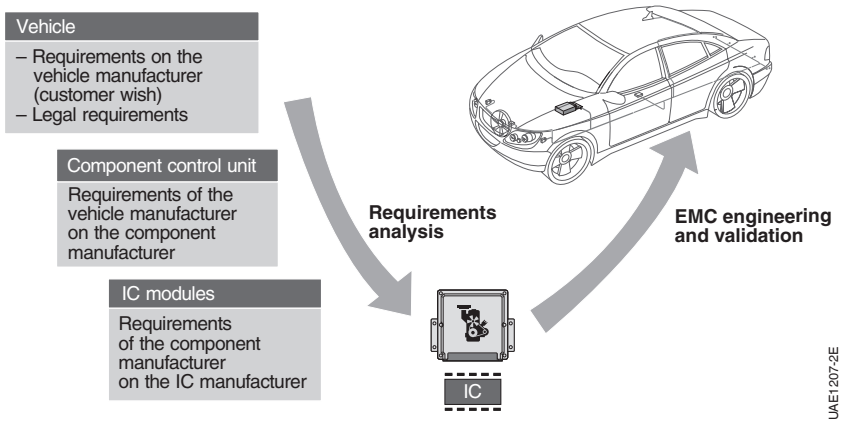
Sources of interference and potentially susceptible devices

During operation, vehicles and their electronic equipment are exposed to various electromagnetic waves, for example from radio, television and wireless transmitters, which are operated at a fixed location, or even from within the same or a neighboring vehicle. Electronic circuits must not experience interference from the electromagnetic fields of the transmitters and the resulting, unwanted voltages and currents.

The large number of electric lines in the wiring harness as well as internal structures in devices (such as printed circuit boards in electronic control units or design technology and joining and bonding techniques in actuators) function as an antenna structure. Depending on their geometric dimensions and the electromagnetic wave frequencies, they receive transmitter signals and conduct them to the semiconductor components. Unmodulated and modulated high-frequency signals can be demodulated at the pn transitions in the semiconductor components. This can lead to level shifts caused by the direct component or to the superposition of transient interference signals as a result of demodulated LF components of the interference signal. The car-

rier frequency $f_{S,HF}$ is usually much higher than the useful-signal frequencies f_N. LF components of the interference signal are particularly critical if its frequency $f_{S,NF}$ is in the range of the useful-signal frequencies f_N. Interference signals with frequencies far lower than those of the useful signals can lead to disturbances due to intermodulations.

Electronic components must be designed in such a way that their function is not impaired by the externally generated interference signals in the electronic circuits.



EMC-oriented development

The importance of EMC-oriented development in automotive electronics is increasing at all levels (see V model). Nowadays, safeguarding of EMC in vehicles influences the design of semiconductor components and of modules (including suitable design technology and the joining and bonding techniques of integrated circuits for components and systems) as well as the configuration of the entire vehicle. Thus EMC-oriented design is an integral part of a state-of-the-art development process at all levels. Today, retroactively suppressing interference is usually no longer possible or, at the very least, extremely time consuming and costly.

EMC requirements analysis

When development of a new electronic system for a motor vehicle begins, necessary requirements must first be analyzed and codified in the customer specifications (Figure 5). In addition, the vehicle manufacturer compiles EMC requirements documents, which take into account legal requirements and expectations of vehicle customers. These EMC specifications contain the requirements for vehicles and the resulting requirements for electric systems and components that are being installed in the vehicles. From these requirements, the system or

Figure 5: Requirements analysis and EMC development based on the V model

component manufacturer derives its own requirements for components and specifies requirements for design elements, electronic wiring and semiconductor components. Finally, IC and component manufacturers derive from this the requirements for their own products.

EMC development and verification

During the development stages, these requirements must be defined immediately at all levels in the customer specifications (Figure 5, see also V-model) and taken in to account early on during the vehicle design stage (e.g. the wire harness configuration and its position in the vehicle, power supply and ground concept, and the installing point of electronic components). The requirements derived from the vehicle must be taken into account, keeping in mind the system and component design (e.g. system topology, circuit design, housing design, circuit board layout, design and joining and bonding techniques). Similarly, the component manufacturer takes into account the EMC requirements during the IC and filter design stages. During the development process, the effectiveness of individual development steps is verified, in which various prototypes are metrologically assessed or variant studies using numerical simulation methods are implemented.

EMC validation

During the closing stages of EMC development, the requirements set out in the functional specifications and resulting customer specifications are validated in order to prove their worth. This validation is typically carried out using standardized test methods in accordance with legal mandates, standards and EMC specifications for component and vehicle manufacturers. The measurements to be carried out, operating statuses used and limit values to be observed are written down in test plans and the results are documented in a qualification report.

EMC measuring techniques

EMC measuring techniques are an important tool with regard to EMC-compliant development. Through the use of suitable test methods, the effectiveness of design standards like a selection of suitable semiconductor components, circuit design, circuit board layout, design and housing design are drafted and checked. On the other hand, the EMC test methods used in assessing are conducive to complying with EMC and legal requirements with regard to the release of components and vehicles.

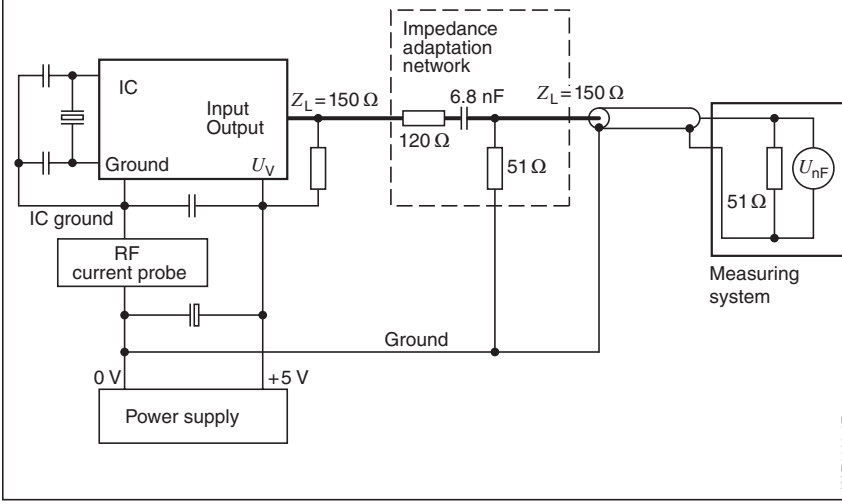
A wide variety of test methods is used for testing interference immunity and interference emission. Depending on the methods used to assess interference phenomena, they can be roughly divided into methods operating in the time domain (pulse generators, oscilloscopes), and those operating in the frequency domain (sine-wave generators, test receivers, spectrum analyzers).

In measuring technology, interference signals are specified as relative quantities of interference emission in dB (decibels). The values for interference suppression (pulse amplitude, transmitter field strengths) are typically specified directly (Table 1).

Table 1: Measured values

Physical quantity	Reference variable	Unit	Calculations
Interference emission			
Voltage L_U	1 µV	dB(µV)	L_U = 20 lg (U/1 µV)
Current L_I	1 µA	dB(µA)	L_I = 20 lg (I/1 µA)
Field strength L_E	1 µV/m	dB(µV/m)	L_E = 20 lg(E/1 µV/m)
Power L_P	1 mW	dB(mW)	L_P = 10 lg (P/1 mW)
Interference immunity			
Voltage U	–	V	–
Current I	–	A	–
Field strength E	–	V/m	–
Field strength H	–	A/m	–
Power P	–	W	–

EMC test methods



EMC test methods are described in relevant standards and divided into methods for the entire vehicle, for the components and systems (e.g. control units, sensors and actuators) and for integrated circuits (IC) and modules.

IC test methods
During the metrological assessment of integrated circuits (IC), the methods used are designed such that only the component itself is assessed instead of the combination of components with a peripheral circuit and larger conductor structures. The goal is to find out more about the EMC peformance of an IC, independent of its various applications, e.g. in order to compare different ICs of the same type. The standardized test methods for this are divided into conducted and irradiated test methods for interference emission (IEC 61967, see Table 3), interference immunity with respect to electromagnetic fields (IEC 62132, see Table 3) and test methods for sending and influencing pulses (IEC 62215, see Table 3) and ESD (electrostatic discharges). Figure 6 shows an example of a test circuit measuring conducted disturbances on individual IC pins.

Component measurement methods
In assessing the devices in the laboratory, conducted test methods involving radiation are used. Test objects are always operated under standardized conditions. The power is supplied via vehicle line impedance stabilization networks (LISN), which simulate a uniform wiring harness. The measurement configuration is typically completed on a laboratory table with a ground plane. The test object is connected to measurement peripherals, which simulate its functioning in a realistic manner. In order to ensure isolation from its surroundings, the test setup is run in a shielded room.

Conducted disturbances
High-frequency interference voltages at the supply lines are capacitively decoupled in the Line Impedance Stabilisation Network, and interference currents are measured using suitable current measurement coils (CISPR 25, see Table 2).

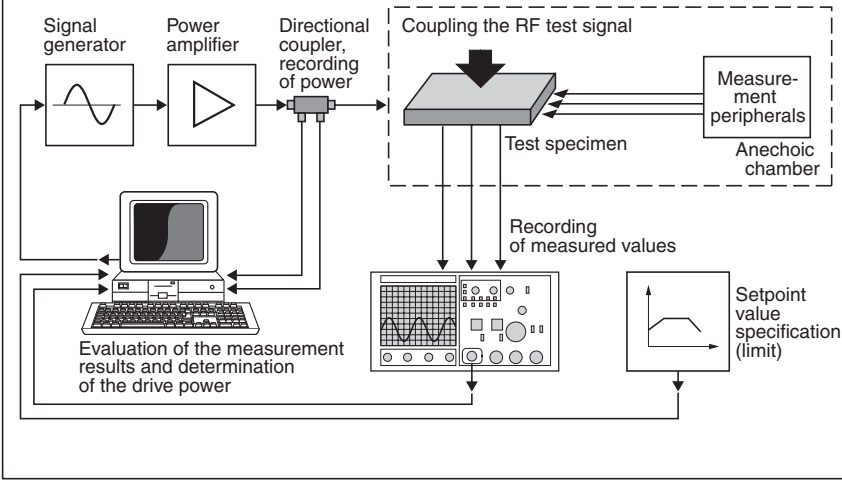
Figure 6: IC measurements, line-bound interference emission (IEC 61967-4)

Immunity to pulsed interference is tested using special pulse generators which produce standardized test impulses in accordance with ISO 7637-2, Table 2. The coupling of pulsed interference on signal and control lines is reproduced using capacitive coupling clamps in accordance with ISO 7637-3. As with high-frequency interference emission measurements, the interference emission of pulses is measured in a standardized test setup through the use of relevant switches and oscilloscopes.

High-frequency interference coupling and interference emission

Interference immunity test

Coupling of electromagnetic waves for component measurements is achieved through the use of TEM waveguides like the stripline and the TEM cell (TEM, transverse electromagnetic mode) or the power coupling procedure BCI (Bulk Current Injection) and irradiation with antennas.



The principal measurement configuration always consists of a coupler for high frequencies in a shielded measuring room, a test object with a wiring harness, measurement peripherals, and devices that produce high frequencies and recording and processing measured values (Figure 7).

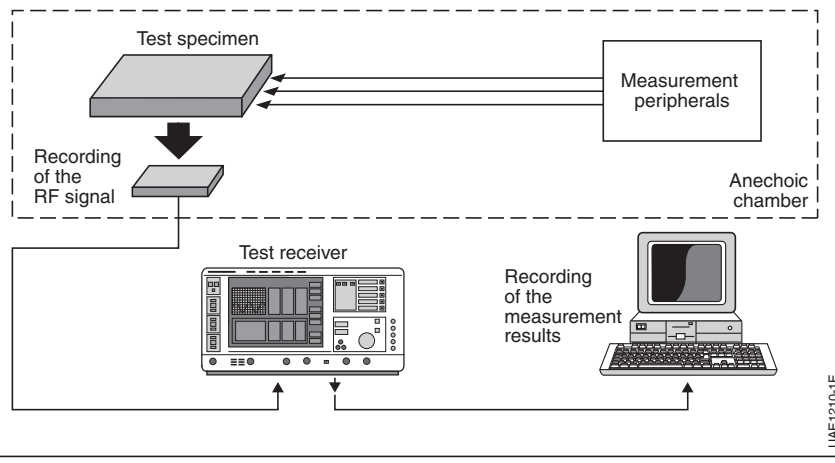
In the case of a stripline, (ISO 11452-5, Table 2) the wiring harness is arranged in line with the direction of propagation of the electromagnetic wave between a strip conductor and a base plate. When a TEM cell is used (ISO 11452-3), the test object and a section of the wiring harness are arranged at a right angle to the propagation direction of the electromagnetic waves. The BCI method (ISO 11452-4) involves superimposing an RF current (radio frequency) on the wiring harness by means of a current clamp.

When the test setup is irradiated, the transmitting antennas are set up at various locations. Through this process, both the coupling of electromagnetic fields in the wiring harness and the coupling in the test object are reproduced.

These and further test methods, such as one for testing low-frequency magnetic fields (ISO11452-8) and test methods for reproducing the interference coupling of mobile transmitters within close range (ISO 11452-9), are described in various portions of the ISO 11452 (Table 2).

Figure 7: Basic design of interference immunity tests

Measuring interference emission
The measuring principles for the immunity test can essentially be used to measure interference emission as well (CISPR 25). The TEM waveguides, current clamps and antennas function as receiving elements for the interference emitted by the test objects. For measuring the interference, the test receivers are connected directly to the receiving measuring instruments (Figure 8).



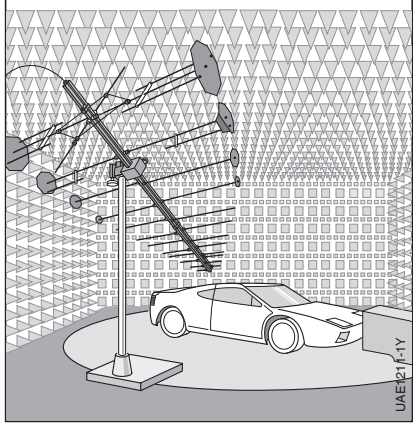
To decouple from the environment – that is, to ensure that only the interference produced by the test specimen is actually measured during interference emission measurements – and to minimize the emission of high-frequency signals in the environment when interference immunity tests are in progress, the testing for high-frequency disturbance values is carried out in electromagnetically shielded rooms. In order to avoid reflections and room resonance, shielded rooms are lined with high frequency absorbers when radiated signals are used.

Test methods for electrostatic discharges
When assessing the interference immunity of ESD, special high voltage impulse generators are used. In these generators, the ESD impulse is reproduced by charging a smoothing capacitor and a targeted discharge via a discharge resistor. The capacity of the smoothing capacitor and the discharge resistor determine the energy output and the pulse shape. With a suitable discharge probe, the ESD pulse is applied to the coupling point, for example a control unit pin, either by a targeted rollover or after contact via a discharge switch in the alternator.

Vehicle testing procedures
Measuring interference immunity
The immunity of electronic systems to electromagnetic fields radiated by high-power transmitters is tested on vehicle level in a special anechoic chambers (Figure 9). Here, high electrical and magnetic field strengths can be generated, and the whole vehicle can be exposed to them (ISO 11451, Table 2).

An interference emission of the entire vehicle is carried out with external antennas, either in standardized open area test sites or in anechoic chambers

Figure 8: Basic design of interference emission measurement



(IEC/CISPR 12, Table 2). The interference effects of the vehicle electrics and electronics on radio reception in the vehicle are measured using highly sensitive test receivers or spectrum analyzers. As far as possible, the original vehicle antenna is left in place, and measurements are taken at the receiver input terminal inside the vehicle in order to collect accurate data. With the help of a suitable test circuit, the impedance of the test receiver is adjusted to the input impedance of the receiver unit. The necessary limit values and measurement parameters like bandwidth and high frequency detectors are derived from the operating parameters of the radio services (IEC/CISPR 25).

Selection of EMC tests

The EMC tests carried out on an electric or electronic device depend on the component's area of application and its internal design. Simple electromechanical devices, which do not contain electronic components, do not have to be tested for interference immunity to electromagnetic fields. On the other hand, a variety of individual tests must be specified and implemented in EMC test plans for components containing electronic parts.

Figure 9: Interference immunity measurement in an EMC anechoic chamber for vehicles

EMC simulation

Nowadays, the application of numerical calculation methods is a method for the EMC development process equivalent to EMC measuring technology. Different calculation methods are employed depending on the problem at hand. What is critical in each case is accurate modeling of the sources of interference, potentially susceptible devices and the coupling path.

If the conducted coupling is dominant or the design of the electrical circuit (for example, filter structures) is to be examined, circuit simulation programs are usually used. If the field-coupled influence is dominant or geometric configurations (such as a metallic structure for shielding the electromagnetic fields or antenna geometry) are to be examined, various methods are used to calculate electromagnetic fields.

Thus the user has to select the method to be used depending on the problem to be solved. The EMC simulation can be used both when developing and assessing individual components, for designing components and systems, and for examining the entire vehicle, for example, to determine the optimum location for an antenna.

A significant advantage of the EMC simulation is that a wide variety of variants (for example, using different components or various geometric configurations) can be examined and compared without having to build and measure a design model for each one.

Legal requirements and standards

EMC type approval

The form of electromagnetic compatibility for motor vehicles is prescribed by law such that, in addition to other requirements (for example, for brakes, light, exhaust gas), requirements concerning interference immunity to electromagnetic fields and regarding the maximum permissible interference emission (interference suppression) also have to be fulfilled for the type approval of vehicles. The currently applicable directive UNECE R10, Revision 5 from 2014 [1] is based on a directive from 1972, which merely contained requirements regarding interference suppression for the vehicle. Since then, this directive has been repeatedly adapted and supplemented to account for technical progress.

The current edition takes into account not only the requirements for conventional motor vehicles, but also requirements for electric and hybrid vehicles with built-in charging devices. Since these vehicles come into contact with the public power grid, there must be assurance of appropriate interference immunity to line-bound interference from the power grid and a corresponding limit to the interference from the vehicle into the power grid.

Two different paths can be taken for the type approval of vehicles. Usually, vehicle manufacturers apply for type approval via type test for the entire vehicle. However, it is also possible to obtain a type approval for electrical and electronic submodules. In this case, in addition to the limit values for interference immunity to electromagnetic fields and the interference radiation, requirements regarding the pulsed interference in the vehicle electrical system also have to be fulfilled.

In addition to regulations governing the type approval procedure for vehicles or components, UNECE R10 also specifies test methods and maximum limits. The test methods are based on the applicable international standards (Table 2); the limit values and precise execution are explicitly specified in the directive.

The defined limit values represent minimum requirements. In practice, just barely complying with the limit values specified is frequently insufficient to ensure interference-free reception or mobile communication in the vehicle. Depending on their vehicle concepts, therefore, the motor vehicle manufacturers specify in their own customer specifications both a raised requirement for interference immunity and a lower interference emission level for protecting radio reception. For the development of electric and electronic components, therefore, these requirements have to be taken into account from the start by consultation between the vehicle manufacturers and suppliers of vehicle electrical systems.

Standards

The individual, different test methods are described in the international ISO and IEC/CISPR standards according to Table 2 for vehicles and their electric/electronic components and systems. The IEC standards according to Table 3 treat the measuring methods for integrated circuits and semiconductor components. Usually the standards do not specify fixed limit values, but limit value classes. Depending on the individual vehicle concepts, this should enable the users of the standards (vehicle manufacturers and suppliers) to provide optimum technical and economical coordination between the requirements regarding interference immunity and interference emission.

Symbols and circuit diagrams

The electrical systems in motor vehicles contain a large number of electric and electronic devices for controlling and managing the engine, and for safety and comfort and convenience systems. An overview of the complex vehicle electrical system circuits is only possible with meaningful symbols and circuit diagrams. Circuit diagrams such as schematic diagrams and terminal diagrams help in troubleshooting, simplify the installation of additional devices, and facilitate fault-free connection when retrofitting or altering the electrical equipment in motor vehicles.

Figure 1: Circuit diagram and circuit symbol of an alternator with regulator
The circuit symbols contains, in addition to the symbol for the alternator/generator G, the symbols for the three windings (phases), the star connection, the diodes, and the regulator.

b) Circuit symbol.

Circuit symbols

Standards

The circuit symbols shown in Table 1 are a selection of standardized circuit symbols which are suitable for automotive electrics. But for a few exceptions, they correspond to the standards of the International Electrotechnical Commission (IEC).

The European Standard EN 60617 (Graphical symbols for diagrams, [1]) corresponds to the International Standard IEC 60617. It exists in three official versions (German, English and French). The standard contains symbol elements, identifiers and above all circuit symbols for the following areas: General applications (Part 2), Conductors and connecting devices (Part 3), Basic passive components (Part 4), Semiconductors and electron tubes (Part 5), Production and conversion of electrical energy (Part 6), Switchgear, controlgear and protective devices (Part 7), Measuring instruments, lamps and signalling devices (Part 8), Telecommunications: Switching and peripheral equipment (Part 9), Telecommunications: Transmission (Part 10), Architectural and topographical installation plans and diagrams (Part 11), Binary logic elements (Part 12) and Analogue elements (Part 13).

Requirements

Circuit symbols are the smallest elements in a circuit diagram and the simplified graphical representation of an electrical device or a part thereof. The circuit symbols show the operating concept of a device and represent in circuit diagrams the functional correlations of a technical sequence. Circuit symbols do not take into consideration the shape and dimensions of the device and the position of the connections on the device. A detached representation in the schematic diagram is possible by abstraction only.

A circuit symbol should have the following properties: It should be easily remembered, easily comprehensible, uncomplicated in its graphic representation, and clearly within a classification group.

Circuit symbols consist of circuit-symbol elements and qualifying symbols. The following are examples of qualifying symbols: letters, numbers, symbols, mathematical signs and symbols, unit symbols, and characteristic curves.

If a circuit diagram becomes too elaborate due to the representation of the internal circuitry of a device (Figure 1a) or if not all the details of the circuit are needed to identify the function of the device, the circuit diagram for this special device can be replaced by a single circuit symbol (without internal circuitry) (Figure 1b).

In the case of integrated circuits which demonstrate a high degree of economy of space (this is synonymous with large scale integration of functions in a component), a simplified circuit representation is preferred.

Representation

The circuit symbols are shown without the effect of a physical quantity, i.e. in a de-energized and mechanically non-actuated state. An operating state of a circuit symbol that deviates from this standard representation (basic status) is denoted by an adjacent double arrow (Figure 2).

Circuit symbols and connecting lines (representing electric lines and mechanical linkages) have the same line width.

To avoid unnecessary kinks and crossings of the connecting lines, it is possible to rotate circuit symbols in 90° increments or show a mirror image of them, provided this does not alter their meaning. The direction of continuing lines can be freely selected. Exceptions are the circuit symbols for resistors (connection symbols are only permitted here on the narrow sides) and connections for electromechanical drives (connection symbols are only permitted here on the wide sides, Figure 3).

Junctions are represented both with and without a dot. Where there are crossings without a dot, there is no electrical connection. Connecting points on devices are for the most part not specifically represented. Connecting point, plug, jack or screwed connections are identified by a circuit symbols only at the points required for installation and removal. Other connecting points are identified as standard by dots.

Contact elements with a common drive are identified in an assembled representation in such a way that on actuation they follow a direction of motion which is established by the mechanical linkage (– – –) (Figure 4).

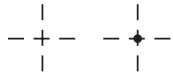
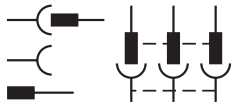
Connections

Line; line intersection, without/with a connection



Shielded line

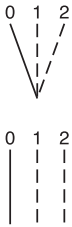
Mechanical linkage; electrical conductor (laid at later stage)



Crossovers (without/with connections)

Connection, general; separable connection (if indication necessary)

Plug connection; socket; plug; three-plug connection

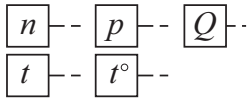


Ground (housing ground, vehicle ground)

Mechanical function

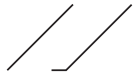
Switch positions (home position: solid line)

Activation is manual, by sensor (cam), thermal (bimetal)



Detent; non-automatic/ automatic return in direction of arrow (button)

Actuator, general (mech., pneum., hydraul.); piston actuation



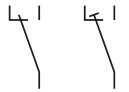
Actuation by rotational speed n, pressure p, quantity Q, time t, temp. $t°$

Variability/adjustability, not intrinsic (external), general

Variability/adjustability, intrinsic, caused by applied physical variable, linear/non-linear

Variability/adjustability, general

Switches



Pushbutton switch, NO/NC contact

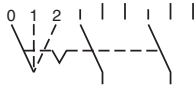
Detent switch, NO/NC contact

Changeover contact, non-bridging/bridging

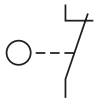
UAS1245-1E

Switches

Two-way normally open contact with three positions (e.g. turn-signal indicator switch)



NO/NC contact

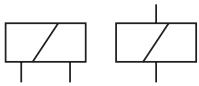


Contact with two makes

Multiple-position switch

Cam-operated switch (e.g. contact breaker)

Thermostatic switch

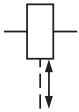


Release/trip device

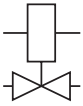
Various components

Actuators with one winding

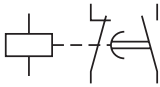
Actuator with two windings acting in same direction



Actuator with two windings acting in opposing directions

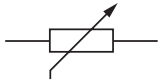


Electrothermal actuator, thermal relay



Electrothermal actuator, linear solenoid

Solenoid valve, closed



Relay (actuator and switch), example: non-delayed-break NC contact and delayed-break NO contact

Resistor

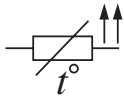
Potentiometer (with three connections)

Heating resistor, glow plug, flame plug, heated window

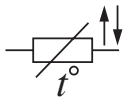
Antenna

Fuse

Permanent magnets



Winding, inductive

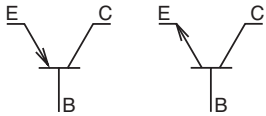


UAS1246E

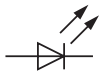
Various components

PTC resistor

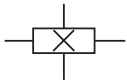
NTC resistor



Diode, general, current in direction of triangle tip



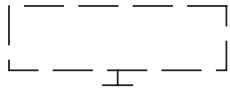
PNP transistor
NPN transistor



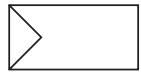
E = Emitter (arrow points in direction of flow)
C = Collector, positive
B = Base (horizontal), negative

Light-emitting diode (LED)

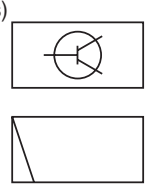
Hall generator



Devices in motor vehicle



Dotted/dashed line used to delineate or group together associated circuit sections



Shielded device, dashed line connected to ground

Regulator, general

Electronic control units (ECUs)

Indicating instrument, general; voltmeter; clock

Rotational-speed indicator; temperature indicator; linear-speed indicator

Battery

Plug-and-socket connection

Light, headlamp

Horn, fanfare horn

Heated rear window (general heating resistor)

Switch, general, without indicator lamp

Switch, general, with indicator lamp

UAS1247E

Devices in motor vehicle

Pressure switch

Relay, general

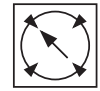
Solenoid valve, fuel injector, cold-start valve

Thermo-time switch

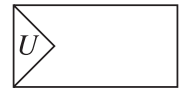
Throttle-valve switch

Rotary actuator

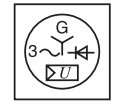
Auxiliary-air valve with electrothermal actuator



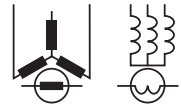
Spark plug



Ignition coil



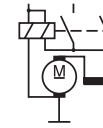
Ignition distributor, general



Voltage regulator

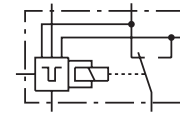
Alternator with regulator (without/with internal circuitry)

Electric fuel pump, engine drive for hydraulic pump



Motor with blower, fan

Starter motor with engagement relay (without/with internal circuitry)



Wiper motor (one/two wiper speeds)

Intermittent-wiper relay

Car radio

UAS1248E

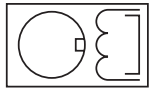
Devices in motor vehicle

Loudspeaker

Piezoelectric sensor

Linear-speed sensor

Voltage stabilizer, stabilizer



Resistance sensor

ABS rotational-speed sensor

Inductive sensor, coritrolled with reference mark

Air-flow sensor

Hall sensor

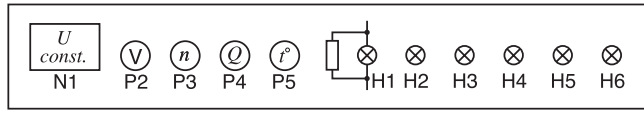
Turn-signal flasher, pulse generator, intermittent relay

Air-mass meter

Converter (rate, voltage)

Lambda oxygen sensor (unheated/heated)

Flow-quantity sensor, fuel-level sensor



Temperature switch, temperature sensor

Inductive sensor

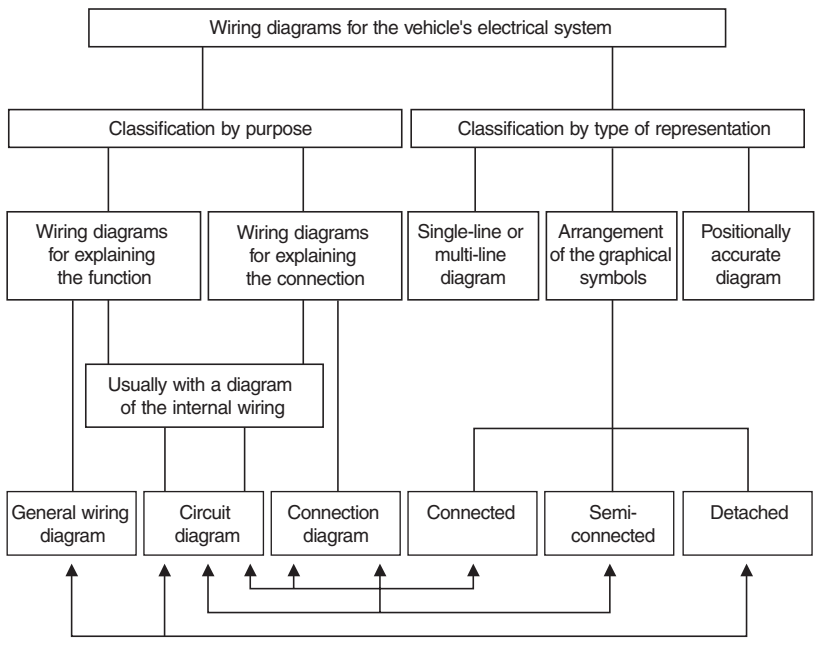
Instrument-cluster device (dashboard)

UAS1249E

Circuit diagrams

Circuit diagrams are idealized representations of electrical devices, rendered in the form of symbols. Such diagrams also include illustrations and simplified design drawings as needed. A circuit diagram illustrates the relationship between the various devices and shows how they are connected to each other. A circuit diagram may be supplemented by tables, graphs, or descriptions. The type of circuit diagram actually used is determined by its particular purpose (e.g. illustrating the operation of a system), and by the way in which the circuit is represented (Figure 5).

For a circuit diagram to be "legible", it must satisfy the following requirements:



– It must comply with the requirements of the appropriate standards, and deviations must be explained.
– Current paths should be arranged so that current flow or mechanical action takes place from left to right or from top to bottom.

In automotive electrics, block diagrams with single inputs and outputs and with internal circuitry omitted provide a swift overview of the function of a system or a device. The schematic diagram in different methods of representation (layout of the circuit symbols) is the detailed representation of a circuit to identify the function and to carry out repairs. The terminal diagram (with terminal locations of the devices) is used by the Aftersales Service when replacing or retrofitting devices.

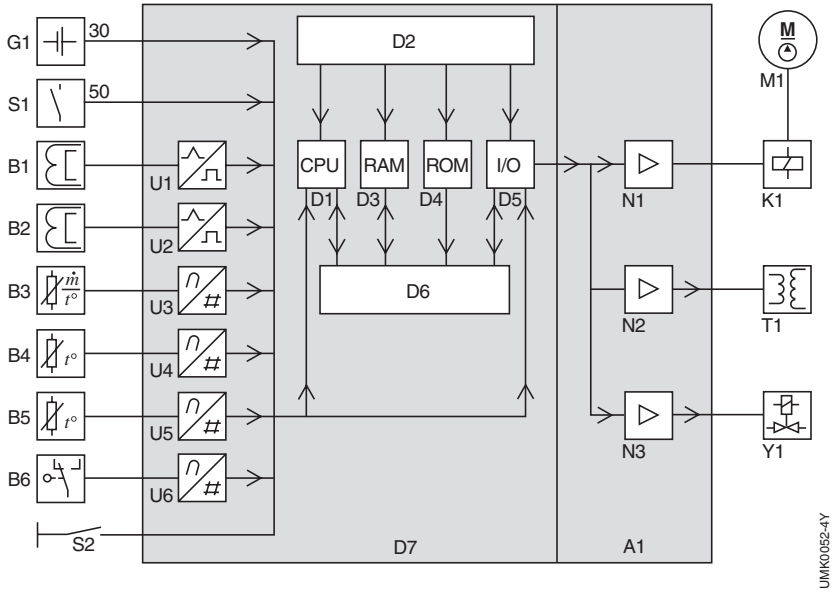
According to the method of representation, a distinction is made between

– single- or multi-line representation, and (according to the layout of the circuit symbols)
– assembled, semi-assembled, detached and topographical representation, which can be combined in one and the same circuit diagram.

Figure 5: Classification of the circuit diagrams (in accordance with EN 81346, Part 1 [2])

Block diagram

The block diagram is the simplified representation of a circuit, where only the essential parts are taken into consideration (Figure 6). It is intended to provide a quick overview of the task, design, structure and function of an electrical system or a part thereof, and to serve as a guide for more detailed circuit documentation (schematic diagram).



The devices are depicted by squares, rectangles and circles with qualifying symbols inside them similar to EN 60617, Part 2. The lines are for the most part drawn as single lines.

Schematic diagram

A schematic diagram is the detailed representation of a circuit. By clearly depicting individual current paths, it also indicates how an electrical circuit operates. In a schematic diagram, the clear presentation of the circuit's operation, which makes the diagram easy to read, must not be interfered with by the presentation of the individual circuit components and their spatial relationships. Figure 7 shows the schematic diagram of a starter motor in assembled and detached representations.

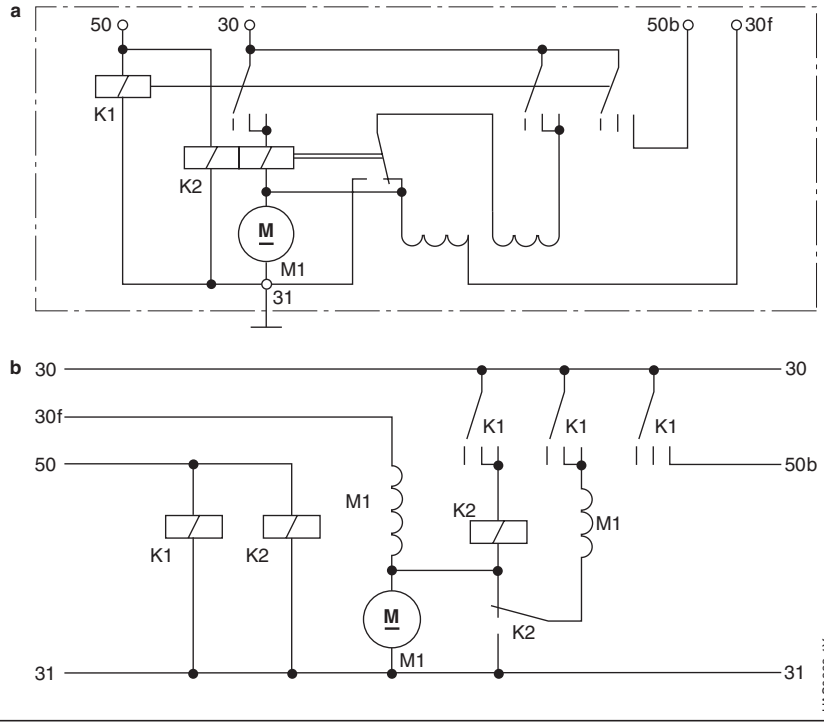
B3 Sensor for air mass, B4 Sensor for intake-air temperature,
B5 Sensor for engine temperature, B6 Throttle-valve switch,
D1 Computing unit (CPU), D2 Address bus, D3 Main memory (RAM),
D4 Program data memory (ROM), D5 Input – Output,
D6 Data bus, D7 Microcomputer,
G1 Battery, K1 Pump relay, M1 Electric fuel pump,
N1 to N3 Driver stages,
S1 Ignition/starter switch, S2 Map changeover switch,
T1 Ignition coil, U1, U2 Pulse shapers, U3 to U6 Analog-digital converters,
Y1 Fuel injector.



The schematic diagram must contain:
– circuit,
– device identification (EN 81346, Part 2, [2]), and
– pin designation and terminal designation (DIN 72552, [3]).

The schematic diagram can contain:
– A complete representation with internal circuitry in order to facilitate testing, fault localization, maintenance and replacement (retrofitting).
– Reference designations to better locate circuit symbols and destinations, particularly in a detached representation.

Representation of the circuit
Mostly multi-line representation is used in the schematic diagram. For the layout of the circuit symbols, there are, in accordance with EN 81346 Part 1, the following methods of representation which can be combined in the same circuit diagram.

Assembled representation
All the parts of a device are directly represented together assembled and connected to each other by a double slash or discontinuous connecting lines to identify the mechanical linkage. This representation can be used for simple, not very com-

Figure 7: Schematic diagram of a KB-type starter motor for parallel operation using two methods of representation

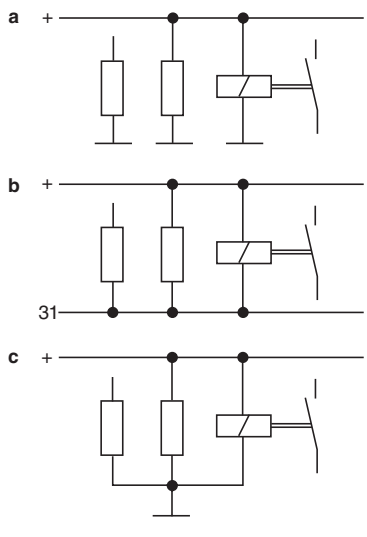
M1 Starter motor with series and shunt windings.
30, 30f, 31, 50b Terminal designations.

prehensive circuits without a loss of clarity (Figure 7a).

Detached representation
Circuit symbols of parts of electrical devices are represented separately and arranged in such a way that each current path can be traced as easily as possible (Figure 7b). The spatial association of individual devices or their parts is not taken into consideration. The priority is for the layout of the current paths to be as linear, clear and crossing-free as possible. The main purpose of this representation is to identify the function of a circuit.

The association of the individual parts must be identified using an identification system in accordance with EN 81346, Part 2. The identification associated with a device is located on each individual, separately represented circuit symbol for that device. Devices shown detached must be indicated once complete and assembled at a point in the circuit diagram if this is necessary to understand the circuit.

Topographical representation
In this representation, the position of the circuit symbol entirely or partially corresponds to the spatial position within the device or part.



Ground representation
For most motor vehicles, the single-conductor system, in which ground (metal parts of the vehicle) acts as the return conductor, is preferred for its simplicity. If a perfectly conducting connection of the individual ground parts is not guaranteed or if voltages in excess of 42 V are involved, the return conductor is also laid insulated from ground.

All the ground symbols represented in a circuit are electrically connected to each other via device or vehicle ground.

All the devices which contain a ground symbol must be connected to vehicle ground and be electrically conductive.

Figure 8 shows different possibilities of ground representation.

Figure 8: Ground representation
a) Individual ground symbols,
b) Ground continuity,
c) With ground collecting point.
31 Terminal designation.

Current paths and lines
The circuits are arranged in such a way as to produce and clear representation. The individual current paths, with the effective direction preferably from left to right or from top to bottom, should generally run parallel to the edge of the circuit diagram as linearly as possible, crossing-free and without changes of direction.

When there is a bundling of parallel lines, these are grouped into units of three lines each, and there follows a gap to the next group.

Boundary lines and framings
Dot-and-dash separating or framing lines delimit parts of circuits in order to show the functional or design association of the devices or parts.

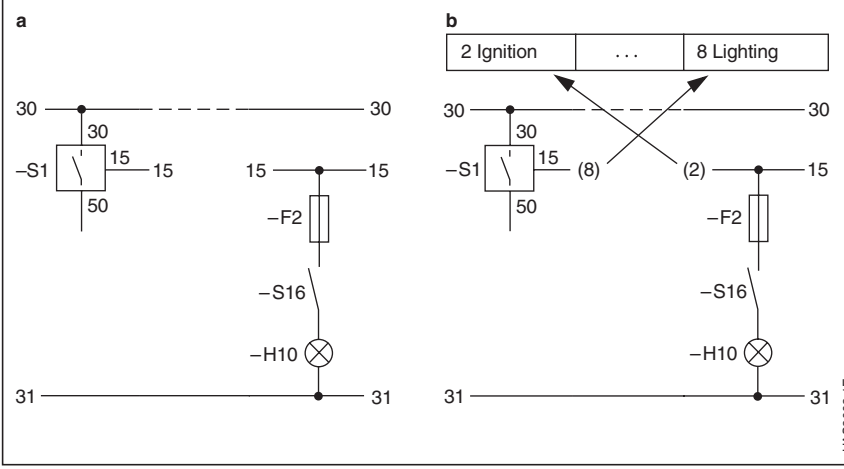
In automotive electrical systems, this dot-and-dash line represents a non-conductive framing of devices or circuit parts; it does not always correspond to the circuit housing and is not used as device ground. In high-voltage electrical systems, this framing line is often connected to the protective earth conductor (PE),

which is also indicated by a dot-and-dash line.

Break points, identifier, destination designation
Connecting lines (lines and mechanical linkages) which run over a longer distance of the schematic diagram can be interrupted in order to improve clarity. Only the beginning and the end of the connecting line are represented. The association of these break points must be clearly identifiable. The identifier and the destination designation are used for this purpose (Figure 9).

The identifier at associated break points matches. Terminal designations in accordance with DIN 72552 (Figure 9a), the specification of the operating concept and specifications in the form of alphanumeric characters serve as the identifier.

The destination designation is enclosed in parentheses so that it is not confused with the identifier; it consists of the section number of the destination (Figure 9b).



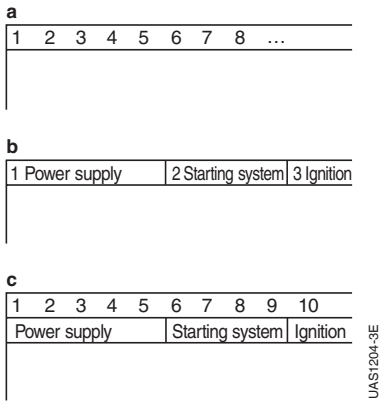
Section designation
The section designation indicated at the top edge of the diagram (formerly called the current path) is used to locate circuit parts. This designation can take three different forms:
– consecutive numbers at the same intervals from left to right (Figure 10a),
– reference to the contents of the circuit sections (Figure 10b),
– or a combination of the two (Figure 10c).

Labeling
Devices, parts or circuit symbols are identified in circuit diagrams with a letter and a number in accordance with EN 81346, Part 2. This identification is placed on the left or underneath the circuit symbol.

The qualifying symbol specified in the standard for the type of devices can be omitted if this does not give rise to ambiguity.

In the case of nested devices, a device is a component part of another, e.g. starter M1 with built-in engagement relay K6. The device designation is then: – M1 – K6.
Designation of associated circuit symbols in a detached representation: Each individual, separately represented circuit symbol of a device is given the designation common to the device.

Figure 9: Identification of break points
a) By terminal designation, e.g. term. 15,
b) By destination designation, e.g. in section 8 and 2.

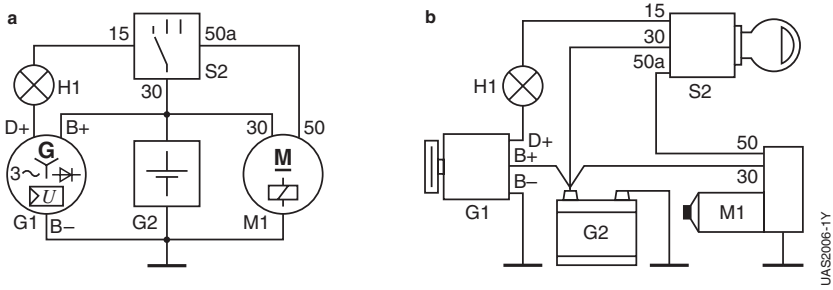


Pin designations (e.g. in accordance with DIN 72552) must be written outside the circuit symbol, and in the case of framing lines preferably outside the framing.

Where the current paths run horizontally: The specifications assigned to the individual circuit symbols are written under the relevant circuit symbols. The terminal designation is located directly outside the actual circuit symbols above the connecting line.

Where the current paths run vertically: The specifications assigned to the individual circuit symbols are written on the left next to the relevant circuit symbols. The terminal designation is located directly outside the actual circuit symbol, on the right if the format is horizontal and on the left next to the connecting line if the format is vertical.

Figure 10: Possible section designations
a) With consecutive numbers,
b) With references to the sections,
c) With a combination of a and b.



Terminal diagram
The terminal diagram shows the terminal locations of electrical devices and the connected outer and – if necessary – inner conductive connections (lines).

Representation
The individual devices are represented by squares, rectangles, circles and circuit symbols or even pictorially represented, and can be topographically arranged. Circle, dot, plug-in connection or only the led out line are used as terminal points.

The following methods of representation are customary in automotive electrics:
– Assembled, circuit symbols corresponding to EN 60617 (Figure 11a).
– Assembled, pictorial device representation (Figure 11b).
– Detached, device representation with circuit symbols, terminals with destination designations (Figure 12a); lines can be color coded.
– Detached, pictorial device representation, terminals with destination designations (Figure 12b); lines can be color coded.

Figure 11: Example of a terminal diagram (assembled representation)
a) With circuit symbols,
b) With devices.

Labeling
The devices are labeled in accordance with EN 81346, Part 2. Terminals and plug-in connections are identified with the terminal designations present on the device (Figure 11).

In the detached method of representation, the continuous connecting lines between the individual devices are omitted. All outgoing lines from a device are given a destination designation (EN 81346, Part 2), consisting of the identification of the destination device and its terminal designation, and – if necessary – the line color is also given (Figure 13).

Assembled-representation diagram
For troubleshooting on complex and extensively networked systems with self-diagnosis function, Bosch has developed system-specific schematic diagrams. Bosch makes assembled-representation diagrams for further systems in a great number of motor vehicles available in ESI[tronic] (Bosch Electronic Service Information). This provides automotive repair shops with a useful tool for locating faults or wiring retrofit equipment. Figure 15 shows as an example the assembled-representation diagram for a door locking system.

In contrast to other schematic diagrams, the assembled-representation diagrams use US symbols that are supplemented by additional descriptions (Figure 14). These include component codes – e.g. "A28" (theft-deterrence system) –, which are explained in Table 2 and an explanation of the wire colors (Table 3). Both tables can be called up in ESI[tronic].

Figure 14: Additional descriptions on assembled-representation diagrams

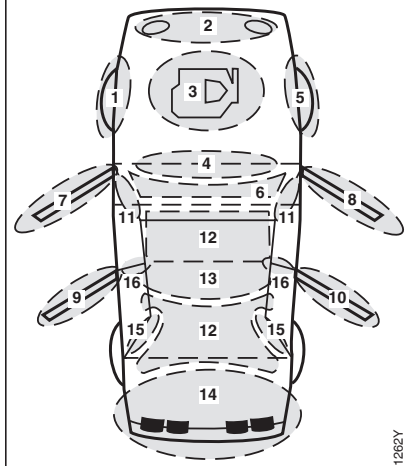
Figure 15: Assembled-representation diagram of a door locking system (example)



The assembled-representation diagrams are subdivided into system circuits and, if applicable, subsystems (see Table 4). Classification of system circuits reflects the standard ESI[tronic] practice as used for other systems, according to which they are assigned to one of four assembly groups:
– engine,
– body,
– chassis/suspension,
– drivetrain.

It is important to be aware of the grounding points, particularly when fitting additional accessories. For this reason, ESI[tronic] includes the vehicle-specific location diagram for the grounding points (Figure 16) in addition to the assembled-representation diagrams.

Designations for electrical devices

The designations in accordance with EN 81346 Part 2 (Table 5) are used to provide a clear, internationally comprehensible identification of systems, parts, etc. which are represented by circuit symbols in a circuit diagram. They appear next to the circuit symbols and consist of a series of defined qualifying symbols, letters and numbers (Figure 17).

Figure 17: Device designation

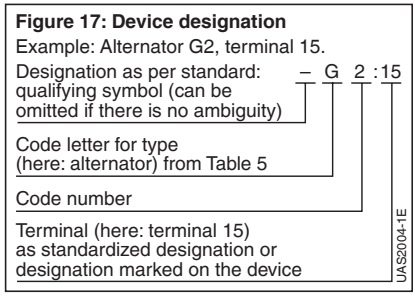

Table 5: Code letters for designating electrical devices as per EN 81346-2

Code letter	Type	Examples
A	System, assembly, component group	ABS ECU, automotive sound system, car radiotelephone, car phone, theft-deterrence system, device assembly, control device, ECU, cruise control
B	Converter of non-electrical into electrical quantities or vice versa	Reference-mark transmitter, pressure switch, fanfare horn, horn, λ oxygen sensor, loudspeaker, air-flow sensor, microphone, oil-pressure switch, sensors of all types, ignition trigger
C	Capacitor	Capacitors of all types
D	Binary element, memory	On-board computer, digital equipment, integrated circuit, pulse counter, magnetic tape recorder
E	Assorted devices and equipment	Heater, air-conditioning system, lamp, headlamp, spark plug, ignition distributor
F	Protective device	Trigger (bimetal), polarity protection device, fuse, current protection circuit
G	Power supply, alternator	Battery, alternator, charger
H	Check device, signaling unit, signaling device	Acoustic signaling unit, function lamp, turn-signal indicator, turn-signal lamp, brake-pad indicator, stop lamp, high-beam indicator, alternator charge indicator, indicator lamp, signaling unit, oil-pressure indicator, optical signaling unit, signal lamp, warning buzzer
K	Relay, contactor	Battery relay, turn-signal flasher, turn-signal relay, engagement relay, starting relay, hazard warning light flasher
L	Inductance	Inductance coil, coil, winding
M	Engine type	Blower motor, fan motor, pump motor for ABS, TCS and ESC hydraulic modulators, windshield-washer and windshield-wiper motors, starter motor, servomotor
N	Regulator, amplifier	Regulator (electronic or electromechanical), voltage stabilizer

Table 5: Code letters for designating electrical devices (continued)

Code letter	Type	Examples
P	Tester	Ammeter, diagnostic socket, rev counter, pressure indication, tachograph, measuring point, check point, speedometer
R	Resistance	Sheathed-element glow plug, flame glow plug, heating resistor, NTC resistor, PTC resistor, potentiometer, regulating resistor, series resistor
S	Switch	Switches and buttons of all types, ignition contact breaker
T	Transformer	Ignition coil, ignition transformer
U	Modulator, converter	DC converter
V	Semiconductor, tube	Darlington, diode, electron tube, rectifier, semiconductors of all types, variable capacitance diode, transistor, thyristor, Zener diode
W	Transmission path, line, antenna	Vehicle antenna, shield part, shielded line, lines of all types, line bundle, ground (continuity) line
X	Terminal, plug, plug-in connection	Terminal stud, electrical terminals of all kinds, spark-plug connector, terminal, terminal strip, electrical cable coupler, line connector, plug, socket, plug connector, (multiple) plug-in connection, distributor connector
Y	Electrically actuated mechanical equipment	Permanent magnet, (solenoid) fuel injector, electromagnetic clutch, electromagnetic brake, electric air slider, electric fuel pump, electromagnet, electric starting valve, transmission control, linear solenoid, kickdown solenoid valve, headlight leveling control, level control valve, switching valve, starting valve, door locking, central locking system, auxiliary-air slider
Z	Electric filter	Screening unit, suppression filter, filter chain, timer

Terminal designations

The purpose of the terminal-designation system for automotive electrical systems specified by the standard (DIN 72552) is to enable the most accurate connection of wires to all the various devices, above all when making repairs and installing spare parts. The terminal designations (Table 6) do not identify the wires because devices with different terminal designations can be connected at the two ends of each wire. For this reason, they need not be written on the wires.

In addition to the terminal designations listed, designations according to DIN VDE standards may also be used on electrical machines. Multiple connectors, for which the number of terminal designations as per DIN 72552 no longer suffice, are numbered by consecutive numbers or letters whose function assignment is not specified by standards.

Table 6: Terminal designations according to DIN 72552

Terminal	Definition
	Ignition coil
1	Low voltage
4	High voltage
4a	From ignition coil I, terminal 4
4b	From ignition coil II, terminal 4
15	Switched positive after battery (ignition-switch output)
15a	Output at the series resistor to the ignition coil and to the starter
	Preheating system
17	Start
19	Preglow
	Battery
30	Line from battery positive terminal (direct)
30a	Battery changeover 12/24 V Line from battery II positive terminal
31	Return wire from battery Negative or ground (direct)
31 b	Return wire to battery Negative or ground via switch or relay (switched negative)
	Battery changeover relay 12/24 V
31a	Return line to battery II negative
31c	Return line to battery I negative
	Electric motors
32	Return line[1])
33	Main terminal[1])
33a	Self-parking
33b	Shunt field
33f	for second reduced-rpm operation
33g	for third reduced-rpm operation
33h	for fourth reduced-rpm operation
33L	Rotation to left (counterclockwise)
33R	Rotation to right (clockwise)

Terminal	Definition
	Starter
45	Separate starter-motor relay, output; starter, input (primary current)
	Dual starters, parallel activation Starting relay for pinion-engagement current
45a	Starter I output, Starter I and II input
45b	Starter II output
48	Terminal on starter and start repeating relay (monitoring the starting process)
	Hazard-warning and turn-signal flashers
49	Input, turn-signal flasher
49a	Output, turn-signal flasher
49b	Output, second turn-signal flasher
49c	Output, third turn-signal flasher
	Starter
50	Starter control (direct)
	Battery changeover relay
50a	Output for starter control
	Starter control
50b	In parallel operation of two starter motors with sequence control
	Starting relay for sequence control of engagement current in parallel operation of two starter motors
50c	Input at starting relay for starter I
50d	Input at starting relay for starter II
	Start-locking relay
50e	Input
50f	Output
	Start repeating relay
50g	Input
50h	Output

[1]) Polarity reversal terminal 32/33 possible

Table 6: Terminal designations according to DIN 72552 (continued)

Terminal	Definition
	Wiper motors
53	Wiper motor, input (+)
53a	Wiper (+), self-parking
53b	Wiper (shunt winding)
53c	Electric windshield-washer pump
53e	Wiper (brake winding)
53i	Wiper motor with permanent magnet and third brush for higher speed)
	Lighting
55	Fog lamps
56	Headlamps
56a	High beam with indicator lamp
56b	Low beam (dipped beam)
56d	Headlamp-flasher contact
57a	Parking lamp
57L	Parking lamp, left
57R	Parking lamp, right
58	Side-marker, tail, license-plate and instrument lamps
58L	left
58R	right
	Alternators and voltage regulators
61	Alternator charge indicator
B+	Battery positive terminal
B–	Battery negative terminal
D+	Alternator positive terminal
D–	Alternator negative terminal
DF	Alternator field winding
DF1	Alternator field winding 1
DF2	Alternator field winding 2
U, V, W	Three-phase terminals
	Audio systems
75	Radio, cigarette lighter
76	Loudspeaker
	Switches
	NC contact/changeover contact
81	Input
81a	1st output, NC side
81b	2nd output, NC side
	NO contact
82	Input
82a	1st output
82b	2nd output
82z	1st input
82y	2nd input
	Multi-stage switch
83	Input
83a	Output, position 1
83b	Output, position 2
83L	Output, position left
83R	Output, position right

Terminal	Definition
	Current relay
84	Input, output, relay contact
84a	Output, drive
84b	Output, relay contact
	Switching relay
85	Output, drive (end of winding negative or ground)
86	Input, drive (start of winding)
86a	Start of winding / 1st winding
86b	Winding tap / 2nd winding
	Relay contact for NC contact and changeover contact:
87	Input
87a	1st output (NC side)
87b	2nd output
87c	3rd output
87z	1st input
87y	2nd input
87x	3rd input
	Relay contact for NO contact:
88	Input
	Relay contact for NO contact and changeover contact (NO contact side):
88a	1st output
88b	2nd output
88c	3rd output
	Relay contact for NO contact:
88z	1st input
88y	2nd input
88x	3rd input
	Turn-signal lamp (turn-signal flasher)
C	1st indicator light
C0	Main terminal for check circuits separate from flasher
C2	2nd indicator lamp
C3	3rd indicator lamp (e.g for dual trailer operation)
L	Left-side turn-signal lamp
R	Right-side turn-signal lamp

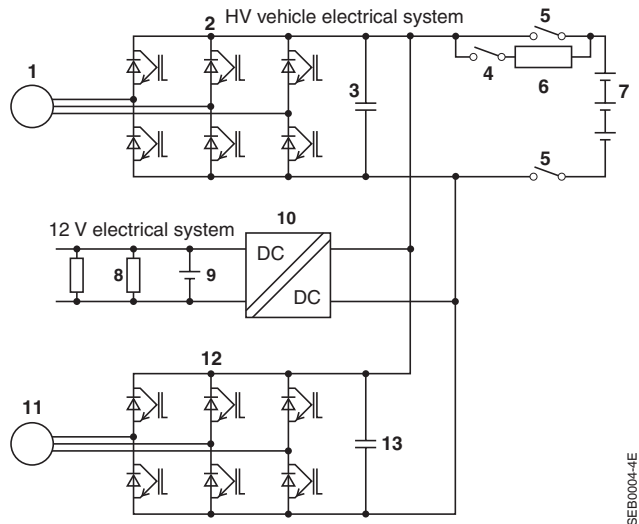
Vehicle electrical systems for hybrid and electric vehicles

While the electrical system of a vehicle with start/stop system (micro hybrid) is very similar to a conventional vehicle electrical system (see 12 V vehicle electrical system), electrical systems for mild- and full-hybrid vehicles and externally rechargeable hybrid vehicles and electric vehicles usually have a high voltage level. They therefore differ significantly from the electrical system of a conventional vehicle.

The electrical system of a hybrid or electric vehicle has the following chief functions:



– storing excess electrical energy from the drivetrain,
– where necessary outputting electrical energy to the drivetrain,
– reliable supply of the electrical consumers,
– for externally rechargeable hybrid and electric vehicles, storing energy from the public power-supply system and supplying the vehicle with it during operation.

Vehicle electrical systems for mild- and full-hybrid vehicles

The function of a mild- or full-hybrid vehicle (see Hybrid drives) requires a large amount of electric power, 15 to 100 kW. This cannot be provided on the 12 V voltage level in a sensible way. Therefore an HV vehicle electrical system (HV stands for High Voltage) with a voltage in the range of 42 to 800 V is additionally required. However, the 12 V standard electrical system is still required to supply the 12 V consumers in the vehicle, especially the ECUs. The individual consumers are supplied from the corresponding vehicle electrical system according to their power requirements (Figure 1). Generally, for cost reasons, automakers attempt to make do with standard 12 V components, as these are available cheaply and in large quantities.

Figure 1: Electrical system of a parallel-hybrid vehicle (typically only one inverter is used for the drive)

1 Electrical machine,
2 PWM inverter,
3 DC link capacitor,
4 Pre-charging contactor,
5 Main contactor,
6 Pre-charging resistor,
7 HV battery,
8 12 V consumer,
9 12 V battery,
10 Isolating DC-DC converter,
11 Air-conditioning compressor,
12 PWM inverter,
13 DC link capacitor.

HV vehicle electrical system

Design

The HV vehicle electrical system consists of an HV battery, at least one PWM inverter to power the electric drive (electrical machine, e-motor), other high-output or HV consumers (e.g., electric air-conditioning compressor) and for voltage-safety reasons an isolating DC-DC converter to supply the 12 V vehicle electrical system (Figure 1).

Operating principle

The HV vehicle electrical system is supplied with voltage via the contactors integrated in the HV battery. When the vehicle is switched off or if there is an accident, the HV vehicle electrical system is de-energized via the contactors, limiting the hazardous high voltage to the battery pack.

The PWM inverter generates a three-phase alternating current from the high direct voltage with a variable current intensity and frequency for the electrical machine (see Inverters).

Power is supplied to the HV vehicle electrical system in hybrid drives when the electrical machine is in generator mode or from the HV battery.

The isolating DC-DC converter transfers electrical energy from the more powerful HV vehicle electrical system (typically 2 to 3 kW power output) to the 12 V vehicle electrical system. Power is thus supplied to this low-voltage vehicle electrical system from the HV vehicle electrical system.

An example of an additional component of the HV vehicle electrical system can be an electric air-conditioning compressor, which depending on the vehicle requires a maximum electric power of 3 to 6 kW and is activated by a second PWM inverter.

HV vehicle electrical system for parallel hybrids

The topologies of the vehicle electrical systems for mild and full hybrids with only one electrical machine each are very similar. The vehicle electrical system of a mild hybrid (compared to the full hybrid) makes do with a lower energy accumulation and lower output capacity, as the vehicle can "crawl" electrically for a very short time at most.

The primary flow of energy of a vehicle with parallel-hybrid drive is from the HV battery to the electrical machine and vice versa. There is also a small flow of energy via the DC-DC converter to the 12 V vehicle electrical system or to other HV consumers.

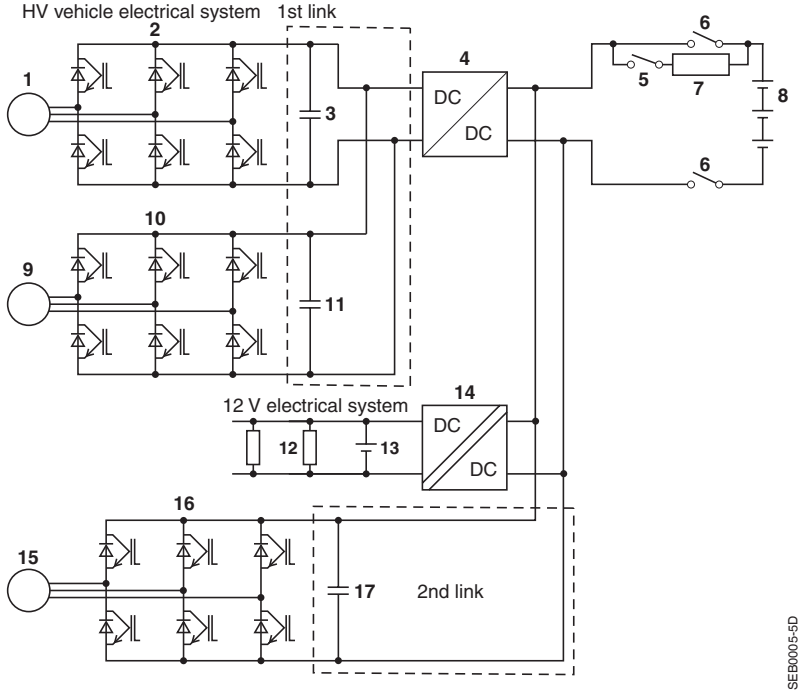
HV electrical system for power-split or series hybrid drives

Vehicles with two electrical machines require an enhanced electrical-system topology.

In the case of "Dedicated Hybrid Transmissions" (DHTs), i.e., power-split or parallel-series drivetrain topologies, high amounts of energy are transferred by the generator machine that can be coupled to the internal-combustion engine to the drive machine. Utilization of the optimal, i.e., low-loss, map ranges must be ensured in the operating strategy.

The battery voltage is determined by their design (cell number and size) according to the required temporary storage of electrical energy (typically for example for full hybrids 200 to 400 V). For optimum-efficiency operation of the electrical machine the DC link voltage of the inverters can however by variably controlled between the battery voltage and a maximum value set by the semiconductors (typically 600 to 700 V). Voltage adaptation and energy transfer are carried out by a suitably powerful step-up converter (non-isolating DC-DC converter, see Figure 2). By managing the DC link voltage just above the maximum value of the rectified induced voltages of the electrical machines it is possible to minimize the switching rate of the inverter switches and with it the electrical inverter losses and additional losses in the machines.

Further HV consumers like the air-conditioning compressor and air or water heater are usually supplied directly from the battery voltage.



12 V vehicle electrical system

The 12 V vehicle electrical system has a similar design for all hybrid vehicles that have both HV and 12 V vehicle electrical systems. It is very similar to the 12 V electrical system of a conventionally powered vehicle except for the fact that it usually does not have a starter and the power is supplied not by an alternator, but by an isolating DC-DC converter from the HV machine and thus from the HV vehicle electrical system (Figure 2).

If the vehicle can drive or crawl electrically, all assisting functions – such as power steering, cooler pumps or braking system – must be operated independently of the internal-combustion engine, i.e., electrically, so that they are also available when the internal-combustion engine is switched off.

Figure 2: Electrical system of a power-split or series hybrid vehicle

1 Electrical machine, 2 PWM inverter, 3 DC link capacitor,
4 Non-isolating high-output DC-DC converter (step-up converter),
5 Pre-charging contactor, 6 Main contactor, 7 Pre-charging resistor,
8 HV battery, 9 Electrical machine, 10 PWM inverter,
11 DC link capacitor, 12 12 V consumer, 13 12 V battery,
14 Isolating DC-DC converter, 15 Air-conditioning compressor,
16 PWM inverter, 17 DC link capacitor.

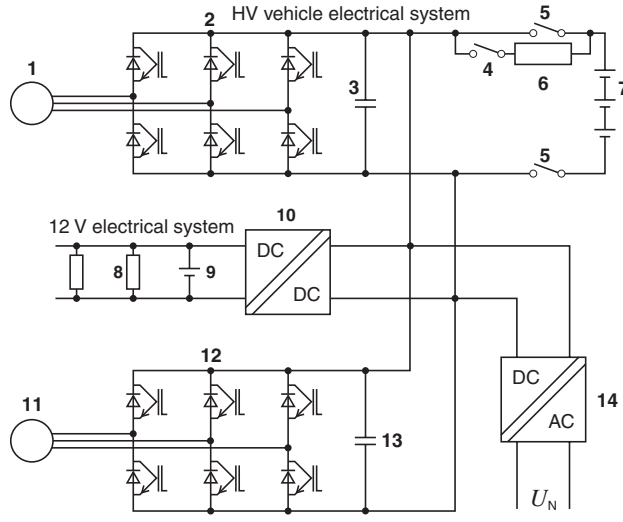
Vehicle electrical systems for externally rechargeable hybrid and electric vehicles

Topology

The electrical system of an externally rechargeable hybrid vehicle (e.g., plug-in hybrid) mostly corresponds – other than having a larger battery with a greater energy-storage capacity and a charging device – to that of the comparable hybrid vehicle without external charging capability.

For a purely electric vehicle, the topology of the parallel-hybrid vehicle with a larger battery and a charging device is used in the simplest case (Figure 3). A charging device can be used that draws electrical energy from a public alternating-current power-supply system (230 V~) or a three-phase-current power-supply system (400 V~) and uses it to charge the battery in a controlled manner. The vehicle's battery management system tells the charging device the charging output it needs. For safety and to protect against overvoltage, this charging device usually has an electrically isolated design.

Alternatively, the battery of an electric vehicle can also be charged with direct current from an externally controlled charging station. In this case, all that is required is a plug-in connection to the HV battery and a communication interface between the battery management and charging station to specify the charging output.



Efficiency

For electric vehicles, the efficiency of the vehicle electrical system is critical, as it has a direct effect not only on consumption, but also the range and the battery size needed. As a result, more expensive and more efficient components can reduce the total costs of the vehicle, as they make the same range possible with a smaller battery. Therefore, for many components of the vehicle electrical system, a review should be carried out to determine whether a less-expensive standard component can be used or it is worthwhile to develop a new, more efficient component.

Particular importance is attached to the energy demand for passenger-compartment climate control.

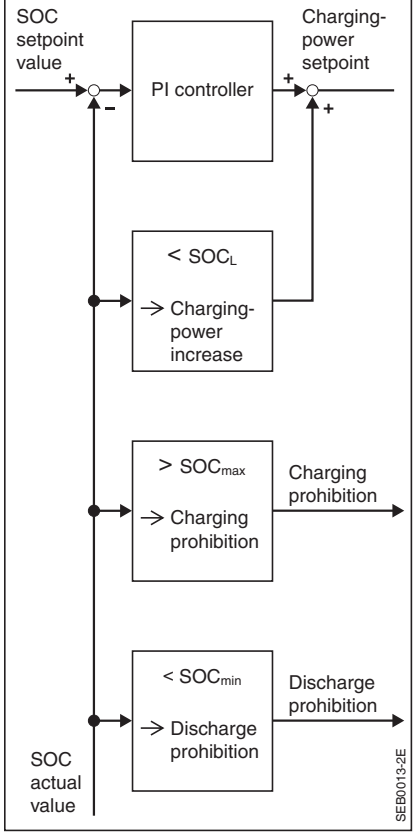
Charging strategy

Cyclical variation
Generally, a battery is damaged and therefore its remaining service life shortened by cyclical charging and discharging ("cyclical variation"). This damage increases exponentially with the magnitude of the stored and re-drawn energy packages and thus the temperature variations of the cells. This cyclical variation is however indispensable for operation of the drivetrain for electric driving and braking (recuperation). The battery is designed on the basis of power output and range and the charging strategy is adapted within the context of optimization between service life, cost, and weight of the battery on the one hand and good hybrid-drivetrain efficiency and greater range for electric vehicles on the other hand.

Usually, the thermal aging processes of the battery cells are accelerated significantly at a high state of charge (SOC). Therefore, the charging strategy should avoid the combination of a high state of charge and high temperature of the cells.

Operating strategy for hybrid vehicles
Normally, the system attempts to keep the battery of a hybrid vehicle in an SOC window of approx. 50 to 70 %. If this window is exceeded, there can be no operating-point shift of the internal-combustion engine and no more recuperation.



When the lower SOC limit (SOC_L) of approx. 50 % is reached, it is necessary to ensure that an adequate battery discharge power is still possible. Therefore, when the lower SOC limit is reached, battery recharging increases if no boost energy is required at the moment. Only when a much lower SOC limit is reached is the discharge power slowly reduced to zero. In normal vehicle operation, the vehicle almost never reaches this lower discharge limit, and the driver always experiences nearly identical acceleration behavior.

The lower SOC limit also plays an important role for reliably maintaining startability and preventing exhaustive discharge, which is detrimental to service life.

The charging strategy (Figure 4) is usually implemented in the engine control unit or in a special hybrid control unit.

Operating strategy for electric vehicles
In a pure electric vehicle, there is only one source of energy – the battery. Therefore, the operating strategy must fulfill the driver's command from this source, regardless of the state of charge. Therefore, strong but less frequent cyclical variation is inevitable to attain the necessary range of the vehicle with a reasonable battery size. The SOC limits are set here in such a way that there no effects that compromise service life. Depending on the battery system, the usable SOC range is between approx. 10 % and 90 %.

Figure 4: Charging strategy of a hybrid vehicle in driving mode
SOC State of Charge,
SOC_{max} Upper SOC limit,
SOC_L Lower SOC limit,
SOC_{min} Lower discharge limit.

Operating strategy for electric vehicles with range extender

For an electric vehicle with range extender – a small internal-combustion engine with an alternator that can supply electrical energy to the HV vehicle electrical system – there is the possibility during a longer journey or if a lower SOC limit value is reached of recharging the battery during the actual journey from this alternator instead of from an external source.

The range extender only has moderate rated power and delivers this as constant power with the best possible fuel consumption to the battery, which buffers the drivetrain power dynamics. There is also the possibility, subject to the appropriate drivetrain design, of coupling the internal-combustion engine of the range extender in a limited speed range directly to the drivetrain and thereby delivering mechanical power to the wheels without a loss of electrical efficiency.

Operating strategy for plug-in hybrid

The HV charging strategy here is a mix of that of an electric vehicle and that of a hybrid vehicle. In the case of a plug-in hybrid the aim for fuel-economy reasons is to drive electrically as far and as frequently as possible. When the battery is exhausted, the vehicle switches to an operating strategy similar to a hybrid (but with a lower SOC limit). However, the vehicle can also drive using only the internal-combustion engine where necessary.

When the battery is charged from the public power-supply system (typically in Germany 3.3 kW for single-phase current, in other countries up to 7.5 kW, up to 11 kW for three-phase current), the charging devices or the power output of the public power-supply system are usually limiting. The first phase of charging is performed at full power; in the second phase current and power are gradually decreased until the battery end-of-charge voltage is reached.

Electrical machines for motor-vehicle propulsion

The electric drive for vehicles with a hybrid or a purely electric drive is typically supplied by an HV battery (see Batteries for electric and hybrid drives) with direct voltage, which an inverter converts into a symmetrical, three-phase alternating-voltage system (Figure 1). The voltage amplitude and the frequency of this alternating-current system can be changed. Figure 2 shows simplified characteristic torque, power, current and voltage curves obtained during inverter operation. In the base-speed range (between standstill and specific speed at which the maximum voltage is achieved in the alternating-voltage system) a constant torque is typically obtained. The range from the specific speed up to the maximum speed is called the field-weakening range. In this range the mechanical power of the drive is approximately constant, which corresponds to a torque reduction proportional to the reciprocal of the speed. However, the behavior in the field-weakening range is actually dependent on the machine type (see section Typical characteristic curves).

This review provides an overview of the most important features and influencing factors of electrical machines for motor-vehicle propulsion (see also [1] and [2]).

Requirements

Figure 3 shows by way of example important operating points for purely electric vehicle operation and their importance to driveability. From these the contents of three of the four requirement groups listed in Figure 4 can be derived: overload operation, continuous operation, and cycle efficiency. These groups and four others (oscillation excitations, installation space, strength, and costs) are explained in more detail in the following.

Overload operation

Figure 5 shows typical characteristic torque and power curves of an electric vehicle drive. Overload operation characterizes driveability in accelerating and passing (overtaking) maneuvers. The electrical machine cannot be continuously operated in overload operation as this would result in at least one limit temperature (for example, winding or magnet temperature) being exceeded. Typical requirement variables are the maximum torque at low speeds, the power at high speeds, and an associated minimum operating time. The characteristic curves of maximum torque and maximum power against speed are independent of the thermal properties of the machine and are called maximum limit characteristic curves. These are determined by the electromagnetic properties of the machine, the maximum supply current, and the battery voltage.

Continuous operation

Continuous operation characterizes driveability during longer trips at approximately constant driving speed and is a measure of the thermal properties of the machine.

2 60 s characteristic curve,
3 Continuous limit characteristic curve.
A Maximum torque,
B Continuous torque at low speeds,
C Overload operation,
D Maximum power at high speeds,
E Continuous power at high speeds.

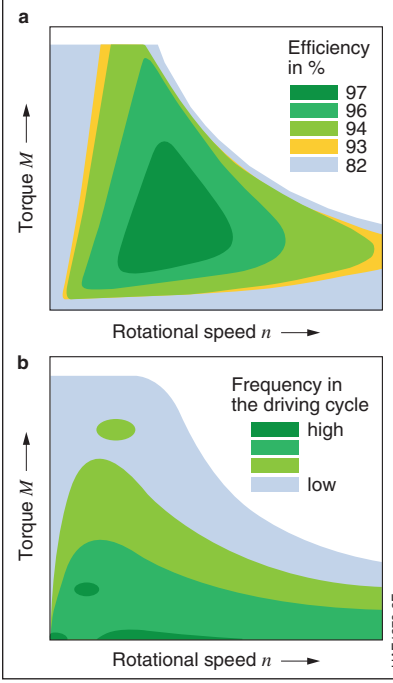
Continuous operation is defined by the reaching of a component limit temperature in thermal equilibrium. Typical requirement variables are the continuous torque at low speeds and a continuous power at high speeds. The characteristic curves of maximum continuous torque and maximum continuous power against speed are called continuous limit characteristic curves. Further characteristic curves with limited periods of time can be defined between the maximal limit characteristic curve and the continuous limit characteristic curve. Reaching the required period of time is dependent on the respective initial temperature.

Efficiency

Figure 6 shows the efficiency map of an electrical machine and the operating-point frequencies in a driving cycle. Depending on the distribution of the operating points in the cycle, other ranges are relevant to the cycle efficiency (typically rather small torques and medium speeds). Within the framework of design operating points below the maximum torque are as a rule calculated in such a way that optimum efficiency is obtained (regulation by the inverter, alternatively regulation to minimized oscillation excitations is also possible).

Oscillation excitations

In order to avoid unwanted sound radiation and service-life-reducing oscillations, oscillation excitations in the radial and tangential directions are calculated and minimized. The effects of torque ripple in the tangential direction depend on the mechanical systems connected to the machine (e.g., transmission). The requisite detailed knowledge of this system is often not available during the design process, which is why for the most part only a maximum peak-peak value of the torque-time characteristic is defined in the requirements.



In the specifications for electrical machines as drives there are frequently maximum curves for the permissible sound-pressure or sound-power level. These can, depending on the quality of the mechanical model be calculated or estimated during the design process with the oscillation excitations in the radial direction.

Installation space

Especially for hybrid vehicles, which are still equipped with an internal-combustion engine as well as the electric drive, it is particularly important to minimize the machine size due to the small installation space available. The smaller this installation space, the greater the utilization of the electromagnetically active parts (laminated cores and windings). For machines which are integrated in the drivetrain of an internal-combustion engine (IMG, Integrated Motor-Generator), it may be sensible for example to prefer the electromagnetically less favorable individual-tooth winding of the distributed winding because the former saves a huge amount of installation space thanks to its very short winding overhangs in the axial direction.

Figure 6: Efficiency map and operating-point frequencies for an electric motor-vehicle drive

a) Efficiency map,
b) Operating-point frequency in the driving cycle.

Strength
The electromagnetic-design requirements frequently conflict with the mechanical-design requirements. Narrow bars are often necessary in the core laminations to direct the torque-generating magnetic flux in the desired direction. These restriction can however become critical from a mechanical perspective if they are no longer able to withstand the loads that occur at high rotational speeds. A coupled optimization, which optimizes the combination of the two functions, is necessary here.

Costs
The development of electrical machines as a motor-vehicle drive at Bosch is geared towards projects with high quantities (> 100,000 units per year). In series production in this field even seemingly small cost savings per machine noticeably pay off overall. Because of the large number of competitors the target market price can only be achieved through massive cost optimization. The foundation for this is laid by a volume-production design with as little materials usage as possible. The rare-earth magnets in permanent-field synchronous machines are, on account of the high prices of the raw materials neodymium and dysprosium, a particularly important cost factor.

From the vehicle manufacturer's standpoint the system costs of the overall drive are to the fore (sum total of battery, inverter, and electrical machine). In the system consideration it is sensible to optimize the components not individually and independently, but taking the overall system into account. This produces systems whose individual components are not necessarily optimum in terms of costs, but are so in terms of the overall system.

Design

Figures 7 and 8 show exploded view of the two most important types of electrical machine for motor-vehicle propulsion. Both machine types are permanent-field synchronous machines (PSM) with cuboidal neodymium-iron-boron magnet blocks which due to centrifugal force load are inserted as "buried magnets" in recesses in the laminated rotor core.

Integrated motor-generator
An integrated motor-generator (IMG) is located in a hybrid vehicle with the internal-combustion engine directly in the drivetrain. It maximum rotational speed is therefore the same as that of the internal-combustion engine. In view of the limited installation space in the axial direction and the high torque required to start the internal-combustion engine smoothly, the laminated cores of this machine type are usually axially short, but have a relative large diameter (typically around 300 mm).

Figure 7 shows the exploded view of an IMG. The stator in this case consists of single tooth-wound coils. These are first wound individually and then pressed into the stator housing. The single tooth-wound coils are contacted via the contact carrier. To this end the wire ends of the single tooth-wound coils are bent onto and connected with the respective contacting rail. The HV connection is joined to the contact carrier. The completed stator is secured for example by means of lugs in the transmission housing of the internal-combustion engine. The inside diameter of the transmission housing is slightly larger than the outside diameter of the stator housing in such a way that a gap is formed between the two. This gap is sealed with the aid of seals (not pictured here) and forms the cooling jacket for liquid cooling.

The heart of the rotor is the rotor carrier. This is usually hollow on account of the very limited installation space. Further components, such as for example a clutch, the torsional-vibration damper or hydrodynamic converters, are mounted inside the rotor carrier.

The rotor laminations with the permanent magnets are pressed onto the rotor

carrier and secured with a support ring. By turning the individual support rings against each other, it is possible to establish a stepping or skewing in the rotor which has positive effects with regard to noise generation in the machine. The rotor laminations can be provided with recesses which, in combination with openings in the rotor carrier and a wet-running clutch, provide spray cooling for the winding overhangs of the single tooth-wound coils. The resolver wheel is also mounted on the rotor carrier and serves in later assembly in combination with the resolver coils not pictured here to determine the position and speed of the rotor. The rotor

carrier itself is connected with the transmission when the drivetrain is assembled and thereby ensures the transmission of torque.

Separate motor-generator
A separate motor-generator (SMG) can be connected with the drivetrain in different ways. This machine type is often used as a final-drive unit with a fixed-ratio transmission in hybrid or electric vehicles. Further applications include the installation of active parts in an electrified transmission or in an "electric axle" which forms a complete unit comprising inverter, transmission, and electrical machine (see eAxle).

Figure 8 shows the exploded view of a typical SMG as a "stand-alone machine" with water-jacket cooling. The drive-end end shield with the shaft end (A-side) is situated on the left. The connection of the water jacket in the housing with the end-face deflection of the coolant in the end shield is provided with seal. The laminated stator core with the stator winding is accommodated inside the housing. Because it is better suited to highly automated production, this machine type is frequently designed with a plug-in winding, where insulated copper rods are inserted into the stator slots, and the ends are bent to other rod ends and then welded together. On the B-side there is another end shield; this time with an integrated connection box for the power supply to the winding. The connection box is sealed with two covers so that the supply lines for the voltage source (inverter) can be installed. The rotor bearings are located in the end shields.

Types of electrical machines

Table 1 provides an overview of the most important types of electrical machines used in hybrid and electric vehicles. In hybrid vehicles a small installation space is for the most part decisive. This requirement can best be fulfilled with a permanent-field synchronous machine (PSM). The biggest drawbacks of this machine type are the relatively expensive rare-earth magnets in the rotor and the danger of these magnets being demagnetized.

Today's pure electric vehicles also contain induction or asynchronous machines (ASM) and electrically excited synchronous machines (ESM). Asynchronous machines with squirrel-cage rotors are characterized by simple, robust construction, but often require rotor cooling due to the additionally occurring rotor heat losses due to current. A very interesting alternative is the electrically excited synchronous machine, which on account of controllable rotor magnetization achieves particularly high efficiency levels and can manage on particularly little supply current. These advantages can lead to lower system costs and reduced energy consumption.

The switched reluctance machine (SRM) is often examined as an alternative with a particularly simple rotor design, but has to date been unable to gain a foothold in any production vehicle due to the increased complexity of the power electronics (3H-bridge instead of B6-bridge, see [1]) and its inherent susceptibility to noise generation.

Typical characteristic curves
The four types of electrical machine in Table 1 essentially come into question for use as traction drives in electric and hybrid vehicles in view of general considerations. Ultimately, the classic machine types are favored: asynchronous machine (ASM), permanent-field synchronous machine (PSM), and electrically excited synchronous machine (ESM) since these best fulfill the functional and economical requirements in the field of electrification.

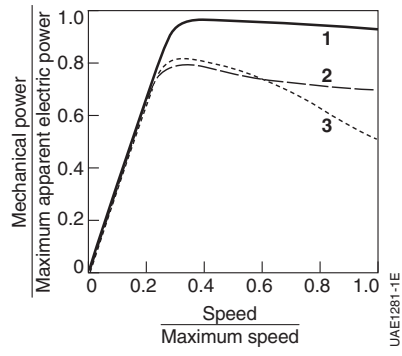
Which of these three machine types is the right solution in any concrete application case can only be ascertained by means of a detailed comparison in which

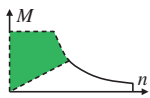
all three machines are designed according to the same requirements and the same installation-space and electrical boundary conditions.

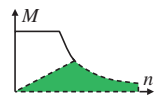
This comparison was conducted on the example of an electric vehicle (220 kW). The result is shown in the form of maximum limit characteristic curves with referred axis quantities in Figure 9. The abscissa represents the rotational speed referred to the maximum machine speed, the ordinate the mechanical drive power referred to the maximum available electric power. The differences between the three machine types on account of the principles involved can be clearly recognized after the maximum mechanical power is reached.

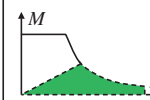
Asynchronous machine
The power of the asynchronous machine (ASM) drops at a markedly greater rate in the direction of maximum speed. The reason for this is the leakage inductance in the stator and rotor, which significantly influences the operational performance in this range. Because of this performance

Figure 9: Mechanical power for different types of electrical machines
1 ESM: Electrically excited synchronous machine,
2 PSM: Permanent-field synchronous machine,
3 ASM: Asynchronous machine.









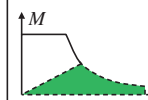


Table 1: Important machine types for electric motor-vehicle drives

Technology	**PSM** Permanent-field synchronous machine	**ESM** Electrically excited synchronous machine	**SRM** Switched reluctance machine	**ASM** Asynchronous machine

Risks	Magnet price Demagnetization Short-circuit resistance	Current-transformer system, rotor Speed strength	Noise Outlay, power electronics	High current demand Rotor heating

SAE1324-1Y

the ASM is less suited to drive cases which also require high power at maximum speed. This is basically the case in expressway/interstate driving close to the vehicle's top speed.

Permanent-field synchronous machine
The characteristic curve of the permanent-field synchronous machine (PSM) is much flatter. Here the amount of magnet material used (for the most part neodymium iron boron, NdFeB, due to the high flux density of these magnets) and the manifestation of the reluctance torque of the magnetic circuit offers plenty of scope in the layout of the characteristic curve. The PSM is therefore highly suitable for universal use and is the preferred solution for drives with high power and torque densities, provided the expensive rare-earth magnets permit economic feasibility of the drive.

Electrically excited synchronous machine
The electrically excited synchronous machine (ESM) has two particularities distinguishing it from the ASM and the PSM: Firstly, the maximum achievable mechanical drive power is for the most part clearly above the other two machine types and, secondly, the characteristic curve runs almost horizontally up to the maximum speed. This is possible due to the additional controllability of the excitation current in the rotor. The ESM therefore best converts the available electric power into mechanical power. Efficiency and power factor are accordingly higher for the ESM than for the ASM and the PSM. However, it is necessary to weigh up whether these advantages justify the design outlay for the excitation-current supply (collector rings or contactless transformers), and whether the effort and outlay associated with rotor cooling and mechanical strength at higher speeds justify its use as a driving machine.

Particularities of the machine types
Aside from the immediate properties which are derived from the characteristic curve, further particularities are to be noted in the machine types: In both synchronous machines requirements with regard to limiting the steady-state and dynamic short-circuit current dramatically influence the design specifically at high speeds. Small short-circuit currents necessitate particularly with the PSM low power at maximum speed.

In asynchronous machines much higher losses occur in the rotor. For this reason, active rotor cooling is for the most part necessary to achieve acceptable thermal conditions. Solutions with direct cooling of the short-circuiting rings in the rotor by oil or shaft cooling by water are possible here.

Essentially, the choice of the electrical machine suitable for the concrete drive case is the result of an overall evaluation of technical and economic characteristics which cannot generally or readily be transferred from one application case to the other. This statement also reflects the fact that all three favored electrical-machine types have been developed by different vehicle manufacturers to series maturity and are used in electrified drivetrains. A standard solution is not discernible at the present time.

Influencing factors on operational performance

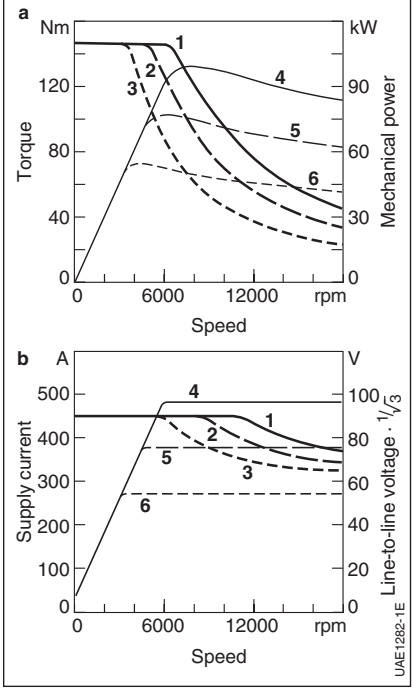
The operational performance of the electric drive is influenced by the battery, the inverter, and the electrical machine. Important influencing factors on the maximum limit characteristic curve of the ASM and the PSM are presented in the following. Diagrams are only shown for the PSM, since the ASM and the PSM perform similarly in most cases.

Figure 1 shows the electric drive consisting of battery, inverter, and electrical machine, and visualizes the influencing variables considered
– battery voltage U_{DC},
– maximum supply current I_{max} of the inverter,
– axial length l of the laminated core,
– number of turns w,
– outside diameter D of the stator,
– turns ratio k of the inverter.

Battery voltage

A higher battery voltage increases the maximum line-to-line voltage U_L. This increases the specific speed of the drive (highest speed at maximum torque, Figure 10).

The battery voltage accordingly has no influence on the maximum torque in the base-speed range. The power in the field-weakening range on the other hand rises with the battery voltage. For the PSM the relationship is approximately linear and for the ASM approximately square.



For the maximum limit characteristic curves in Figure 10 it is presupposed that the battery can also provide the necessary power for the maximum limit characteristic curve. Otherwise the achievable power on the maximal limit characteristic curve is limited by the battery power.

Maximum supply current of the inverter

The maximum supply current has no influence on the power at maximum speed, since the current limit of the inverter is usually not reached here (Figure 11). The maximum torque in the base-speed range on the other hand rises with the maximum supply current. Disregarding saturation, the relationship for the PSM is linear and for the ASM square. With a greater supply current the losses on the maximum limit characteristic curve also increase, above all in the base-speed range. This reduces the permissible overload time, i.e., the time until the electrical machine's temperature limit is reached.

Figure 10: Influence of battery voltage U_{DC} on the maximum limit characteristic curve of a PSM

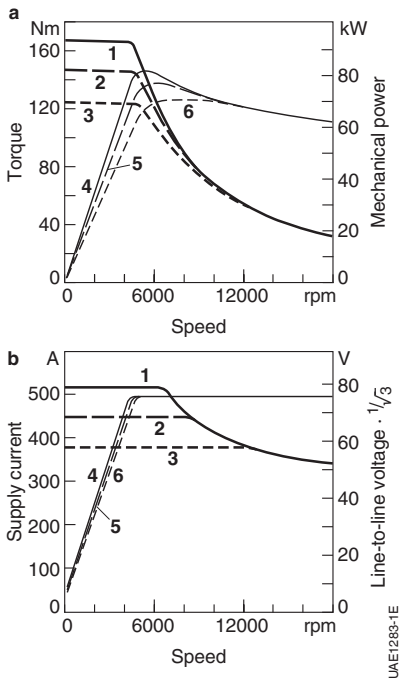
a) Torque curve and mechanical power,
b) Supply current and line-to-line voltage.
1 Torque (a) and supply current (b) for U_{DC} = 230 V,
2 Torque (a) and supply current (b) for U_{DC} = 180 V,
3 Torque (a) and supply current (b) for U_{DC} = 130 V,
4 Mechanical power (a) and line-to-line voltage (b) for U_{DC} = 230 V,
5 Mechanical power (a) and line-to-line voltage (b) for U_{DC} = 180 V,
6 Mechanical power (a) and line-to-line voltage (b) for U_{DC} = 130 V.

Axial length of the electrical machine's laminated core

The maximum torque in the base-speed range is proportional to the axial length of the laminated core (Figure 12). For the PSM the power remains virtually constant at high speeds. For the ASM on the other hand the power decreases at high speeds with increasing axial length. The cause is the increased leakage inductance.

Figure 11: Influence of maximum supply current I_{max} on the maximum limit characteristic curve of a PSM

a) Torque curve and mechanical power,
b) Supply current and line-to-line voltage.
1 Torque (a) / supply current (b) for I_{max} = 520 A,
2 Torque (a) / supply current (b) for I_{max} = 450 A,
3 Torque (a) / supply current (b) for I_{max} = 380 A,
4 Mechanical power (a) / line-to-line voltage (b) for I_{max} = 520 A,
5 Mechanical power (a) / line-to-line voltage (b) for I_{max} = 450 A,
6 Mechanical power (a) / line-to-line voltage (b) for I_{max} = 380 A.



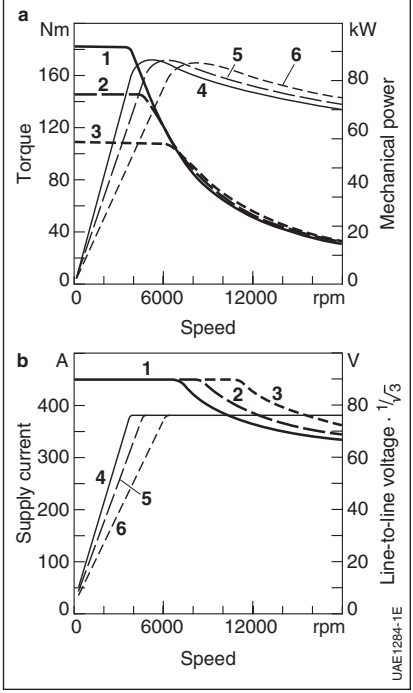


Figure 12: Influence of standardized axial length l/l_0 of the laminated core on the maximum limit characteristic curve of a PSM

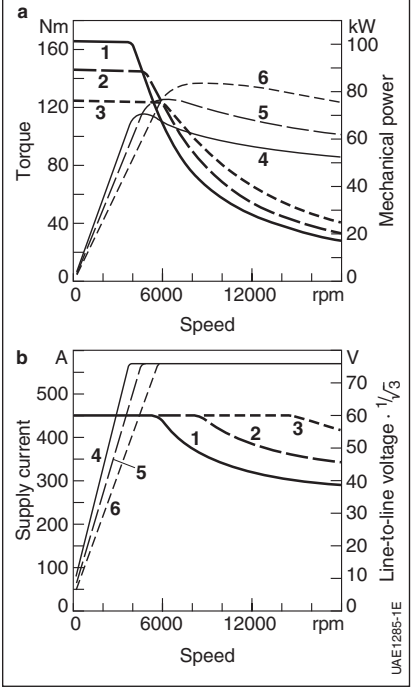
a) Torque curve and mechanical power,
b) Supply current and line-to-line voltage.
1 Torque (a) / supply current (b) for l/l_0 = 125 %,
2 Torque (a) / supply current (b) for l/l_0 = 100 %,
3 Torque (a) / supply current (b) for l/l_0 = 75 %,
4 Mechanical power (a) / line-to-line voltage (b) for l/l_0 = 125 %,
5 Mechanical power (a) / line-to-line voltage (b) for l/l_0 = 100 %,
6 Mechanical power (a) / line-to-line voltage (b) for l/l_0 = 75 %.

Number of turns of the electrical machine

If the number of turns is increased on the ASM or the PSM, the maximum torque in the base-speed range increase on account of the higher slot current linkage (Figure 13). The power at high speeds is on the other hand reduced, since the inductance of the electric machine is proportional to the square of the number of turns and thus the maximum phase voltage is reached earlier. The slot's copper space factor (i.e., the ratio of copper space to slot space) is limited by the respective production engineering, therefore the conductor diameter must be re-

Figure 13: Influence of standardized number of turns w/w_0 on the maximum limit characteristic curve of a PSM

a) Torque curve and mechanical power,
b) Supply current and line-to-line voltage.
1 Torque (a) / supply current (b) for w/w_0 = 115 %,
2 Torque (a) / supply current (b) for w/w_0 = 100 %,
3 Torque (a) / supply current (b) for w/w_0 = 85 %,
4 Mechanical power (a) / line-to-line voltage (b) for w/w_0 = 115 %,
5 Mechanical power (a) / line-to-line voltage (b) for w/w_0 = 100 %,
6 Mechanical power (a) / line-to-line voltage (b) for w/w_0 = 85 %.



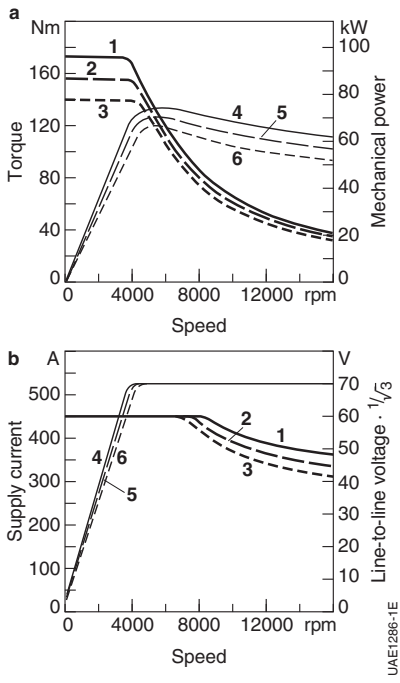


Figure 14: Influence of outside diameter D on the maximum limit characteristic curve of a PSM

a) Torque curve and mechanical power,
b) Supply current and line-to-line voltage.
1 Torque (a) / supply current (b) for D = 200 mm,
2 Torque (a) / supply current (b) for D = 180 mm,
3 Torque (a) / supply current (b) for D = 162 mm,
4 Mechanical power (a) / line-to-line voltage (b) for D = 200 mm,
5 Mechanical power (a) / line-to-line voltage (b) for D = 180 mm,
6 Mechanical power (a) / line-to-line voltage (b) for D = 162 mm.

duced if the number of turns is increased. In all, the winding resistance increases such that the losses on the maximum limit characteristic curve increase, above all in the base-speed range. This reduces the permissible overload time, i.e., the time until the electrical machine's temperature limit is reached.

Outside diameter of the stator

The influence of the stator outside diameter is considered whereby the entire lamination section of the electric machine is linearly scaled with the outside diameter. In the base-speed range this produces a greater torque when the outside diameter is increased for the ASM and the PSM (Figure 14). For the chosen scaling it must be noted that the maximum supply current of the inverter and the number of turns of the electrical machine have remained the same. With increasing outside diameter the current density decreases and the overload time increases.

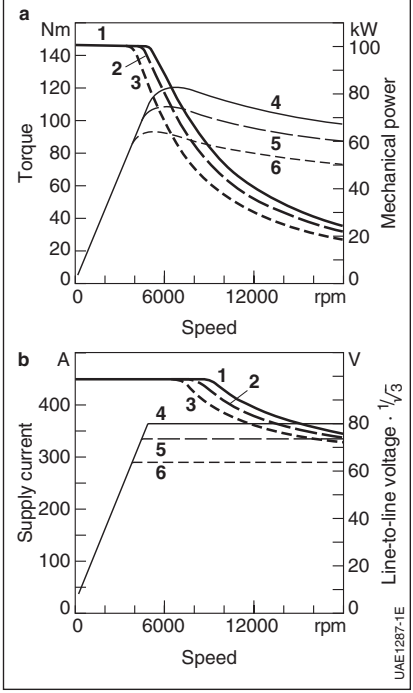
Higher power is obtained for the PSM in the field-weakening range. For the ASM the power in the field-weakening range can also increase depending on design, but can also remain constant.

Turns ratio of the inverter

The turns ratio k describes the relationship between the battery voltage U_{DC} and the maximum voltage of the fundamental component $U_{L,max}$ (line-to-line voltage) of the alternating-current system:

$$U_{L,max} = \sqrt{3}\, k\, U_{DC}\,. \qquad (1)$$

Different modulation techniques which give rise to different turns ratios can be used in regulation of the inverter. Common techniques and the associated ideal turns ratios are



– sine-wave modulation, k = 0.3535,
– space vector modulation, SVM; space vector pulse width modulation, SVPWM, k = 0.4082,
– block clocking, k = 0.4502.

Voltage drops via the power semiconductors are disregarded in the specified values.

Depending on the modulation technique used, the battery voltage is utilized differently and there are different voltage limits (Figure 15). k therefore has no influence on the maximum torque in the base-speed range. With higher turns ratios the voltage limit is only reached at greater speeds so that higher power is achieved in the field-weakening range.

Figure 15: Influence of turns ratio k on the maximum limit characteristic curve of a PSM

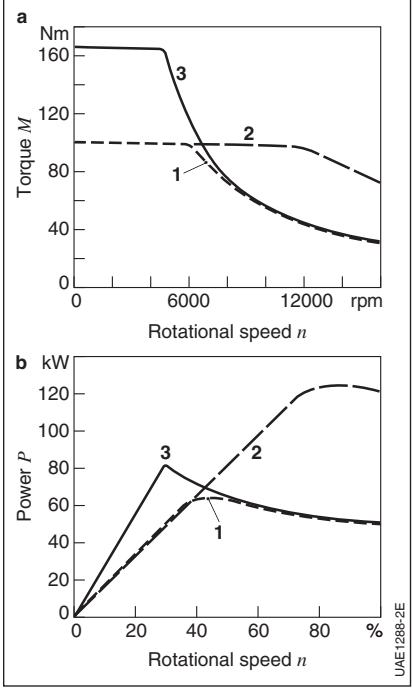
a) Torque curve and mechanical power,
b) Supply current and line-to-line voltage.
1 Torque (a) / supply current (b) for k = 0.4502,
2 Torque (a) / supply current (b) for k = 0.4082,
3 Torque (a) / supply current (b) for k = 0.3535,
4 Mechanical power (a) / line-to-line voltage (b) for k = 0.4502,
5 Mechanical power (a) / line-to-line voltage (b) for k = 0.4082,
6 Mechanical power (a) / line-to-line voltage (b) for k = 0.3535.

Maximum apparent power
The maximum apparent power of the electric drive is

$$S_{max} = \sqrt{3}\ U_{L,max}\ I_{max}\ . \qquad (2)$$

For a given modulation technique the following thus applies

$$S_{max} \sim U_{DC}\ I_{max}\ . \qquad (3)$$



The maximum apparent power is decisive in determining which maximum limit characteristic curve can be achieved with an electric drive.

The behavior of the electric drive when the battery voltage (influence on the power at maximum speed), the maximum supply current (influence on the maximum torque in the base-speed range) and the number of turns of the electrical machine (exchange of torque in the base-speed range for power in the field-weakening range) are changed is described in the previous sections. In practice, however, these parameters are not adapted alone, but matched to each other by reference to the available maximum apparent power S_{max}.

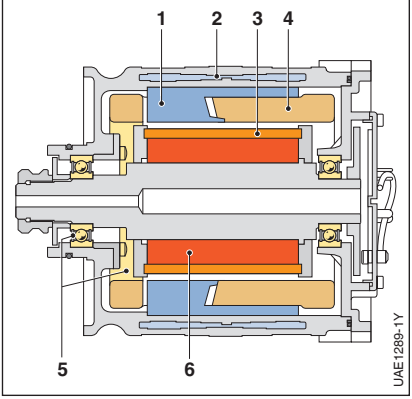
By varying the number of turns the same maximum limit characteristic curve can be set for different combinations of U_{DC} and I_{max} as long as S_{max} remains constant. This is illustrated with reference to Figure 16. The starting position is an electric drive with the battery voltage $U_{DC} = U_0$, the maximum phase current $I_{max} = I_0$, and the number of turns $w = w_0$. This has the maximum limit characteristic curve 1 from Figure 16. If the battery voltage is now doubled, this produces the characteristic curve 2 from Figure 16 (similar to Figure 10); the maximum apparent power is doubled. To obtain the starting characteristic curve again, first the number of turns w must be doubled (characteristic curve 3 in Figure 16, similar to Figure 13) and then additionally the maximum phase current I_{max} halved (characteristic curve 1 in Figure 16, similar to Figure 11).

Adapting the number of turns produces in both cases (both settings for characteristic curve 1 in Figure 16) the same maximum limit characteristic curve. Battery voltage and maximum phase current are indeed different, but the maximum apparent power is according to equation (3) constant. It must be noted that the number of turns can only be changed in discrete steps and therefore deviations can arise in reality.

Figure 16: Setting the maximal limit characteristic curve of a PSM by varying the number of turns w at the same apparent power
Settings:
1 $U_{DC}/U_0 = 1$, $I_{max}/I_0 = 1$, $w/w_0 = 1$ and $U_{DC}/U_0 = 2$, $I_{max}/I_0 = 1/2$, $w/w_0 = 2$.
2 $U_{DC}/U_0 = 2$, $I_{max}/I_0 = 1$, $w/w_0 = 1$.
3 $U_{DC}/U_0 = 2$, $I_{max}/I_0 = 1$, $w/w_0 = 2$.

Losses in electrical machines

Figure 17 shows a schematic longitudinal section of an electrical machine in which the most important assemblies are indicated and the associated types of loss are assigned to these.



Heat losses due to current
Heat losses due to current which in the first approximation are proportional to the square of the effective value of the current occur in the stator winding, in the rotor case of an asynchronous machine, and in the excitation winding of an electrically excited synchronous machine. For optimized designs, current-displacement and proximity effects as well as parasitic circulating currents in parallel and delta connections must additionally be taken into account.

Iron losses
Iron losses occur due to rapid magnetic reversals predominantly in the laminated stator core of the machines. On account of the principles involved, synchronous and asynchronous machines exhibit absolutely no or only low-frequency sinusoidal components of flux through their basic fields in the rotor. The magnetic losses are usually broken down into two components:
– hysteresis losses $\sim B^2 f$,
– eddy-current losses $\sim B^2 f^2$.

Here B denotes the flux density and f its frequency. Because of the high speeds and the accompanying high frequencies in automobile drives, the task of minimizing the eddy-current losses in particular poses a huge challenge. This is usually achieved by accordingly optimizing the lamination section and by using particularly thin core laminations (usually ≤ 0.35 mm) which are insulated against each other and stacked in the axial direction to form the laminated core.

Parasitic effects such as for example harmonic fields or harmonic components generated by the inverter can generate significant eddy-current losses both in the stator and in the rotor which must be taken into consideration in the design process.

Figure 17: Types of loss in an electrical machine
1 Iron losses in the stator lamination,
2 Eddy-current losses in the housing,
3 Ohmic losses in the rotor cage (ASM), ohmic losses in the excitation winding (ESM), eddy-current losses in the magnets (PSM),
4 Ohmic losses in the stator winding,
5 Friction losses (bearing friction and windage),
6 Iron losses in the laminated rotor core.

Eddy-current losses
Further eddy-current losses can occur in the magnet blocks of a permanent-field synchronous machine and in structural parts (e.g., housings or end shields) due to the magnetic alternating fields generated by the machine. Of particular importance here are the eddy-current losses in the magnets, since these directly heat the magnetic blocks which are thermally for the most part poorly connected to the cooling system and consequently under high field load can lead to irreversible demagnetization.

Friction losses
The rotational movement of the rotor causes bearing-friction and windage losses, which on the one hand reduce efficiency and on the other hand can even result in unacceptable heating in the bearing itself. Particularly in hybrid vehicles, in which the electrical machine always rotates but is not always actively in use, the friction losses have a significant influence on cycle efficiency.

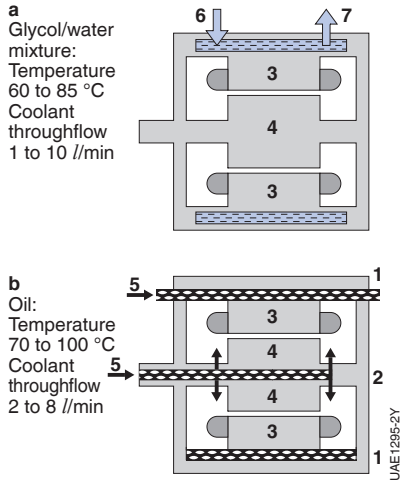

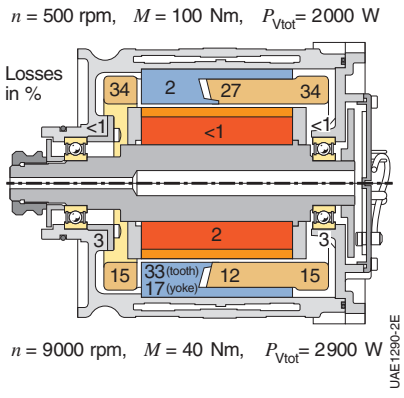

Figure 19: Typical distribution of losses of an electrical machine

Designations, see Figure 17. Percentage values in the top half apply to the operating state mentioned above. Values in the bottom half apply to the operating state mentioned below.

Cooling of the electrical machine

The losses are dissipated in the machine to cooling media. A powerful cooling system protects the individual components against overheating. Insufficient dissipation of the individual heat losses from the electrical machine restricts the permissible continuous power. In overload operation the thermal mass (heat capacity) limits the time until a limit temperature is reached.

Cooling types

Different cooling media are provided on the vehicle side to cool the electrical machine (Figure 18).

Water cooling
The type most commonly encountered is water cooling, i.e., integration in a water/glycol circuit, which can also be used to Cooling the power electronics. Here the stator core is encased in a water-cooling jacket.

Oil cooling
Oil cooling is advisable for integration in the manual transmission or final-drive differential. Cooling is also effected at the stator jacket. But the rotor and the stator winding can also be cooled directly.

Air cooling
Air cooling is also used. Here air flows through a fan via large-area cooling fins along the stator jacket or even axially along the rotor.

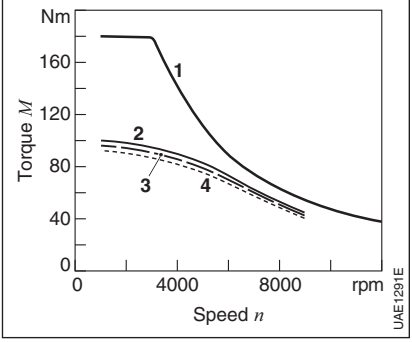
The cooling effect is crucially determined not just by the cooling type, but also by the coolant temperature and the coolant throughflow.

Heat dissipation

Evaluation of the cooling of an electrical machine requires knowledge of the individual, locally resolved losses and describes the heat paths to the cooling fluid. This is performed at the stator essentially by heat conduction from the winding to the cooling duct and at the rotor without internal cooling by convection. Mass node models and also CFD techniques (Com-

putational Fluid Dynamics) are used for design purposes.

In the case of jacket cooling the main stator heat flow (90 %) proceeds from the winding via the stator-slot insulating paper to the stator core and from there to the housing with cooling duct. A specific role is assigned to winding cooling here. Electric insulation by paint, impregnating resin and insulating paper causes heavily directionalized thermal insulation. Cooling optimization here requires the interaction of electromagnetic design, production development, and thermal design.



Heat dissipation via the stator winding overhangs to the cooling housing by air can be increased by fans or additional oil cooling. Alternatively, a heat-conducting connection by casting materials can be established.

The rotor is thermally connected via the air gap to the stator and convectively connected via the side faces to the housing. It is heated or cooled by the stator, depending on the operating situation.

The distribution of losses in the electrical machine changes with the speed (Figure 19). At low speed (top half of the picture) primarily heat losses due to current are effective; at high speed (bottom half of the picture) iron losses are predominant. In this way, the different cooling paths work on the basis of speed.

Figure 20: Example of a continuous limit characteristic curve of an electrical machine

Continuous limit characteristic curves with variation of the cooling-fluid temperature. Cooling-fluid throughflow is in all cases 6 l/min.
1 Maximum characteristic curve for torque,
2 Continuous torque for 65 °C,
3 Continuous torque for 75 °C,
4 Continuous torque for 85 °C.

Thermal limitation

When the electrical machine has a high power density, the maximum power is typically above the continuous power. Protection of the components against overheating is then ensured by a limiting function of the inverter's activation software. Limitation is performed typically for the limit temperatures of the stator and the rotor. In the case of the stator the insulation resistance limits the maximum winding temperature (e.g., 210 °C). Here the frequency distribution from vehicle operation is taken into account for the service-life evaluation. The rotor limit temperature is established for the PSM by the demagnetizing resistance of the magnets. This value must be derived from a worst-case analysis for the demagnetizing field at the limit temperature of the magnet (e.g., 160 °C).

Determination of the stator and magnet temperature during operation is subject to tolerances and requires a reduced control limit. Figure 20 shows by way of example the continuous limit characteristic curve of a water-cooled PSM. Limitation for the stator temperature is effective here. Lowering the coolant temperature increases the drivable continuous torque.

Inverters for electric drives

Area of application

Function

Inverters – also known as converters – contain the power electronics used to supply multi-phase electrical machines (EM) (Figure 1). Exclusively PWM inverters are used for supplying direct voltage (direct current, DC) in automotive engineering. The direct voltage can, depending on the drive system, be supplied directly by the traction battery or via an upstream DC-DC converter for voltage adaptation.

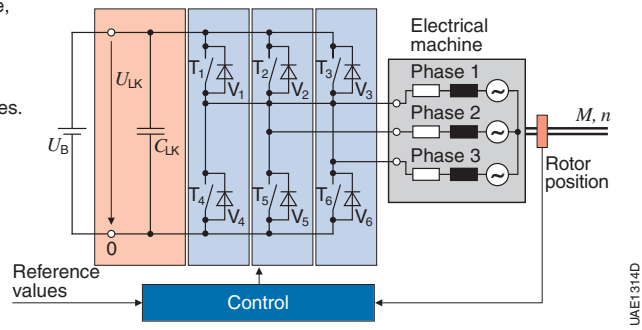
Requirements

Compared with industrial inverters, inverters used in electric vehicles are subject to much more critical requirements or demands with regard to coolant temperatures, environmental factors (corrosion, vibration, and tightness demands), and in particular electrical and functional safety.

Currently the most challenging application for an inverter is its use in plug-in hybrids because here the installation spaces and the coolant temperatures are rendered particularly critical by the additional presence of an internal-combustion engine and a traction battery.

All the components in the HV circuit (High Voltage) of a vehicle (HV vehicle electrical system) are for touch-voltage safety reasons isolated from the vehicle body ("frame" or "ground" of the 12 V vehicle electrical system, body potential), the inverter housing, and the control circuits connected to the 12 V vehicle electrical system.

Performance classes



Electric drives are used in vehicles of widely differing performance classes. The drive power per drive in the passenger-car sector ranges between 60 and 200 kW for a battery end-of-charge voltage typically of 450 V. The three-phase machine currents ranges between 250 and 600 A. Two or three drives may be present in the vehicle, depending on the application.

Batteries with a voltage of 800 V are used for passenger cars in the upper performance segment and in the commercial-vehicle sector. The attainable power is therefore 250 to 600 kW at similar currents.

The current intensity is limited with the power-module technology used. Three-phase current systems with six phases can also be used with appropriately lower current intensity for high power.

Function and circuitry

Three-phase current system

The inverter power switches "pulse" the direct voltage (DC) in specific switching patterns to the electrical-machine windings. Alternating voltages whose fundamental components generate the alternating currents (AC) in the electrical-machine stator windings are applied at the windings. In the case of polyphase (induction) machines there are at least three winding phases which are supplied with alternating currents that are symmetrically offset in relation to each other, the so-called three-phase current system.

Basic inverter circuit

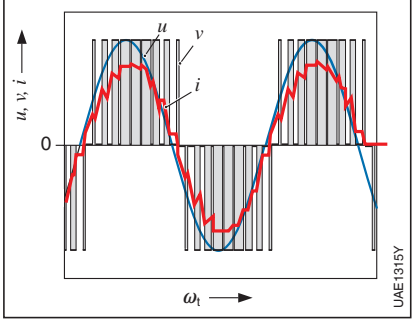
Six power switches are required in an inverter's basic circuit. At each of the three winding phases one of the power switches is connected to the positive polarity and one is connected to the negative polarity of the feeding direct voltage (Figure 1). The power switches connected to the positive polarity are called "high-side switches" and those connected to the negative polarity are called "low-side switches". These six switches in all form a three-phase bridge connection. The combination of a high-side switch and a low-side switch is called a half-bridge. A three-phase bridge connection therefore consists of three half-bridges.

Design variations of power switches

Depending on the required current-carrying capacity, each of the power switches can consist of one or more parallel-connected individual transistors. IGBT transistors (Insulated Gate Bipolar Transistor) are used as power transistors in the vehicle traction-voltage range of 150 to 800 V. These transistors, however, only route the current in one direction so that antiparallel (in the direct-voltage reverse direction) connected diodes (free-wheeling diodes) are required for free-wheeling and recovery time ranges of the current characteristics. In recuperation mode these diodes direct the current generated by the winding phases to the battery.

It transpires that in the medium term power transistors made of SiC (silicon carbide) instead of pure Si are used in applications with higher supply voltages (e.g., 800 V) and to reduce losses. These have MOS-transistor properties, are consequently reverse-conducting and therefore do not require an antiparallel-connected diode.

Switching the machine currents



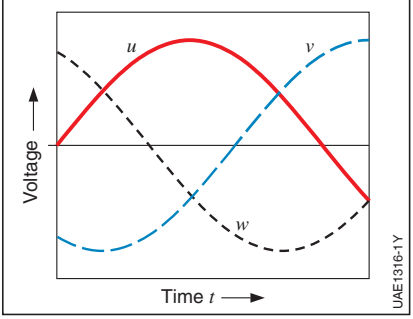
When the inverter is clocked, the voltages at the machine supply lines jump (phase voltages, Figure 2). In view of the inductances in the electrical machine, the alternating currents in the windows however have a strongly smoothed course, ideally a sinusoidal shape. The clock frequency T is for the most part constant, typically 10 kHz. The clock frequency can, depending on the operating point, be reduced in order to reduce switching losses in the inverter and additional losses in the electrical machine. This however results in a low-frequency noise excitation. The noise level may rise, depending on the natural frequencies of the mechanism.

The sinusoidal characteristic in Figure 2 illustrates the first order, i.e., the fundamental component from the Fourier analysis of the switched voltage characteristic. Harmonics are made visible in the current characteristic. These lead to harmonic fields and thus certain losses (additional losses) in the machine's iron core.

The sequential switching of the machine current between the two polarities

Figure 2: Time characteristics

v Phase voltage (measured to star point of machine winding),
u Sinusoidal fundamental component,
i Resulting machine-current characteristic (with harmonics),
ω_t Angular frequency.



of the direct voltage (high- and low-sides) is called commutation. The switching patterns selected by the inverter control gives rise to an effective machine terminal voltage which drive the required instantaneous machine alternating current (Figure 3). The amplitude of the phase currents in the machine supply lines essentially determines the machine torque, the frequency of the current determines the rotational speed. The sum total of the voltage-time phases produces in conjunction with the phase currents a continuous active-power flow on the DC side of the inverter.

Function of the link

Parasitic inductances in the mechanical circuit arrangement create voltage peaks at the power switches during commutation. The link capacitor is required to reduce these voltage peaks and the AC component (ripple content) in the battery voltage and to smooth the power pulses in the direction of the traction battery. It must meet strict demands with regard to low-inductance design, low losses, and high current-carrying capacity. Film capacitors which offer a good compromise between performance and cost are currently used here. Power switches and link must be set up in a low-inductance arrangement so that the resulting commutation circuit can achieve rapid current build-up and current reduction in the transistors of the power switches and free-wheeling diodes with simultaneously low voltage peaks.

Figure 3: Ideal three-phase voltage system with time characteristic

u, *v*, *w* Phase voltages.

Secondary functions of the inverter

As well as supplying the electrical machine, the inverter has the following secondary functions:

– Discharging the direct-voltage link during deactivation and in an emergency.
– Protecting the traction electrical system against overvoltage.

Overvoltage protection

Overvoltage protection in the event of a fault with a permanent-field synchronous machine (PSM) as the result of its rotational-speed-induced voltage is particularly critical. In the event of an inverter-control failure, the induced machine voltages are rectified via the free-wheeling diodes of the PWR inverter. When the battery is connected a braking torque builds up at the machine at higher speeds. Opening the battery contactor does prevent this braking torque, but results in the power switches being destroyed by excessive voltages.

A (usually) low-resistance failure of a power-switch transistor gives rise to an unacceptable braking torque at the electrical machine here as well.

A safe drive state can only then be achieved by opening the battery contactors and all-pole short-circuiting of the electrical-machine terminals. The three high-side switches or the three low-side switches are short-circuited, depending on the type of fault involved. In the event of a switching-transistor fault with a conducting failure, the neighboring switches are conductively connected; in the event of a blocking failure, the three opposite switches. It is essential to avoid a simultaneous switching-through of opposite transistors, as otherwise a short-circuit of the battery would occur if the battery contactors were not yet opened.

If a PSM machine has to be permanently short-circuited at higher rotational speeds and the vehicle is nevertheless to be moved (towed) at a not inconsiderable speed, this constitutes a considerable thermal load on the inverter – there is no short-circuit current flow.

Immunity against interference

The high rates of voltage rise at the machine windings when the terminal voltages are switched in the commutation process create in the machine capacitive crosstalk to the stator core and the rotor. These high-frequency voltages emit EMC interference (electromagnetic compatibility) to the environment and must be damped in the best way possible. Damping measures entail shielding the supply lines to the electrical machine and to the battery and filtering the direct voltage (DC) at the inverter input. DC input filtering in the simplest case consists of film capacitors to the inverter housing or to vehicle ground (Y-capacitors) to short-circuit these parasitic voltages in as short a route as possible via the ground path. Depending on the specification, the outlay can extend up to multi-stage filters of capacitors and inductors. With the pi filter, capacitors are switched between HV+ and HV–; an inductor is longitudinally switched between these X-capacitors. This produces a diagram in the form of the Greek π.

When shielding the machine supply lines it must be noted that, as a result of the different time characteristics of the phase currents, when the individual strands are shielded circulating currents can develop in the shields and across the connection elements to the inverter and the machine of a similar magnitude to the machine current. If possible, the machine supply lines should be subjected to common shielding (cumulative shield).

The voltage overshoots at the power switches during the commutation process must be taken into account in the reverse-voltage capability of the semiconductors. The higher these voltage peaks are, the higher – for a given (usually standardized) semiconductor reverse voltage – the supplying battery voltage and thus the operable drive power can be selected. For this reason a low-inductance design of the commutation circuit and if necessary voltage-limiting protective circuits (active clamping) of the power switches (transistors) provide for the best possible inverter performance.

Mounting

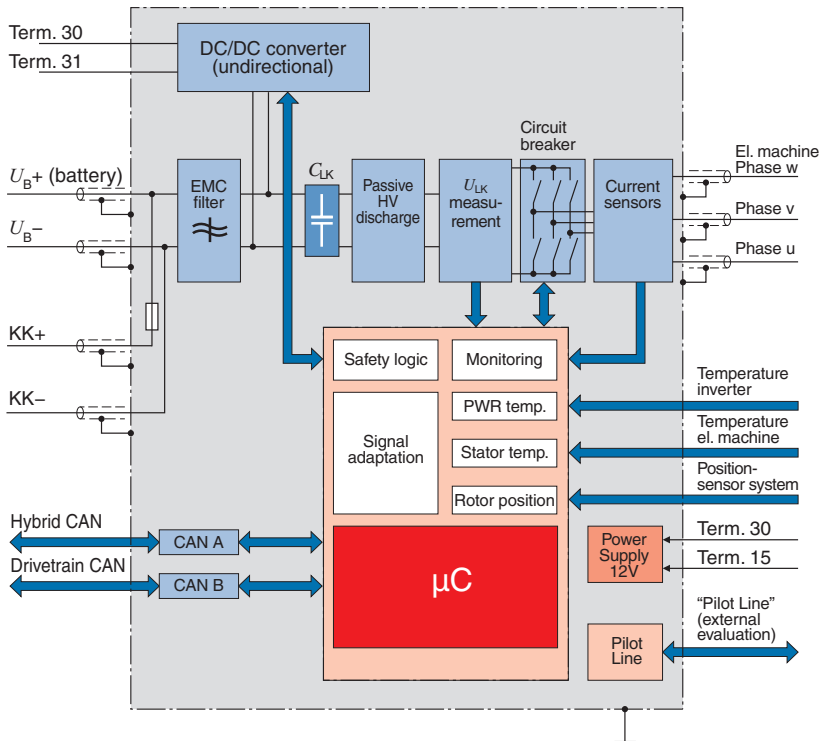
While for small three-phase AC drives in the vehicle (e.g., radiator fans, transmission oil pumps, electric air-conditioning compressors) the inverters are currently usually mounted directly on the end face of the electrical machine, this is not yet standard practice for the vehicle drives. The inverter is for the most part assembled as a single device or in combination with a DC-DC converter. The latter serves to provide the isolated supply of the 12 V vehicle electrical system and its consumers from the HV vehicle electrical system.

In hybrid-vehicle applications with one or two electrical machines for the drive in the main drivetrain and if necessary an additional electric final-drive unit (e.g., for hybrid vehicles with all-wheel drive) several inverters are installed in a double or triple inverter unit. In the near future, however, there is an increasing trend towards inverters mounted directly on the electrical machine or the transmission in order to spare the complex (shielded) three-phase AC supply lines to the electrical machine and its HV connections – both in electric final-drive units and in transmissions for hybrid drives.

Activation and control

Function

The driver adjusts the torque required for propulsion via the accelerator pedal. The aim of drive control is to make available according to the request of the higher-level vehicle system an electrical-machine torque that for a constant setpoint value exhibits as smooth a torque/time characteristic as possible so as not to excite the mechanical structures of the drivetrain and the vehicle to noise generation or oscillations.



Inverter control

Inverter control is based on a central microcontroller (µC) that for control and monitoring purposes evaluates various signals (e.g., rotor position of the machine, supply voltage, machine currents and temperatures) and generates the switching signals for the power switches in accordance with the setpoint-value requests (Figure 4).

The EMC filter damps the transmission of interference voltages caused by inverter switching to the HV vehicle electrical system in order to avoid radio-reception interference. Shielding of the HV cables is a further supporting filter measure here.

Because the link capacitor stores a comparatively high amount of energy, it must in the event of a fault be discharged within 5 seconds. This is performed by a special discharging circuit or discharging

Figure 4: Circuit structure of an inverter, here with additionally integrated DC-DC converter
U_B Voltage of traction battery, C_{ZK} Link capacitor, KK Air-conditioning compressor.

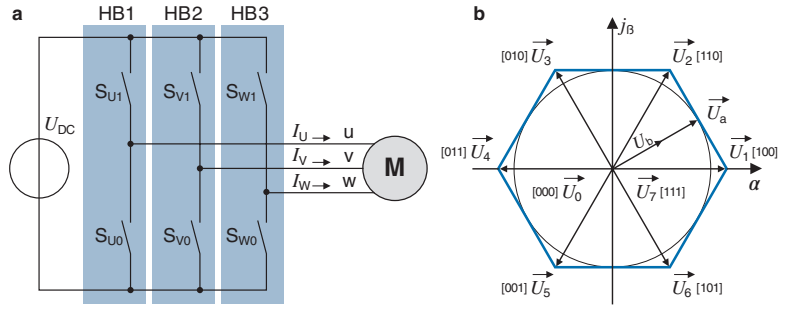
function. Isolated measurements of the DC link voltage and the phase currents to the machine and of the current position of the machine rotor are required for drive-torque control. For safety reasons all three phase currents are recorded although on the condition that the total current is zero only two of these would be required.

The derating functions, i.e., the thermally based measures for power reduction, are if necessary controlled from the recording of the component temperatures or the downstream observer models.

The inverter is in communication via a number of communication interfaces (CAN or FlexRay, high-speed CAN with up to 500 kBit/s) with the vehicle's other intelligent control components, in particular the vehicle control (see VCU, Vehicle Control Unit).

The "pilot line" is a hardware wire which forms a closed conductor loop via additional contacts at each critical HV connection point or on covers which could be opened in the vehicle. Its status is monitored for integrity by way of resistance measurement by the safety technology in the battery. The battery main contactors open in the event of a fault.

The internal power supply for the control electronics is delivered from the 12 V vehicle electrical system and in the interest of safety also with an additional backup supply via a DC-DC converter from the HV vehicle electrical system. The trigger circuits (gate-driver circuits) for the power transistors, but also their monitoring circuits, must have an isolated design.



Three-phase voltage system

From the eight possible switching states of the six power switches the three phase voltages are applied at the machine terminals in the form of pulse patterns. Table 1 shows the various possibilities. The switching state 1 means that the upper switch of a half-bridge is closed. In the switching state 0 the lower switch is closed. Only one switch of a half-bridge is ever closed; two closed switches of a half-bridge would cause a battery short circuit.

The "space vector" (representative sinor) is used in the representation of a three-phase voltage system in a mathematically complex formulation . It describes in a simple mathematical notation – and illustrated on the complex level as a vector – the amplitude and the phase angle of the instantaneous value of the voltage system (Figure 5). The eight switch-position variants are thus assigned six active space-vector states and two "zero-voltage vectors" (U_0 and U_7). The states with all three half-bridges simultaneously fed through to the high-side or low-side are equivalent with regard to the machine terminals; they constitute the zero-voltage vector or terminal short circuit.

The length of the space vector describes the voltage amplitude; it is ad-

Figure 5: Switch position and space-vector assignment
a) Circuitry, b) Space vector.
U_{DC} Battery direct voltage, I Phase current, U_n Phase voltage at machine terminals, HB Half-bridge, S Switching state, M Electrical machine.

justed by means of the pulse durations of the activation. The orientation of the space vector describes the phase angle of the system; this is adjusted by pulse-duration-modulated oscillation between two adjacent switching states.

The ideal representation of a three-phase voltage system would be achieved if the vector moved continuously – without pulse-related jumps – on a circular path. This is not possible for the inverter due to the few possible discrete switching states. But because the current due to the machine inductance follows a strongly smoothed voltage, it approaches a sinusoidal shape with the frequency of the voltage fundamental component. This oscillation constitutes the machine supply frequency. The sinusoidal shape could be represented more ideally by increasing the inverter pulse frequency, but this would be accompanied by an increase in inverter losses. Today's IGBT inverters for vehicles operate with a pulse frequency of around 10 kHz. In particular drive configurations (above all in hybrid vehicles) it is also possible, for reducing losses in certain operating ranges, to work with a reduced pulse frequency, particularly when the battery voltage is adapted by upstream power-electronics controllers to the electric drive's power demand.

Control strategy

The switch-control strategy for sinusoidal supply is called SVPWM (space vector pulse width modulation). It is the basis of most control strategies. In order on the other hand to achieve further current and torque increases, i.e., better specific inverter power, it is possible however to deviate from this control strategy (overmodulation, block operation).

Control-engineering implementation

Electric vehicle drives have complex closed-loop control circuits to reduce torque and avoid drivetrain vibrations. Current control forms the innermost, fastest circuit. Coordinating this is torque control, which derives an estimated actual torque value from measurements of stator current and current rotor position and estimation-model calculations for the magnetic fluxes in the machine and the temperatures of the critical assemblies. Drive control and the real-time observer simulations required considerable microcontroller power and signal-acquisition precision. This actual torque value must be formed as precisely as possible because it not only is used for driving-comfort purposes but also forms the basis of the drive safety concept.

Working with asynchronous machines is in terms of control engineering much simpler than using synchronous machines. Synchronous machines create their torque by “displacing” the magnetic fields of a current-fed stator and a rotor equipped with magnets. It is therefore necessary here to know precisely the absolute rotor rotation-angle position. Today these are usually sensed by reluctance resolvers or eddy-current position sensors in combination with specialized evaluation-electronics modules.

Derating concept

The temperatures of critical components (e.g., the PSM rotor equipped with permanent magnets) are estimated in real

Table 1: Switching state and phase voltages

Basic voltage space vector	Switching state			Phase voltages		
	S_{U1}/S_{U0}	S_{V1}/S_{V0}	S_{W1}/S_{W0}	U_{UV}	U_{VW}	U_{WU}
U_0	0	0	0	0 V	0 V	0 V

U_5	0	0	1	0 V	$-U_{DC}$	$+U_{DC}$
U_6	1	0	1	$+U_{DC}$	$-U_{DC}$	0 V

time by means of observer models using measured values and other available data in order to operate the drive components in their safe operating ranges. If critical limits are reached, limitation strategies intervene to reduce loads gradually and thereby prevent damage to the components.

Closed-loop control-circuit influences
Closed-loop control-circuit influences for taking account of the elasticity of specific drivetrains (subject area of comfort) are already in use today. It is foreseeable in future that, in the case of high-power electrifications (typically electric vehicles) with the electric drive heavily involved in braking, the braking functions will also in part be integrated in drive control in order to avoid communication dead times.

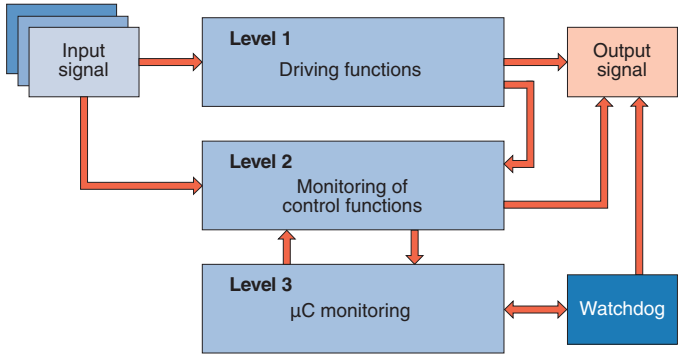
Software and functional safety

Requirements
The inverter software must satisfy requirements that are comparable with those of an internal-combustion engine. As well as a vehicle immobilizer and safeguarding against unintended movement and acceleration by the three-level concept (comparison with EGAS concept for gasoline-engine control), increased functional-safety requirements (ISO 21212, [1]) with regard to the safety objective "unintended torque" however must also be satisfied. The ASIL levels B through D (Automotive Safety Integrity Level) must be realized here, depending on vehicle size, drive power, front- or rear-wheel drive, and if necessary the use of sufficiently safe signals from other ECUs in the vehicle. These safety levels are essentially achieved by redundancies in the sensor system, the supply, and the software, if necessary also with diversity. In other words, not only is the system redundant in design, but also different solutions are used.

ASIL is a risk-classification scheme which is defined in the standard ISO 26262 [2].

Three-level concept
The three-level concept (Figure 6) monitors on a lower software level (level 2) the plausible function of the actual control software and the functional software (level 1), whereby it continuously monitors the ranges of values in which the variables move. At a further lower monitoring level (level 3) the microcontroller (μC), its memories, and the function of the sensors are monitored, whereby test operations are fed in. An error counter in the assigned watchdog hardware module aggregates registered errors and if necessary triggers the "safe state" of the electric drive. This is currently defined in the case of a PSM machine as its three-phase all-pole short circuit.

Figure 6: Principle of the three-level concept for ECU monitoring [3]



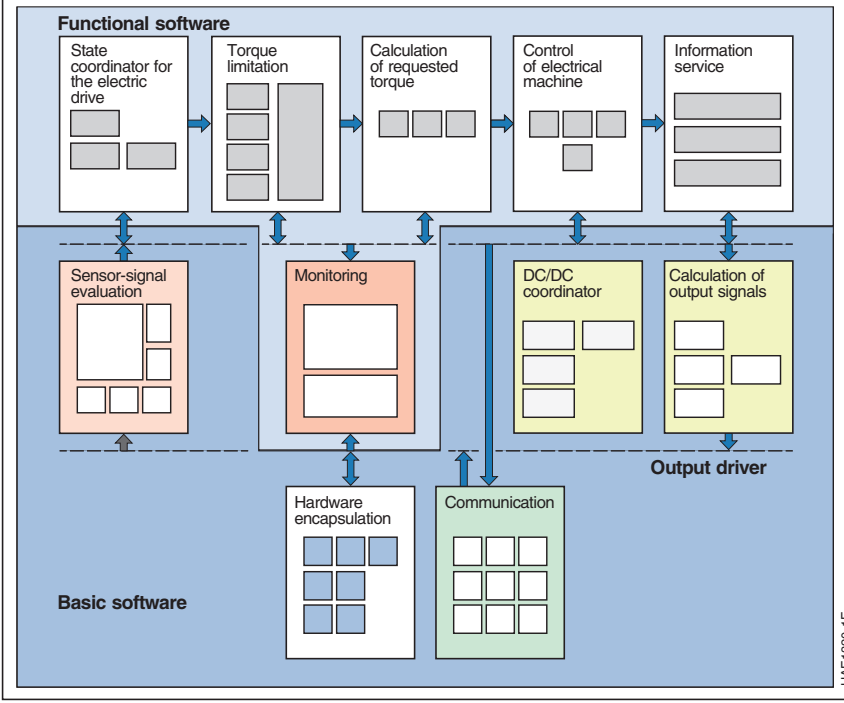


Figure 7: Software-structure design

Functional safety
Not only the ECU computer is monitored within the framework of functional safety. Also – depending on the requirement level – hardware redundancies and diversities are introduced in the components used. This does not necessarily have to be realized in an ECU (here in the inverter). It is perfectly possible to realize these functionalities on the vehicle level by combining the various ECUs and their data. The aim of monitoring is to state definitively that the actual torque of the drive is in a permitted tolerance band for the current operating point around the setpoint value.

In addition to the functional software for the drive which is subject to monitoring here, further program sections are required for time-critical reading-out of sensors and activation of the power switches (the so-called complex drivers), for communication and the hardware-related basic software for operating the ECU (Figure 7). The functional software can come from a single source or in parts from different sources (software sharing by vehicle manufacturer and different suppliers). However, this calls for the appropriate level of co-ordination and each supplying party must provide its specific monitoring function. The basic software is supplied in each case by the equipment manufacturer.

Equipment mechanics

Mounting the inverter
Today's inverters are for the most part tested devices with cable connection or designed for directly mounting on the electrical machine or transmission housing. A market for tested inverter assemblies seems to be emerging. In which partitioning and installation situation an inverter is used is in part specific to each vehicle manufacturer. Standardization in the market is difficult to conceive.

Cooling
The loss-generating inverter assembly (essentially the power modules and the link capacitor) is in most cases liquid-cooled with coolant mixed with glycol. The typical volumetric flow is usually max. 10 liters per minute, the maximum temperature depending on the application is between 65 °C and 85 °C.

Inverter design concepts
The heart of the inverter, the power-switch module, comes in a variety of designs.

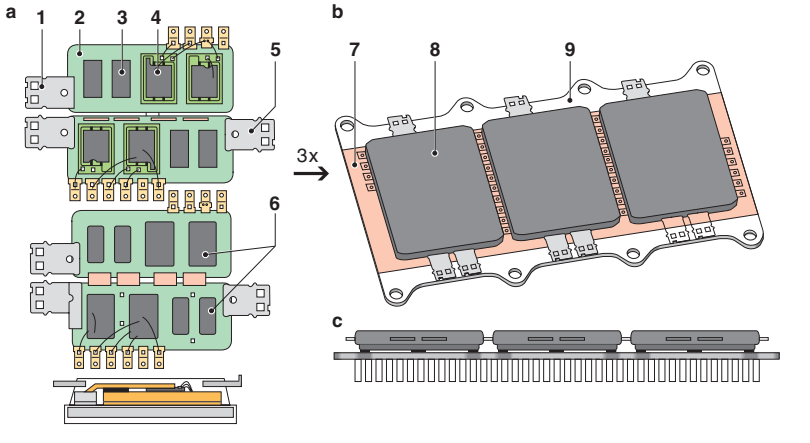
Bond-frame module
The bond-frame module is sintered with semiconductor chips or soldered to an insulating ceramic metallized on both sides (AMB, Active Metal Brazing; DCB, Direct Copper-Bonding; made of Al_2O_3, AlN or Si_3N_4). The top surfaces of the chips are contacted with thick-wire bonds or with soldered or sintered flat conductors. The entire module is passivated with gel.

Mold module
The semiconductor chips are soldered or sintered to lead frames, the top surfaces are contacted with lead frames. The entire module is packed with transfer mold. Owing to the size, it is for the most part designed as a half-bridge module, but sometimes also as a single switch. Insulation from the cooler is provided by laminate or intermediate ceramic layers.

Cast module
This module has the same design as the mold or the bond-frame module, but is passivated by synthetic-resin casting compound.

Soldered bond-frame modules
This technology is no longer state of the art in that the risk of solder fatigue significantly limits service life and load capacity.

Low-temperature silver sintering
Alternatively, there is a trend in chip bonding towards low-temperature silver sintering with significantly longer service life. Mold and casting technologies likewise offer significantly longer service life for soldering joints.



Heat dissipation
Pin-fin concept
Virtually all of today's power modules make use of a pin-fin heat sink made of aluminum or copper for heat dissipation. These are baseplates onto which the power modules are mounted and whose other side projects with so-called pin-fins (finger-shaped surface-area enlargements and turbulence generators) into the water cooling circuit (Figure 8). Related measures to improve heat dissipation are used in other cases.

Because an inverter uses power from 100 to 200 kW at 96 to 98 % efficiency, losses of several kilowatts must be dissipatable.

Cooler types
Two basic types of cooler are currently in series production:
– The water path is created in the aluminum housing and sealed with the pin-fin on the other side.
– When the cooler is closed the pin-fins are also connected with the other side of the water path. This cooler has the advantages of higher pressure resistance and better heat dissipation.

Design
Link capacitor

the power modules (primary current flows via conductor bars in close proximity to the capacitor or if necessary also through the capacitor busbar). It is advantageous to run the primary current past the capacitor elements over as short a route as possible and essentially only to apply the ripple current to the busbar of the elements. Capacitors for inverters in the upper power range have for the most part a connection to the cooling medium (Figure 9).

4 Microcontroller control circuit,
5 DC-DC converter.

Commutation circuit
The busbar of the commutation circuit between the link capacitor and the DC inputs of the power module must be designed to be as low-inductance as possible, i.e., the potential surfaces must be routed as closely as possible to each other and the current paths during commutation between the switches should encompass as few surfaces as possible.

Gate-driver circuit
The gate-driver circuit is placed as close to the power switches as possible, but the electromagnetic fields for the most part must be shielded in the area of the power modules so that there can be no interference with the control circuits even in the event of extreme transient currents.

HV connections
The HV connections also deserve special attention since they too are affected by losses and adequate heat dissipation must be provided for or the creation of heat loss should be avoided as far as possible (screw connections are advantageous).

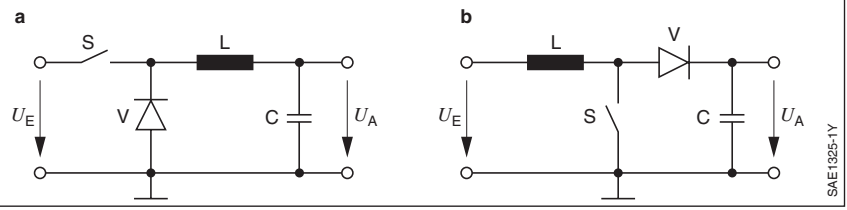
DC-DC converters

Application

A DC-DC converter, also called a voltage transformer, is an electric circuit that converts a direct voltage into a different direct voltage [1]. Conversion serves to
– adjust a different voltage level,
– adjust a stable voltage,
– facilitate a variably adjustable voltage or
– electrical isolate two voltage supply systems.

A number of these requirements can be simultaneously achieved with a voltage transformer.



Voltage levels
Conversion of high to low voltages
Every vehicle has for power-supply purposes a 12 V electrical system, consisting of a current source, an energy accumulator/storage device (battery), and the distribution (cables). This is also the case for electric and hybrid vehicles, which have a traction battery with a voltage level of 400 V or 800 V.

Whereas an alternator serves as the current source in conventional vehicles with internal-combustion engines and solely a 12 V vehicle electrical system, a supply from the traction battery via a DC-DC converter is used in electric and hybrid vehicles. This system converts high direct voltage (HV) into low direct voltage (LV) for the 12 V vehicle electrical system. Power ranges typically between 2.4 and 3.5 kW; peak demands over and above this power output are buffered by the 12 V battery (predominantly a lead-acid battery, in future also a lithium-ion battery). The advantages of a supply from the traction battery via the DC-DC converter compared with the alternator in a conventional 12 V electrical system are higher efficiency and a supply of energy that is not dependent on engine speed.

Conversion from 48 V to 12 V
In mild-hybrid vehicles the 12 V electrical system is supplied from the 48 V battery. Therefore voltage transformation with a DC-DC converter is also required here.

Requirements
DC-DC converters are subject to different requirements on account of the voltage levels. There are therefore essentially two distinct categories: non-isolating (electrically connected) and isolating (electrically isolated) DC-DC converters.

Figure 1: Diagrams of electrically connected DC-DC converters (block diagrams)
a) Forward converter (step-down converter),
b) Blocking converter (step-up converter).

S Switch, V Diode, L Coil (inductor L), C Capacitor (C).

Non-isolating DC-DC converters

Basic design and operating principle
DC-DC converters essentially consist of switches, diodes, and energy storage devices (inductors or capacitors, or both). There are various ways to wire up these elements and there are several ways of classifying them. Some arrangements have gained acceptance in practice, and these will be described in the following.

Electrically connected DC-DC converters are the simplest type, most notably the step-down converter and the step-up converter (buck converter and boost converter).

With reference to these two simple converters a further distinguishing feature may be introduced: forward converter and blocking converter. The step-down converter in Figure 1a is called a forward converter because it transfers energy to the output during the switch's conducting phase. With the blocking converter in Figure 1b, on the other hand, the energy transfer to the output takes place during the switch's blocking phase.

Step-down converter
In the case of the step-down converter (Figure 1a) the switch S can assume two states: switched on ("on") and switched off ("off"). Power-electronics components such as MOSFET and IGBT are used as switches. The switch S can conduct either the input voltage U_E or no voltage to the subsequent circuit. Taking the repetition period of a switch-on and switch-off operation as duration T (period duration, and derived from this the switching frequency) and keeping this constant, a square-wave voltage is obtained whose components U_E and 0 are dependent on the duty ratio t during a period. The ratio of t to T is defined as the duty cycle D and provides the relationship between input and output voltages.

However, the voltage downstream of the switch has a non-constant square-wave shape and must still be changed to direct voltage. This task is performed by the two energy-storing elements, namely the coil (inductor L) and the capacitor (C), which in their arrangement act as a second-order low-pass filter. The switch S interrupts and conducts the current alternately, which results in a discontinuous flow of current. Discontinuous flows of current through inductors result in high induction voltages. In order to avoid these high induction voltages, the current must flow continuously through the inductor. This is ensured by a free-wheeling diode. The is the diode V, which ensures that, with the switch S in the off state, the current can flow via the inductor L, the load (not shown in Figure 1) in the output circuit and C via V back to the inductor L. The diode V blocks when the switch S is closed. The capacitor C serves to smooth the ripple output voltage. Consequently, the low-pass filter generates from L and C the mean value from the chopped DC input voltage downstream of the switch S. The output voltage is obtained as the Dth part of the input voltage:

$$U_A = D\,U_E, \text{ mit } D = \frac{t}{T}.$$

In this way the input voltage U_E is converted to a lower voltage U_A.

Step-up converter
Here too the switch S can assume two states: switched on and switched off (Figure 1b). In this way the switch S can apply the input voltage U_E to the inductor L, which results in a build-up of current in the inductor. The diode V is blocked in the process. During this phase the capacitor C at the output maintains the voltage and supplies current to the load circuit. When S is switched off, the inductor drives the current with the energy from the previously built-up magnetic field further across the diode V to the output. The inductor is now with its induced voltage in series with the input voltage and thus the output voltage U_A is higher than the input voltage:

$$U_A = \frac{1}{1-D}\,U_E.$$

48 V-12 V voltage transformers

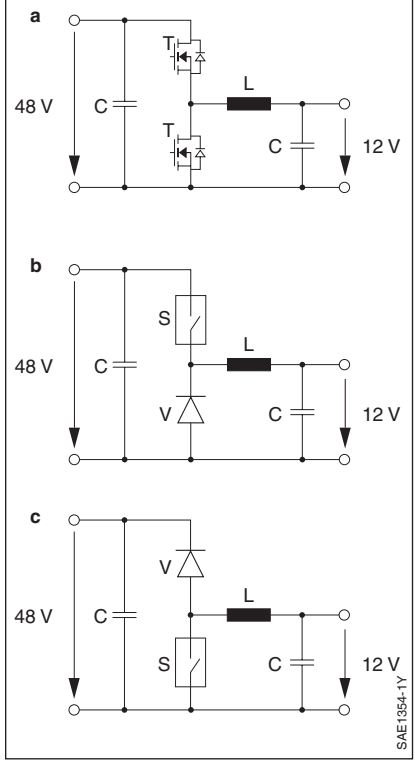
DC-DC converters are used in vehicles with 48 V and 12 V electrical systems to connect the two electrical subsystems to each other. These voltage transformers are therefore always bidirectional and can work in both directions

– from 48 V to 12 V as step-down converters and
– from 12 V to 48 V as step-up converters.

Because no electrical isolation is required on account of the voltage of 48 V, the simple topology of the step-down and step-up converters is preferred (see Figure 1). An active rectifier with a MOSFET is used instead of a passive rectifier with a diode. MOSFETs have an inherent source-drain diode (also known as a body diode) which can be used for rectifier purposes. If the MOSFET is actively switched on during the diode's conducting phase, the losses in the now “active” rectifier decrease. Consequently, the MOSFET is now able to perform the two “switch” and “diode” functions, depending on its activation.

Figure 2a shows the basic circuitry of such a DC-DC converter with two MOSFETs arranged as a half-bridge. This circuitry can also be seen in Figure 3. For the step-down converter the upper MOSFET is used as the switch, the lower MOSFET operates as the diode (Figure 2b). This arrangement corresponds exactly to Figure 1a.

For the step-up converter the lower MOSFET operates as the switch, while the upper MOSFET operates as the diode (Figure 2c). This corresponds to the mirrored arrangement of Figure 1b.



In other words, the DC-DC converter can operate from 48 V to 12 V as a step-down converter and from 12 V to 48 V as a step-up converter. Only the switch and rectifier functions change between the two MOSFETs.

For higher currents a number of phases are connected in parallel to create multiphase converters. These operate with the same switching frequency, but with a phase shift. This on the one hand splits the power and on the other hand delivers benefits through the superimposition of the voltage ripples of the phases with the result that the converter switching frequency virtually increases. Smaller voltage ripples and benefits in filtering are thereby obtained.

Figure 3 shows a possible topology. One phase consists of two MOSFETs and one inductor. The “filter” functions are jointly used by all the phases. Even the safety switches which isolate the converter from the vehicle electrical system in the event of a fault are jointly used and therefore feature only once per side. There is if nec-

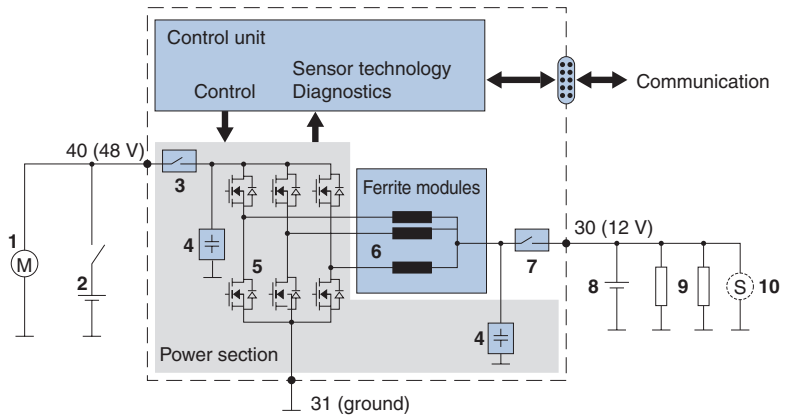
essary also polarity reversal protection on 12 V side of the converter. The control (or closed-loop control to be exact) ensures that the setpoint values for the respective output voltage are constantly set even under varying load conditions and fluctuating input voltage. The duty cycle of the half-bridges is set accordingly for this purpose.



Traction-electrical-system DC-DC converters

Traction-electrical-system DC-DC converters are likewise non-isolating converters and usually operate with the same topology as 48 V-12 V voltage transformers. They are used to adapt the voltage in the traction electrical system of a vehicle; this is the HV vehicle electrical system (high voltage) between the traction battery and the inverter. The traction battery has a voltage that is dependent on the state of charge; this has a noticeable impact on the maximum available drive power. To prevent this, the traction-electrical-system DC-DC converter regulates the inverter input voltage to a stable voltage, regardless of the changing battery voltage.

Because traction-electrical-system DC-DC converters are designed for a much higher power range than 48 V-12 V voltage transformers (> 50 kW), these are set up with IGBTs (with parallel-connected freewheeling diodes) and operated with lower switching frequencies than 48 V-12 V converters.

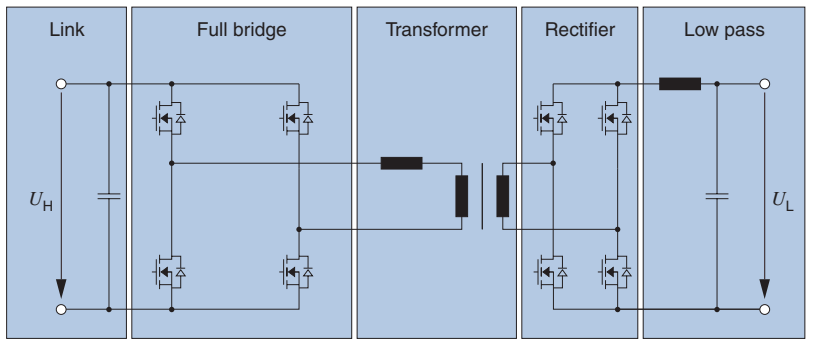
Isolating DC-DC converters

DC-DC converters of high voltages to 12 V

Design

For safety reasons the traction electrical system in the vehicle is designed as an electrically isolated network (floating network) with no connection to vehicle ground. Energy transfer from the traction electrical system to the 12 V vehicle electrical system is therefore always performed with electrical isolation. This prevents dangerous situations in the event of single faults in the system. A transformer is used in the voltage transformer for electrical isolation. Full-bridge converters are usually used for this performance class. Figure 4 shows the basic design of an electrically isolated DC-DC converter.

Operating principle



First the input direct voltage (high voltage) is “chopped”, i.e., converted into an alternating voltage, by the full bridge. The transformer transmits the alternating voltage from the primary side to the secondary side, in the course of which the voltage can be adapted via the turns ratio between the primary and secondary coils. A step-down ratio of 1:10 to 1:13 is customary here. Now the adapted, electrically isolated output voltage is applied as alternating voltage at the transformer's secondary coil. This alternating voltage is converted by the rectifier into a pulsating direct voltage and smoothed by the output filter (LC filter) to become the output direct voltage.

The output voltage is set to the desired value by a modulation of the full bridge. There are two modes to choose from for the modulation:

– PWM activation, whereby the output voltage is adjusted via the duty cycle and
– phase shifting, whereby each half-bridge is activated with a duty cycle of 50 % and the output voltage is adjusted via the phase relation of the two half-bridges.

Both methods have benefits and drawbacks; phase shifting has gained acceptance for isolating DC-DC converters in vehicles. Accordingly, this method is referred to as the phase-shifted full-bridge (PSFB). A key advantage of the PSFB is that the leakage inductance of the transformer (shown in Figure 3 in series with the transformer's primary coil) can be used together with the 50 % operation of the half-bridges for a soft-switching operation of the DC-DC converter. This lowers the switching losses of the semiconductors so that efficiency and switching frequency can be increased. A higher switching frequency has a favorable impact on the installation space and the costs of the passive components.

Figure 4: Design of an electrically isolated DC-DC converter
U_H High voltage,
U_L Low voltage.

Typical switching frequencies range between 70 and 100 kHz and sometimes also around 140 to 145 kHz. The choice of these frequencies avoids the range around 125 kHz in which radio systems for vehicle access or tire-pressure monitoring frequently operate. From 150 kHz upwards the restrictions imposed by EMC regulations governing emitted interference (electromagnetic compatibility) take effect such that the switching frequency should be much lower.

Further functions of the DC-DC converter in the vehicle

Most of the methods used are also capable of reverse operation and consequently can supply energy from the 12 V vehicle electrical system to the traction electrical system. This is used for two functions. The first function is for precharging the capacitors in the traction electrical system; this saves on costs and installation space for the charging contactors in the traction battery. The second function of reverse operation is the test pulse for the 12 V battery. Here the 12 V battery is briefly subjected to a discharge current; the HV battery absorbs the energy as charging current. From this the battery sensor determines the current performance of the battery.

Future functions will promote the redundancy of the energy supply to the 12 V vehicle electrical system so that safety-relevant consumers and their function – in spite of a single fault in the DC-DC converter – can continue to be supplied with energy at least for a certain amount of time.

DC-DC converters of high voltages to 48 V

DC-DC converters with input voltages of several hundred volts and an output voltage of 48 V are very similar in their design to DC-DC converters with a 12 V output. Essentially the transformation ratio of the transformer is changed. Furthermore, the secondary-side circuits must be adapted to the higher output voltage. The rectifiers need a higher reverse voltage, the filter capacitors need higher dielectric strength, and the sensors for current and voltage must be adapted to the other current and voltage.

Because primarily current is a crucial design parameter for DC-DC converters, higher output power can be achieved with little additional outlay thanks to the higher voltage compared with the 12 V DC-DC converter.

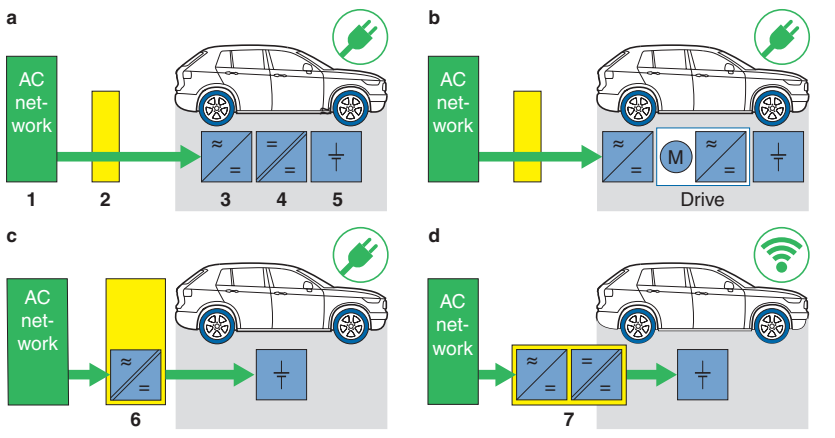
On-board charger

Application



The component in externally rechargeable hybrid, fuel-cell and electric vehicles which is responsible for charging the traction battery is called the charger. All externally rechargeable vehicles are typically equipped with an on-board charger which is carried – permanently installed – in the vehicle. The connection to the power-supply network (infrastructure) is established via a charging station with the aid of a charging cable, which is why such charging concepts are also called conductive chargers (Figure 1).

Alternating-current charging

The public low-voltage network serves as the infrastructure for today's conductive charging concepts because it is comprehensively available and thus can be used directly. The basic design of an on-board charger with AC interface (alternating current) between the vehicle and the power-supply network is illustrated in Figure 1a. Alternating current is supplied to the vehicle (hence also the term AC charging); the voltage is transformed from alternating current to direct current in the on-board charger inside the vehicle. The traction battery can be charged with this direct current.

Figure 1: Basic design of on-board chargers

5 Traction battery, 6 Charging post for DC charging with integrated charging electronics,
7 Inductive charger (transformer primary coil of the DC-DC converter in the charger, secondary coil in the vehicle).
M Electrical machine, DC Direct current, AC Alternating current.

Integrated charging concept
Aside from standalone chargers there are also charging concepts in which components already installed in the vehicle (e.g., inverter or electrical machine) are used for the charging process (Figure 1b). Because for the most part the inverter is the integral component of such concepts, the term inverter charging is also used in this context. Such chargers are however generally not electrically isolated and for that reason they will not be discussed further here.

Direct-current charging
Direct-current (DC) charging plays a central role in the area of fast charging. Here the actual charging electronics is installed in the charging station (Figure 1c), and for that reason weight and vibration-strength requirements are less relevant. The charging station ascertains the desired charging current by communicating with the vehicle. Wires carried in the charging cable are used for communication.

In future DC networks (micro-networks), such as those featured for example in companies, could be used for charging. This could dispense with rectification inside the charger. The charging stations contain a DC-DC converter which adapts the charging voltage to the vehicle demand.

Inductive charging
For the sake of completeness it should be pointed out that engineers are already working on inductive chargers for electrified vehicles in which the energy transfer to the vehicle takes place via a split transformer between infrastructure and vehicle (Figure 1d) and the charging process can start automatically with the vehicle appropriately positioned on the charger. This transformer assumes the function of the transformer in the DC-DC converter (see DC-DC converters). The primary coil is located in the charger, the secondary coil is situated with the rectifier in the vehicle.

Requirements

The fundamental requirements imposed on an on-board charger are laid down by the standards to be observed on the network side and by the vehicle-side battery and safety-concept requirements.

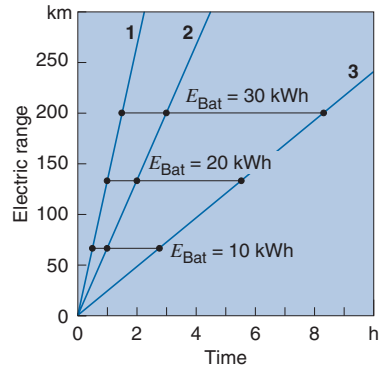
Network-side requirements
To ensure that a charger can be used on a worldwide scale, a voltage range of 85 to 265 V (with 50 or 60 Hz) is typically provided for. It is important to take into account that typically a power adjustment is made under the nominal voltage of 230 V.

The current harmonics to be maintained in the public network (IEC 61000-3-2 [1]) constitute a further network-side requirement which has a direct influence on the charger topology. These necessitate the use of an active power-factor correction (PFC, see Power-factor correction).

Vehicle-side requirements
On the vehicle side above all the traction-battery requirements must be taken into consideration. Aside from the voltage range to be covered, stretching in current electric vehicles from 240 V to 450 V (for passenger cars), the charger should provide as smooth a charging current as possible, i.e., with low ripple. This requirement plays a central role in single-phase chargers because the charging current exhibits a strong ripple if the pulsating power consumption from the AC network is not smoothed.

Aside from the battery requirements, the safety concept of a charger plays a central role in its integration in the vehicle. Electrically isolated on-board chargers are state of the art. The power-supply network and the vehicle can be decoupled by means of electrical isolation, which makes it easier to bring potentially occurring insulation faults under control. This is because the vehicle body is connected to the ground conductor of the power-supply network during the charging process. It should basically be pointed out that electrical isolation proves to be disadvantageous with regard to achievable efficiency.

Future requirements
Aside from the classic traction-battery charging function or providing electrical energy for example for vehicle climate control prior to starting a trip, further functions will gain in importance in future:
– V2L (Vehicle to Load),
– V2H (Vehicle to Home),
– V2G (Vehicle to Grid).



What these new functions have in common is the required bidirectional energy transfer of the charger. This means that future chargers must be able to transfer energy not only from the supply network to the traction battery but also from the traction battery back to the network. While V2L merely permits the operation of a simple consumer (e.g., electric grill) from the vehicle, V2H is concerned with the intelligent integration of the vehicle storage device in the existing domestic electrical installation in order to be able, by including the vehicle battery, to better utilize for example the electrical energy self-generated by a photovoltaic system.

The concept with the greatest complexity is V2G, with which parked vehicles make available some of their battery capacity for appropriate payment in order to participate in the energy control market so as ultimately to get rid of the expensive peak-load power stations and at the same improve the stability of the power-supply system through a better balance between generation and consumption. For the V2G approach to work, sufficient numbers of vehicles must always be connected to the network, which presupposes an appropriate degree of market penetration by electromobility.

Charging power

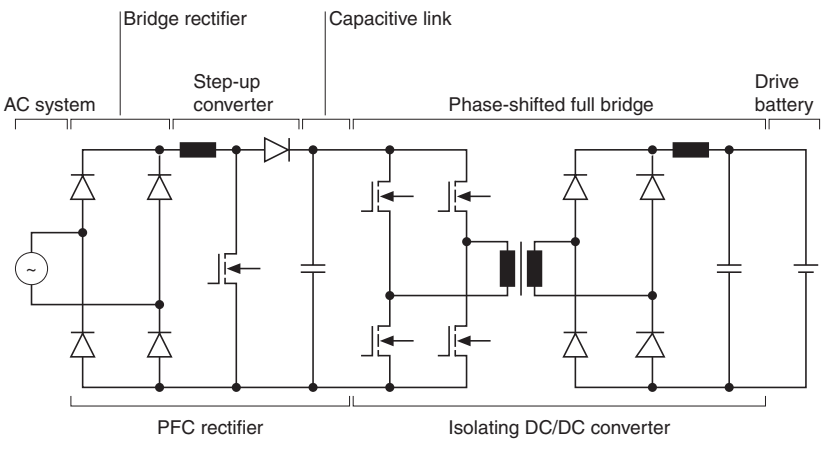
The available charging power is very important since its has a direct bearing on the rechargeable energy in a specified time. The higher the charging power, the greater the recharged energy to the traction battery during the charging time and hence the possible range with the electric drive. While it takes just a few minutes to refuel a conventional vehicle with an internal-combustion engine, it can take several hours to charge electrified vehicles, depending on the available charging power and the battery capacity. To illustrate this, the electric range that can be achieved with the recharged energy (i.e., the range under electric-only driving conditions) is plotted against the charging time for different charging-power figures in Figure 2. Around 1.5 hours are needed even with a charging power of 10 kW in order to be able to recharge for example the energy for a range of 100 km. The battery and charger losses are disregarded in the idealized treatment given here. It

Figure 2: Electric range as a function of charging time and charging power
Graph applies to a vehicle with 1 t weight and a specific energy demand of 150 Wh/km.
1 P_B = 20 kW,
2 P_B = 10 kW,
3 P_B = 3.6 kW.
P_B Charging power,
E_B Energy content of battery.

is furthermore assumed that the vehicle can be continuously charged with the full charging power.

The charging-power figures of today's on-board chargers are based on the country-specific conditions of connection to the public low-voltage network. They utilize from one up to all three network phases of the existing three-phase AC networks in the power-supply network. The charge power here ranges from 3.6 kW (single-phase, 230 V, 16 A) through 7.2 kW (single- or two-phase) up to 10 kW (single- or three-phase, 400 V, 16 A) or 20 kW (three-phase, 400 V, 32 A).

Basic design and operating principle



The basic design of a charger is explained in the following with reference to a single-phase charger. Figure 3 shows a state-of-the-art two-stage charger consisting of a step-up-converter-based PFC rectifier (see Power-factor correction) with a downstream isolating DC-DC converter.

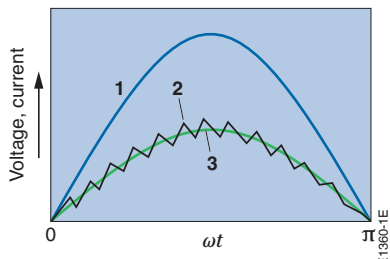
The fundamental operating principles of a step-up converter and of an isolating DC-DC converter are not described here (see DC-DC converters). Rather, the specifics of the established circuit topologies when used in a charger are elaborated here.

Power-factor correction

Conventional rectifiers with a downstream smoothing capacitor are, in view of their non-sinusoidal current consumption, referred to as nonlinear consumers. The line currents of such rectifiers are composed of the superposition of higher-frequency current harmonics, which results for example in higher losses in the line transformers, but also negatively influences the compensation of the circulating currents in the neutral conductor of three-phase AC networks. To avoid these problems, it is necessary to utilize an active pow-

Figure 3: Charger in the vehicle
PFC Power-factor correction.

er-factor correction which adheres to the legally stipulated limit values for current harmonics in the range of 100 Hz to 2 kHz and makes possible a power factor (ratio of effective to apparent power) close to the value 1.



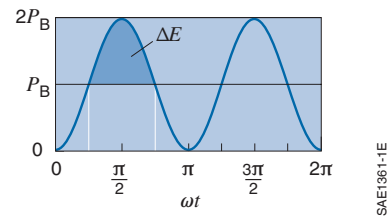
The PFC rectifier presented here consists of a conventional step-up converter with an upstream bridge rectifier which rectifies the network-side alternating voltage. For the most part step-up-based circuit concepts are used as power-factor-correction filters since these exhibit advantages over step-down systems due to their continuous input current (low filter outlay). Because of the step-up-converter approach, the DC link voltage must always be greater than the rectified line voltage. In conjunction with the 230 V AC network a DC link voltage of around 400 V is obtained which is referred to in the following as the input voltage for the subsequent DC-DC converter stage.

Because of the constantly changing input voltage the duty cycle D of the step-up converter must be continuously tracked:

$$D = 1 - \frac{\hat{U}_{pk}}{U_{ZK}} \; |\sin(\omega t)|,$$

$\hat{U}_{pk}$ = line-voltage amplitude,
U_{ZK} = DC link voltage,
ω = angular frequency of line frequency
= 2π · line frequency.

Figure 4: Network-side current and voltage characteristics of the PFC rectifier
1 Rectified line voltage,
2 Please current through step-up choke,
3 Current from the network, equal to the mean current through the step-up choke.



The network-side current characteristic of the PFC rectifier is illustrated for a continuous choke current (CCM, continuous conduction mode) in Figure 4. The triangular shape of the switched choke current is also shown in addition to the direct proportionality between the rectified line voltage and the mean current through the step-up choke. Typical switching frequencies for a PFC rectifier are in the range of 100 kHz in order on the one hand to be able to have compact passive components and on the other hand to achieve good efficiency in conjunction with hard-switching operation (switching losses).

The interference generated by the high-frequency switching of the PFC rectifier is suppressed with the aid of a passive network filter, which for reasons of clarity is not shown in Figure 3 [2].

Power smoothing

Located at the output of the step-up converter is the DC link, which is designed as a capacitive energy storage device with the aid of electrolytic capacitors. The need for power smoothing in single-phase chargers can be derived directly from the requirements of a line-frequency-free charging current. Because constant power cannot be drawn from the AC network, without power smoothing the pulsating power would be transferred to the output. Generally, it must be borne in mind that a constant power consumption is first possible in conjunction with a three-phase AC system.

Figure 5: Idealized time characteristic of the pulsating power consumption from the AC network
P_B Charging power,
ΔE Energy when charging and discharging the DC link.

The characteristic of the pulsating system power at the AC network is shown by way of example of a sinusoidal line current in phase with the line voltage in Figure 5. It must be recognized that the power input pulsates between zero and twice the mean charging power P_B with double the line frequency.

The pulsating system power is smoothed in the DC link by the input and output of the excessively or insufficiently delivered power, whereby the link capacitor is continuously charged and discharged. The storage and discharge of the energy ΔE in the link capacitor leads to a voltage ripple in the DC link which must be taken into account in the design of the subsequent DC-DC converter.

Electrical isolation

An overview of isolating DC-DC converters and their operating principles is provided elsewhere (see DC-DC converters). Reference is made at this point, as shown in Figure 3, to the familiar topology of the phase-shifted full-bridge (see Phase-shifted full-bridge). But also other soft-switching switching topologies, such as for example the LLC resonant converter [2], are suitable for use as isolating converters in a charger.

The function of the isolating DC-DC converter at the charger output is, aside from decoupling the vehicle from the supply network, to provide as smooth a charging current as possible to the traction battery. To this end the converter sets the requested charging current from the DC link voltage stipulated by the PFC rectifier.

Three-phase chargers

On advantage of the analyzed single-phase charger is the possibility of three-phase enhancement. Owing to the electrical isolation utilized a number of such designed chargers can be connected in parallel at the output and operated from different network phases so that a three-phase system is obtained by wiring up a single-phase system accordingly.

But, essentially, pure three-phase circuit systems also exist. In the case of such systems it must be noted that the circuit topology, aside from providing three-phase operation, must typically also be able to charge from the single-phase AC network because currently access to the three-phase AC network across the board cannot be assumed.

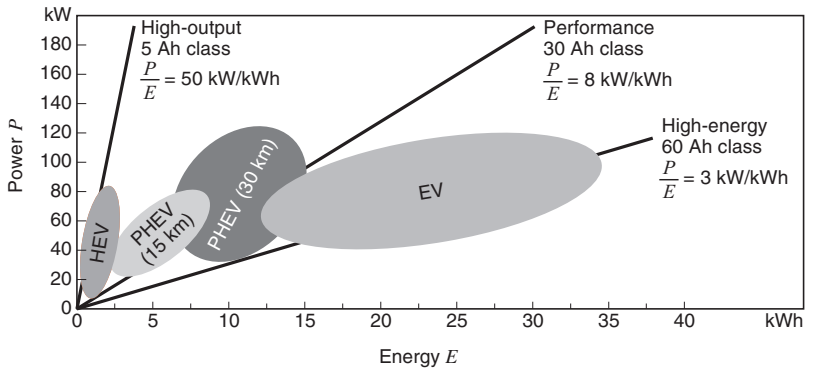
Batteries for electric and hybrid drives

Requirements

Hybrid and electric vehicles require a battery as an energy accumulator or storage device to operate the electrical machine. The traction battery in modern electric vehicles often accounts for more than two-thirds of the weight, size and cost of all components in the electric drivetrain. Therefore, the main challenge for the future is to improve and optimize the battery in terms of these three criteria.

There are essentially three different voltage ranges. In the LEV segment (Light Electric Vehicle) the nominal battery voltage is up to 48 V, providing an achievable power output of around 30 kW. 48 V batteries are also used for mild-hybrid systems in passenger cars. Batteries for hybrid and electric vehicles in the passenger-car sector are designed for voltages up to 400 V and can provide a power output of up to 450 kW. In the commercial-vehicle sector heavy vehicles require even higher power outputs. The DC link voltage is therefore increased to 800 V, making possible a power output of around 800 kW. Because increasing the battery voltage makes reduced charging times possible, some passenger-car manufacturers also opt for 800 V technology.

A traction battery is built from different components, not all of which need to be located in the same housing. The so-called battery pack consists of many cells, a sensor system, and a monitoring unit (BCU, battery control unit). Together with a battery management system (BMS) and safety switches, it makes up a usable battery system.



The (sometimes conflicting) requirements described below must be taken into account when developing and designing the cells and other components in the battery system.

Safety

The safety of vehicle occupants and the environment must be guaranteed in all situations. This applies to hazards that result from the electrochemical properties of the battery, for example, preventing fire. It must also take electrical safety into account, particularly in batteries with voltages larger than 60 V.

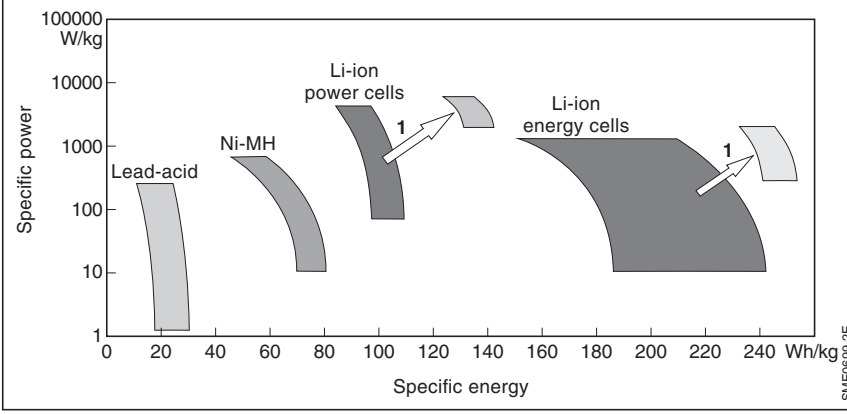
EV Electric vehicle.

Performance
For use in vehicles, batteries are required to be low in weight while simultaneously having high performance. Achieving this requires batteries with high energy and power density. There are different requirements for this depending on the vehicle. Figure 1 shows the typical values for the respective characteristics and the ratio of performance P to energy E. This results in various requirements for the cells used. Various cell sizes and designs are required to be able to cover all vehicle segments.

Operation in the automotive sector requires a service life usually lasting more than ten years or a running performance of typically 250,000 km. In purely electric vehicles, approximately 3,000 complete charging cycles occur throughout the life of the vehicle, while applications in hybrid vehicles often have over a million partial charging cycles. The largest challenge by far is to reduce the costs with the goal of reaching total costs comparable to those in systems with internal-combustion engines.

Storage technologies



Today, lithium-ion (Li-Ion) batteries are usually used as electrical energy accumulators in electric vehicles, hybrid vehicles and plug-in hybrid vehicles. Nickel-metal hydride batteries (NiMH) are still used in isolated cases. However, it is to be expected that these will be gradually replaced by lithium-based battery systems.

Figure 2 shows a comparison of specific output and specific energy of various technologies.

Nickel-metal hydride technology
Electrochemical principle
In an NiMH cell (nickel-metal hydride), a metal alloy which can accumulate hydrogen is used as the anode [1, 2]. The active material of the cathode is nickel(II) hydroxide. During the battery-charging process active hydrogen is created from H_2O at the anode (Figure 3b). This hydrogen is absorbed by the metal alloy (M) of the anode and a metal hydride (MH) is created. The remaining OH^- ion migrates through the electrolyte and the ion-permeable separator to the cathode, where it reacts with the nickel(II) hydroxide to form NiO(OH).

During discharging the accumulated hydrogen at the anode oxidizes with the OH^- ions created at the cathode to pro-

Figure 2: Typical specific energies and capacities for various storage technologies (Ragone plot)

duce water (Figure 3a). The following reactions take place during the discharging process; these are reversed during the charging process.

Anode: $MH + OH^- \rightarrow M + H_2O + e^-$ (0.828 V)

Cathode: $NiO(OH) + H_2O + e^- \rightarrow Ni(OH)_2 + OH^-$ (0.450 V)

Redox equation: $MH + NiO(OH) \rightarrow Ni(OH)_2 + M$ (1.278 V)

Application

Nickel-metal hydride batteries have already been in use as traction batteries for a few years, in particular for hybrid vehicles. They deliver high currents and have a high charging capacity while simultaneously being low in weight. The primary disadvantage of cells in nickel-metal hydride technology, however, is the lower energy density at a specific power that is also usually lower compared to lithium-ion batteries. Nickel-metal hydride cells achieve a specific energy of up to 80 Wh/kg at a voltage of typically 1.25 V per cell. Nickel-metal hydride cells also have higher self-discharge than lithium-ion cells (approximately 1 % per day at room temperature), limiting their use to devices with short downtimes.

Lithium-ion technology

Electrochemical principle

The lithium-ion battery utilizes the reversible inclusion and withdrawal of lithium ions (Li^+) in a lattice (intercalation electrode, [1, 2]). Graphite (C) in various modifications, for example, is used as the anode material. The cathode is based on a structure of lithium transition metal oxides. The active material today consists for the most part of a combination of nickel, cobalt and manganese (Ni Co Mn), each constituent making up around a third of the overall compound. Lithium ions are exchanged during the charging and discharging process via the electrolyte between the anode and the cathode. The cathode and the anode are insulated against each other by the ion-permeable separator.

Figure 3: Electrochemical processes in a nickel-metal hydride battery

R Resistance, *I* Charging current.

The following reactions occur (Figure 4):

Anode: $Li_xC_n \rightarrow n\,C + x\,Li^+ + x\,e^-$.

Cathode: $Li_{(1-x)}(NiCoMn)O_2 + x\,Li^+ + x\,e^- \rightarrow Li(NiCoMn)O_2$.

Balance equation: $Li_{1-x}(NiCoMn)O_2 + Li_xC_n \rightarrow Li(NiCoMn)O_2 + n\,C$.

Another established cathode material is lithium iron phosphate ($LiFePO_4$).

Depending on the anode used (graphite, soot, "coke carbons"), which is expressed by the index n, the proportion x of the lithium ions that can be intercalated changes. The electrolyte consists of anhydrous organic solvent mixtures (e.g., organic carbonates such as ethylene carbonate, dimethyl carbonate, diethyl carbonate, and ethyl methyl carbonate), various additives, and conducting salts (e.g., $LiPF_6$).

Application

The lithium-ion battery is characterized by a high energy density and thermal stability. The nominal voltage is around 3.7 V per cell, where the voltage limits during use are between around 2.8 V and 4.2 V.

The simultaneous optimization to a high output and energy density is a technical challenge. A high power density requires large electrode surfaces with low-resistance conductors, while a high energy density requires the opposite: compact electrodes with a large amount of active material. Typical characteristic values of today's automotive cells include 5,000 W/kg for the specific performance of power cells and 180 Wh/kg for the specific energy of energy cells. Lithium-ion systems with a higher specific energy are in development (see Figure 2).

System monitoring

Lithium-ion systems – compared to other technologies – require more elaborate system monitoring and control systems using a battery management system. A lithium-ion battery must be kept within strictly defined charge, current and temperature limits for service life and safety reasons. In particular, lithium-ion cells do not tolerate overcharging. A battery management system (BMS) is used to prevent this.

Service life

The service life of electrochemical cells depend in an existing chemical system on the following parameters: number of cycles, depth of discharge, temperature, and mechanical load. Above all processes such as the formation of coatings, irreversible compounds, cracking, and loosening of the active material due to changes in volume take place at the electrodes. These processes manifest themselves electrically in an increase in the internal resistance, which results in reduced power and a reduction of the energy content that can be drawn. The definition of end of life (EOL) in a specific application depends on the boundary conditions of that applications; these are primarily the demands imposed on the operation of vehicles.

Further developments

It is to be expected that cells with innovative separator systems or based on electrochemical approaches, such as lithium-sulfur or lithium-air, are able to provide significantly higher energy and power densities at equal or even lower costs. However, systems based on this are still being researched. The capability for mass production for use in the automotive industry has yet to be proven.

Basic structure of a battery system

Traction batteries also differ in their internal structure due to each of the different technical requirements and individual installation situations in the vehicle. However, most follow a similar basic concept, which is depicted below.

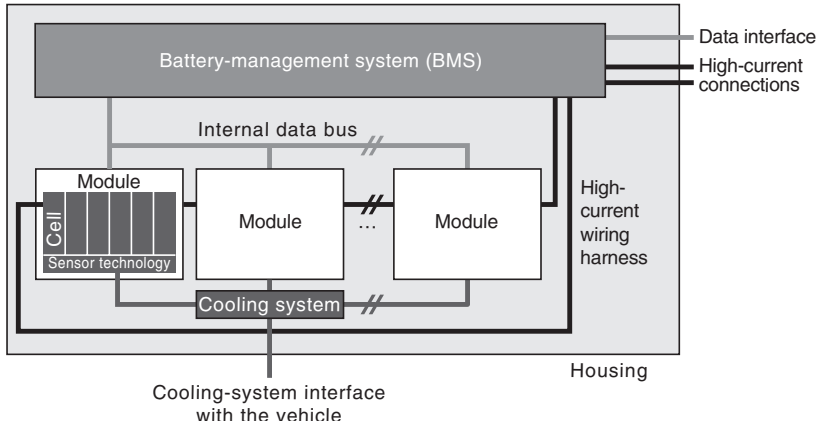
A battery system usually consists of multiple modules, each of which, in turn, contains multiple cells. The modules are connected to each other via a high-voltage wiring harness and are integrated together with the battery management system and the (air or liquid) cooling system in a battery housing. Interfaces for the vehicle include the high-voltage terminals of the battery, a data interface and usually an additional connection for the cooling system (Figure 5). The battery management system can be situated outside the battery housing.

Components of a lithium-ion battery system

Lithium-ion cells

Depending on the application, a drive battery consists of battery cells, ranging from ten to one hundred and, in individual cases, even thousands, which are connected in series or in parallel. Here, cells are used in three different designs (shown in Figure 6) for use in automotive industry.

Designs



Cells with cylindrical metal housing have major cost advantages in manufacturing when compared to the other designs.

Prismatic cells with a housing made of laminated metal foil (pouch cells) have a particularly homogeneous temperature distribution and permit highly compact battery systems of flexible sizes.

Prismatic hardcase cells also permit a very compact construction and are also stable in comparison.

It is still uncertain whether one of the three cell types will prevail for automotive applications. Currently, there are examples of all three designs. There are global efforts to standardize the types of cell housing for automotive applications as well.

Figure 5: Schematic representation of the architecture of a battery system

Design of a lithium cell

Figure 7 shows the cross-section of a prismatic hardcase cell. The active materials required for the chemical process in the anode (e.g., graphite) and the cathode (lithiated metal oxide such as Li (Ni Co Mn) O_2 or lithiated metal phosphate such as Li Fe PO_4) are present as coating on a copper film (anode) and an aluminum film (cathode). The metal films are each used here as shunts. The films, coated on both sides, are separated by a separator film that prevents a direct electrical connection between the anode and cathode, but is permeable to ions. The ion-conductive electrolyte (organic liquids with fluoric conducting salts) is also located between the anode and cathode. This sequence of anode, separator and cathode is wound into a flat coil of cells, the electric shunts at the anode and cathode lead to the negative/positive electric terminal of the cell.

An additional safety valve is also located on the cell. If the pressure in the cell rises in the case of a malfunction, it opens to prevent the cell from bursting.

Safety requirements

When a technology-dependent temperature threshold in the cell (typically around 100 °C) is exceeded, a self-reinforcing, irreversible exothermic process called "Thermal Runaway" starts and can no longer be stopped by external influences. This can cause the cell to catch fire or burst and spread to other cells. Therefore, corresponding measures (voltage and current monitoring, cooling) must be taken to ensure that this process is not triggered by improper operation. This is the function of battery management.

Mechanical and electric components

Cells have to be interconnected in a suitable form and mechanically integrated for use in vehicles. This accounts for the mechanical and electrical safety requirements that are particularly applicable for batteries with high voltage. Typical automotive industry requirements also apply here, both in use (e.g., protection against vibration protection or splash water) and in potential cases of malfunction (e.g., protecting occupants and the environment in case of an accident).

Module
The module (Figure 5) is usually the first integration level of cells for a battery pack. Here, a different number of cells is connected in series depending on the cell type. A parallel connection of cells makes it possible to deliver greater energy contents without increasing the system voltage. Usually, care has to be taken to ensure that a module voltage of 60 V is not exceeded in order to prevent high-voltage requirements at the module level.

The cells are mechanically integrated into a network and their terminals are connected by a high-voltage cable harness. Additionally, sensors for temperature, voltage and current measurement and evaluation electronics are frequently integrated into the module (control unit on the module level). The focus here is to ensure the most compact design engineering possible that allows flexible, cost-effective and high-quality battery production.

While small battery systems can only consist of one module, battery packs for electric vehicles often use over ten modules. The modules are connected to each other electrically via a high-voltage cable harness.

Housing
The battery housing, along with holding together the cells and protecting them from mechanical loads, is also used for contact protection against high voltages. On the outside of the battery housing, there are high-voltage connections for connecting to the electric drivetrain, which can be disconnected from the supply by a safety switch when the battery is removed, a communication interface for data exchange with the higher-level vehicle control unit for the electric drive (e.g., engine management system) and, in many places, interfaces for the cooling system.

Battery management system
Determining characteristics of the battery system, complying with the permissible operating limits and regulating the cooling system are necessary for safe and reliable battery operation. The battery management system (BMS) assumes these tasks. It is usually implemented in a control unit located inside the battery. However, individual functions can also be assumed by external control units.

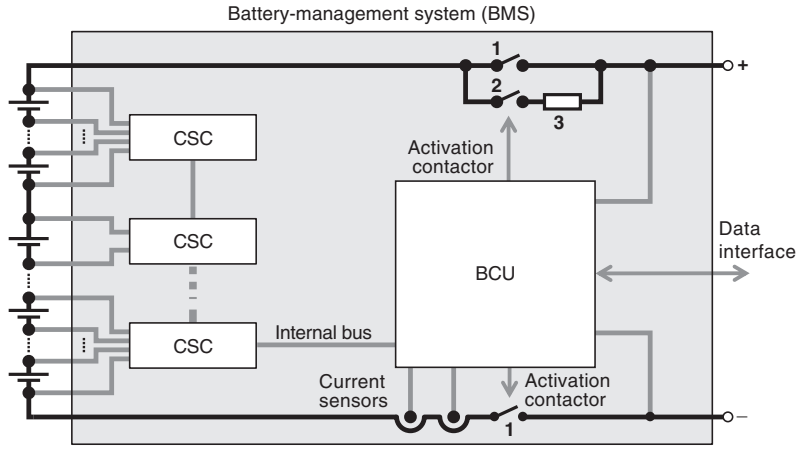
Operation
The battery management system determines the instantaneous battery parameters and stores these if necessary to be able to run fault analysis or else for decision guidance for later applications outside the vehicle (e.g. “second-life applications” as stationary a storage device in solar installations). It uses the measured values to determine the state of charge of the cells (SOC) and their state of health (SOH). The currently available battery rating and maximum permissible battery current can be determined based on this. The battery management system can also carry out “balancing” to match the cells’ state of charge. This information is transmitted to the central vehicle control unit (VCU) in the vehicle's electric drivetrain. The vehicle control unit controls the power electronics in the electric drivetrain or the charging device based on the information sent by the battery management system to configure a corresponding charging process.

The battery management system protects the cells by preventing or reducing the current flow in cases when the battery is overcharged, the safe operating window is exited due to overvoltage or undervoltage, or in the event of excess or insufficient temperature. This occurs by instructing consumers to switch off the vehicle control unit in case of emergency by shutting down the battery on its own.

Even if the battery itself has to be assigned to the electrochemical domain, the functional safety standard (ISO 26262 [3]) for electrical and electronic components must be taken into account when developing the battery’s safety concept for the battery management system. Safety-related components of the battery management system, particularly the sensor technology, are, therefore, redundant.

Architecture
The architecture of a battery management system is illustrated by way of example in Figure 8. Other architecture variants are also used, particularly for hybrid electric vehicles (HEV).

The battery management system consists of a central battery control unit (BCU), cell supervisory circuits (CSCs), current, voltage and temperature sensors, and a contactor circuit. The cell supervisory circuits monitor the battery cells in terms of their voltage and temperature.



Conducting of current
The contactor current allows the vehicle electrical system battery of the electric drivetrain to be electrically isolated. If an accident is detected or another potential hazardous state is identified, a control logic opens the contactor that is located at each positive or negative battery terminal. To prevent a safety-critical condition, this logic can open the contactor even if the battery system is overloaded. The terminals of the battery system are thus de-energized.

The battery is connected to the vehicle electrical system of the electric drivetrain with its buffer capacitor via a charging contactor and a pre-charging resistor. This prevents an excessively large initial charge current when the buffer capacitor is discharged. During normal operation, the battery is connected to the vehicle electrical system with low impedance via the main contactor.

Balancing
Due to manufacturing tolerances and side reactions that depend on cell parameters and the cell temperature, the individual cells eventually have a different state of charge. This is problematic insofar as the cell with the lowest state of charge sets the discharge limit, and the cell with the highest state of charge sets the charge limit. For this reason, the state of charge of a battery's cells has to be balanced from time to time. This is done by a balancing circuit, which is usually integrated in the cell supervisory circuits. In automotive applications, balancing is typically a passive process; that is, it occurs by discharging individual cells via a resistor connected in parallel.

Thermal management
To ensure safe and reliable operation of the battery even when the load is fluctuating and to maximize the service life of the cells, the temperature of the cells should be kept in a range typically from 20 °C to 40 °C. The service life of the cells is largely

Figure 8: Overview of the battery system
1 Main contactor, 2 Charging contactor, 3 Pre-charging resistor.
CSC Cell Supervisory Circuits,
BCU Battery Control Unit.

reduced as the temperature increases, because many aging processes are temperature-dependent. This is particularly relevant for use in hot climate zones. At low temperatures, the capacity of the cells noticeably decreases.

In vehicles, there are various systems used to control the temperature of cells.

Liquid cooling
Liquid-cooling systems are usually used in systems with high requirements for regulating temperature. The battery is equipped with a separate cooling circuit, in which circulates a special coolant, such as a water-glycol mixture. The coolant temperature is controlled by a heat exchanger, which is connected to the vehicle's air-conditioning system. Frequently a heater element is also integrated, so that the battery can be heated at low temperatures.

It is connected to the cells via cooling plates. Temperature sensors monitor the temperature of the cells. The central thermal management system, often integrated in the battery management system, controls the flow rate and coolant temperature depending on the situation and temperature.

Batteries with a liquid-cooling system can be built very compactly, but require additional effort due to the cooling plates, the piping and the connection to the vehicle's air-conditioning system.

Refrigerant cooling
An alternative to a liquid-cooling system is the refrigerant cooling system, in which the cooling components of the battery are designed as evaporators and directly integrated into the refrigerant circuit of the vehicle's air-conditioning system. Systems of this kind have been used only rarely to date.

Air cooling
Air-cooled systems are the most cost-effective designs. However, they require more space due to the need for space between the cells. Moreover, the air interfaces mean that hermetically sealed battery cases are not possible, or they can be implemented only with great effort.

Air-cooled systems are often used for batteries with lower cooling requirements, for example, in systems with lower specific power requirements and for use in moderate climate zones.

In air-cooled systems, fans controlled by a thermal management system take in air that is usually precooled. This is blown through the battery system; the fan speed can be controlled depending on the cell temperature determined by the temperature sensors.

Some systems for low power requirements have no fans; in that case, the cells are simply cooled by natural convection.

Charging method for lithium-ion batteries

Lithium-ion batteries are generally charged according to the IU method, i.e., with constant current up to a specified voltage, then further with constant voltage at a specified maximum current. The battery can be charged relatively quickly with very good efficiency up to a state of charge of around 80 %; this is exploited by fast-charging methods. The limit values for current and voltage are specified by the cell manufacturer and vary depending on the electrochemical system used. Adherence to these limit values is monitored by the battery management system (BMS) because exceeding these limit values may give rise to safety-critical states.

Recycling of lithium-ion vehicle batteries

Lithium-ion vehicle batteries consist of a large number of cells and of housing and electrical and electronic components, and have significant economic value. To utilize these batteries to their full potential, scientists and engineers are currently examining the possibilities of their stationary use after automotive use. This is referred to as "second life". Applications may include for example the storage of solar power.

The batteries are subjected to a recycling process when they reach the end of their service life. For this purpose the batteries must be fully discharged for safety reasons and then mechanically disassembled to the cell level. The housing and the electrical and electronic components are processed further in accordance with tried-and-tested methods. The cells are further disassembled mechanically and later the substances of content are recovered by means of hydrometallurgical and pyrometallurgical processes. The aim is recover the substances of content of such quality as to permit their use in electrochemical cells. Processes are currently being tested to assess their economic viability.

Supercapacitors

Application

Supercapacitors are classed among the rechargeable electric storage cells such as, for example, electrolytic capacitors and lithium-ion cells. In capacitors, electrical energy is stored in an electric field; in a battery, energy is stored through the process of an electrochemical reaction. To achieve a voltage that can be utilized for vehicles (e.g., 12 V for vehicle electrical systems or 400 V for electric drives), it is necessary to connect in series both supercapacitors and electrochemical storage cells since the individual cell voltages are restricted by the stability of the electrolytes and electrode materials used. The required energy for the electric storage devices is, taking account of the finally required voltage, then set by the capacitance of the individual cells and the number of cells connected in parallel.

Table 1: Comparison of storage principles

Electric double-layer capacitors

Storage principle

In supercapacitors of this type, energy is stored in the electric field of the electrochemical double layers of the negative and the positive electrodes. This creates opposing charges of different polarities in the area of a solid/liquid interface. There is surface enrichment and enrichment of electrons on the solid side, while positively and negatively charged ions are accumulated on the liquid-electrolyte side. There is no electrochemical reaction involved.

Figure 1: Double-layer capacitor
a) Real geometry,
b) Equivalent circuit diagram,
c) Potential profile.
DSB Double-layer range.

Electrode materials

Large surface-area carbon materials (especially activated carbon) are used as electrode materials [1], which are applied in an open-pored structure together with binders and conductive additives (e.g., soot) to metallic collectors. Different methods (e.g., rolling, pressing, spraying), with or without the use of solvents, may be used to coat the collector film. The positive and negative electrodes can be made of the same materials.

Properties

Different working-voltage ranges may result, depending on which electrode materials are used and whether aqueous or non-aqueous electrolytes are used. Thus, the maximum cell voltage for non-aqueous electrolytes can be up to 3 V (a high voltage is beneficial for a high energy density); for aqueous electrolytes roughly only half of this value is achieved. The significantly better conductivity of aqueous electrolyte is beneficial for the internal resistance and the specific power of the component.

The use of new electrode and electrolyte components as well as additives offers optimization potential for increasing energy densities (unit: Wh/*l*) and power densities (unit: W/*l*). The aim here is in particular to extend the utilizable voltage window and to reduce the internal resistance. However, scientists and engineers are working on increasing effective surface areas, which includes pore geometries adapted to ion radii.

Like lithium-ion cells, large-capacity supercapacitors are also available in the cylindrical, “pouch”, and prismatic formats (see Batteries for hybrid and electric drives and [2]). The inner cell structure can also take the form of a coil or stack here.

Electric double-layer capacitors are characterized by very high specific power which is available in a comparatively large temperature window (roughly –40 °C to 70 °C) depending on the current direction. Furthermore, on account of the absence of electrochemical reactions for the stor-

age principle in question, they have very long cyclical and calendar lifespans and can be exhaustively discharged down to a cell voltage of 0 V. On the flip side, compared with power-optimized electrochemical lithium- or nickel-based storage cells, they have an energy density (unit: Wh/*l*) that is lower by a factor of 10 to 30 (see Table 1).

With regard to their electrical management in the system network, it is often sufficient to monitor only the voltages and temperatures. In addition, passive balancing methods – based on parallel-connected voltage dividers – are often sufficient to achieve equal voltages in a series connection.

Areas of application

In fully and partially electrified drivetrains, supercapacitors can assume the role of a reversible, electric storage device with high power output, for example for efficient energy storage during recuperation and to provide assistance when accelerating. Power, energy content, and voltage must be configured in accordance with the load requirements and the power-electronics peripherals. Double-layer capacitors can also be used in vehicles to power electric actuators and starters. Current applications for road vehicles are centered on the 12 V to 48 V range.

Hybrid supercapacitors

The term hybrid in the context of electric storage devices refers to an electrical linking of different storage technologies. This linking can be achieved by an electrical connection at the cell level or pack level, but also inside a storage cell, whereby storage materials of different technologies (e.g., supercapacitor and lithium-ion battery) are combined.

A significant increase in the specific energies (unit: Wh/kg) and energy densities (unit: Wh/*l*) of supercapacitors is achieved through the application of the principle of hybridization already at the storage-cell level. Here, the purely electric storage principle of double-layer capacitors is complemented by energy storage by means of reversible, electrochemical, Faraday processes. Such processes are characterized by an electron transfer at the boundary layer from solid to liquid. Hybrid supercapacitors currently on the market for the most part use electrodes and electrode materials along similar lines to those used in lithium-ion cells (or nickel cells for aqueous electrolyte concepts). The hybridization of energy storage can be realized in the area of just one or also both storage-cell electrodes. Finally, the capacitances of the storage processes active at the capacitor's respective voltage operating point are added up. An exhaustive discharge down to 0 V is for the most part not possible with this type of supercapacitor.

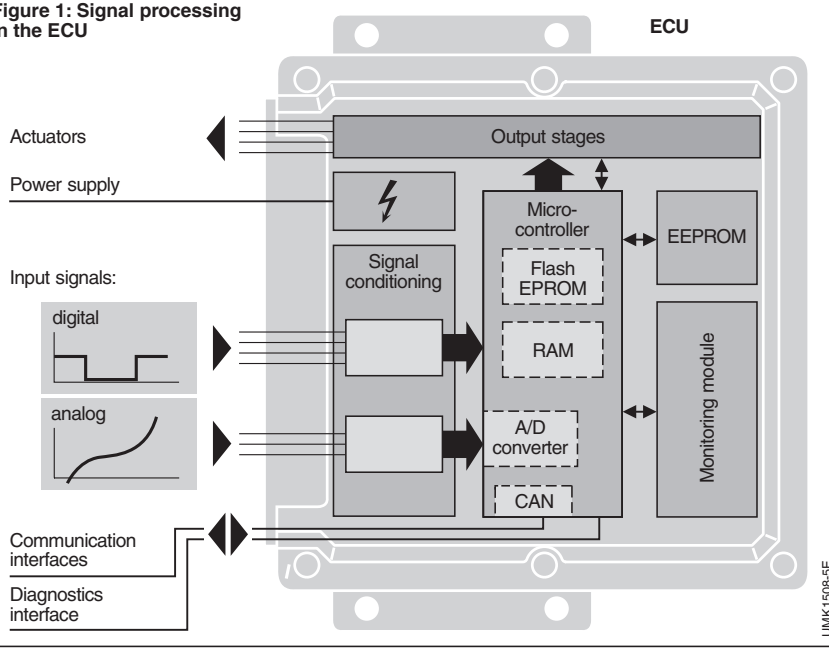
Electronic control unit (ECU)

Functions

Architecture

Digital technology with programmable controllers has revolutionized automotive engineering. A whole range of functions can be realized with this technology. Many influencing factors are taken into account in the control of the systems in the vehicle. The ECU (Figure 1) receives the electrical signals from the sensors, evaluates them, and calculates the triggering signals for the actuators. The control program – the "software" – is stored in a memory (e.g., flash EPROM). A microcontroller runs the program. The ECU components are called "hardware".



Examples of ECUs

Engine management, for example, performs the entire open- and closed-loop control of the engine (e.g., ignition in a gasoline engine and fuel injection) and of many assemblies in its periphery (e.g., for exhaust-gas turbocharging and exhaust-gas recirculation). Without these possibilities it would not be possible to adhere to current emission limits and low consumption figures under high engine-performance conditions.

Microcontrollers with high computing-capacity requirements are required for electronic open-loop control of systems. The electronic components are accommodated in an electronic control unit (ECU). The number of ECUs in a vehicle has increased sharply in the last few years; more and more systems are being electronically controlled. Further examples include:

– ECU for transmission control,
– ECU for driving-dynamics control (electronic stability program with antilock braking system and traction control system),
– vehicle power supply control unit,
– A/C control unit,
– door control unit.

Figure 1: Signal processing in the ECU

Compared with the ECU for driving-dynamics control for example the range of functions and the derived performance e.g. with regard to a door control unit, which controls the power-window drives, are low. Accordingly, less powerful components are used in the ECU for this purpose.

Electric and hybrid drives, which are increasingly penetrating the market, also have a large range of functions and thus impose high demands on the performance capability of open- and closed-loop control.

Operating principle
All ECUs operate according to the same principle. The ECU detects signals from sensors and control elements, evaluates them, and activates actuators (Figure 1). The ECUs are networked with each other via communication interfaces (e.g., CAN bus) so that they can exchange information with each other. An ECU network is thereby established. For example, the driving speed, which is required as the input signal in many ECUs, is only calculated in one ECU from the signals from the wheel-speed sensors and forwarded via the data bus to the other ECUs.

Future
Because of the performance capability of the electronic components in the ECU, systems can be combined in a single ECU. There are thus already systems in which engine-management and transmission control are combined in one ECU. The trend is towards “vehicle computers” (VCs) with high computing capacities and much more storage capacity which supplement the previous microcontroller-based ECUs. As a result, functions from conventional ECUs can be transferred to centralized “vehicle computers”.

Requirements

Operating conditions
High demands are made of ECUs. They are exposed to different and sometimes also extreme loads, depending on their installation location. Thus, for example, an engine ECU installed in the engine compartment or directly on the engine is subject to influences that are quite different from the door control unit installed in the passenger compartment. Irrespective of this, all ECUs must meet high requirements with regard to functionality, quality, and service life.

ECUs may be exposed to the following loads:
– ambient temperatures from –40 °C to +125 °C,
– temperature changes,
– vibration accelerations up to 20 g in a frequency range of 10 to 1000 Hz,
– effects of moisture and humidity, also from salt water,
– operating fluids such as oil, fuel and brake fluid.

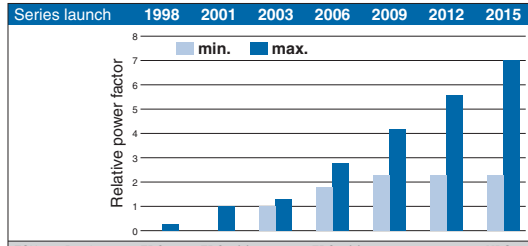
The following additional demands are made of ECUs:
– operational reliability in the event of voltage fluctuations in the vehicle electrical system (e.g., voltage drop when cold starting),
– power dissipation up to 70 W,
– electromagnetic compatibility (resistance to electromagnetic radiation and low radiation of high-frequency interference signals),
– service life of 15 years for passenger cars, 30 years for commercial vehicles,
– active service life of at least 6,000 to 8,000 h for passenger cars, 30,000 to 50,000 h for commercial vehicles,
– kilometrage of 240,000 km (passenger cars) or 1,000,000 to 1,500,000 km (commercial vehicles).

Requirements imposed on ECUs are standardized in ISO 16750 [1]; there are also company standards for all automobile manufacturers.

Range of functions and data-processing speed

The performance of the electronic components used in an ECU is increasing continuously and facilitates ever more complex control algorithms. This applies particularly to the engine-management system, which must take ever more stringent emission limits into consideration. In response to new requirements the range of functions and thus the demand for memory capacity are increasing continuously, while the trend is toward ever-decreasing external device dimensions. Development is therefore heading towards greater functional integration and to miniaturization of both electronic and mechanical components such as plug-in connections.

The increasing range of functions is accompanied by an increase in data-processing speed. Functions must be executed within a specified time frame. Many program sections must be reliably executed with a predefined time period so that the processes in the ECU keep pace with the physical processes (in the sense of real-time capability).



Development of complexity

The last few years have witnessed the use of ever more powerful microcontrollers with increasing computing speed and greater memory resources. At the beginning of the 1990s 32 kByte for the program memory, 8 kByte for the data memory and 12 MHz clock frequency were sufficient for an engine-management system. Microcontrollers currently used have program and data memories several MByte in size and several computer cores with several 100 MHz clock frequency.

The rising requirements imposed on ECUs (e.g., electronic engine management) and the growing number of functions are reflected in the computing capacity and in the memory capacity of the computers used. Conversely, it allows the advances in microelectronics made by information technology (IT) and the "consumer" sector to make this increased computing capacity available at relatively constant costs. Moore's Law [2] up to now also applies to automotive electronics (Figure 2). As a rule of thumb it can be assumed that the structure widths of the microcontrollers used in current engine control units will for around two to four generations (corresponding to around three to six years) will follow those of the current microprocessors. Currently (2021) structure widths of 7 nm are state of the art in the microprocessor field and 28 nm for engine control units in the microcontroller field.

And development continues apace, with microcontrollers with many computer cores being used in ECUs in the future (manycore computers).

Figure 2: Development of complexity of ECUs using the example of engine management for diesel engines [3]

ECU components

The ECU is the control device of an electronic system. It detects the operating conditions via sensors, processes them and activates actuators. Signal processing takes place in the ECU's computer core.

Computer core

Microprocessor

The microprocessor (also MPU or microprocessor unit) represents the integration of a computer's central processing unit on a single chip. Microprocessor design ensures that units can be programmed to meet the varied requirements associated with specific operating conditions. There are two different main groups of processor. Earlier PCs (personal computers) used CISC processors (CISC: Complex Instruction Set Computing). A very large amount of special commands which are executed in a specific number of clock pulses is implemented in these processors.

RISC processors (RISC, Reduced Instruction Set Computing) are usually used in ECUs, i.e., also in vehicle ECUs. The advantage of RISC processors lies in the fact that the commands usually only require one clock pulse and can be implemented by the simpler and faster commands of higher-performance systems.

Today's RISC processors with more than 300 commands have more commands than older CISC processors, therefore the more accurate difference between CISC and RISC is the mean number of clock pulses for a command and no longer – as before – the number of commands.

An important variable for comparing the computing capacity of a computer architecture is the DMIPS specification (Dhrystone Million Instructions Per Second). It must be noted here that the computing capacity that can be achieved in current systems by system properties such as buses, technology and memory fluctuates by more than a factor of 5 (example: a 4 k DMIPS embedded MCU (microcontroller unit) needs 25 k DMIPS on an MPU). DMIPS is a very good specification for applications which require a very high bandwidth (predictable instructions and no interrupts). However, it is not suitable for embedded-control applications like engine-management systems in which the delay of the system in response to events in the time and angle ranges is important (e.g., crankshaft-angle sensing and angle calculation for injection, calculation and output of pulses for injection timing).

A microprocessor cannot usefully operate by itself; it always acts as part of a microcomputer.

Microcomputer

A microcomputer consists of a microprocessor serving as the central processing unit (CPU). The microprocessor contains the controller and the arithmetic-logic unit (Figure 3). The arithmetic-logic unit performs arithmetic and logic operations and operations involving digital signal processing, while the controller retrieves the commands and data from the memory. Pipeline stages, which preprocess the commands (e.g., retrieval of instructions and data, writing of data), are used to achieve higher clock frequencies. The arithmetic-logic unit is integrated in the pipeline.

The program memory (ROM, Read Only Memory; PROM, Programmable Read Only Memory; EPROM, Erasable Programmable Read Only Memory, or Flash EPROM) contains the non-volatile working program (user program) (see Program and data memory). The data are still available after switching on again even when there is no supply voltage. In current applications the program memory is usually a flash EPROM.

The data being run at any given time are stored in the data memory. These data change, and are stored in a RAM (Random Access Memory).

A cache as a high-speed buffer memory for program and data memories (in series production in Bosch engine-management systems since 2006) can be integrated on the microcomputer. If the required commands and data were always sent over buses and there were no cache, the high data rates (which the processor needs for working) and the relatively slow access to the memories would drastically reduce CPU speed and there would be no use in deploying a high-speed processor.

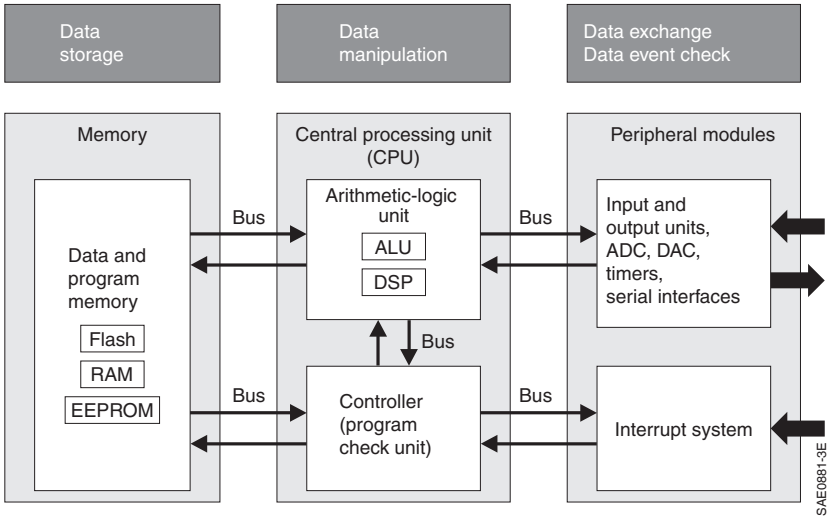
The bus system links the individual elements in a microcomputer. A clock generator makes sure that all the operations

in the microcomputer take place within a specified time frame.

Logic circuits are chips that carry out special tasks, such as for interrupts (interrupt) or the reset logic (to reset the microprocessor).

Input and outputs units (I/O) are required to connect with the peripherals. The peripherals include, for example, inputs for the crankshaft and camshaft signals, operating switches, analog inputs, and power drivers such as H-bridges (e.g., for throttle valve or exhaust-gas flap) or switch outputs (e.g., for heating of the λ sensor or relays).

Microcontroller unit (MCU)



In-car applications are subject to the requirement that the sequence of the ECU program keep pace with the physical sequences. Thus, system must respond within the shortest possible time to, for example, changes in input signals. The systems must therefore have "real-time capability". Modern microcontroller unit have some circuit modules to facilitate this.

Computer core

The clock frequency for the computer core is up to 800 MHz. The computer core consists of up to eight cores which can alternatively be operated in lockstep mode. In other words, two cores receive the same data or instructions, the first core directly and the second core delayed by x clock pulses. The results of the first core are then temporarily stored for x (usually two) clock pulses so that they can be compared with the results of the second core (which come delayed by the x clock pulses). If the hardware is OK, the two results are identical. If not, there is a fault. In this way, ASIL C/D (classification regarding the criticality of the properties of a systems anticipated by the company – ISO standard for safety-relevant electrical and electronic systems in motor vehicles, ISO 26262, [3]) – can be supported.

Figure 3: Structure of a microcontroller

CPU Central Processing Unit, ALU Arithmetic-Logic Unit, DSP Digital Signal Processor, RAM Random Access Memory, EEPROM Electrically Erasable Programmable Read Only Memory, ADC Analog-Digital Converter, DAC Digital-Analog Converter.

Semiconductor memories
Semiconductor memories are required for the program code and for data (for details, see semiconductor memories).

DMA (Direct Memory Access)
This unit can transport data between the modules and thus relieves the CPU.

Interrupt controller
The interrupt controller signals to a computer core that, due to a time-critical event in the peripherals or in a different core, the processing of the current task may have to be interrupted.

Hardware accelerator
This is a module in which certain computing functions are implemented in hardware and not calculated by the computer core. The e-function and the MAC unit (Multiply Accumulate) are an example of this. MAC is a computing operation for the efficient calculation of mathematical expressions – two values are multiplied and added to the previous multiplications. This makes it possible today for example to process Gaussian functions by more than a factor of 50 faster than in a computer core based on functions programmed in a programming language. These accelerators will be necessary in future MCUs because a clock-frequency increase to provide this necessary computing capacity is neither technically possible nor commercially sensible.

GPIO
"General Purpose Input Output" switch inputs and switch outputs are read in and read out within 10 to 20 ms. Consequently this means no real-time capability.

Analog-digital converters
Analog-digital converters (AD converters) generated from an analog voltage signal (e.g., voltage generated by a thermistor located in a voltage divider) a digital value which can be processed in the processor. There are two basic principles here:
– Converter with a high absolute accuracy: The SH converter (Sample and Hold) stores the input voltage in a capacitor and then converts it with different processes into a digital value.
– Converter which continuously provides values with a high resolution: In the case of an SD converter (Sigma-Delta) only the delta for the previous measurement in output positively or negatively with a preset clearance as bit 0 or 1 for further processing in the module internally.

GTM (General Timer Module)
The function of the timer unit (today mostly GTM for embedded systems) is to encapsulate the real time. There are two basic principles here – capture and compare.

The capture function for input signals assigns a time or angle stamp (angle as reference for example to the crankshaft) to the events at the input and stores the capture values in registers. Thus the processor does not have to process the signal further immediately; it can first close the running software routine (e.g., a highly prioritized interrupt routine) and then process the capture values.

The compare function for output signals generates an event (e.g., switching of the ignition coil at the moment of ignition) at the output pin at a specific time or angle. These values are stored beforehand in registers.

Microcontrollers
Microcomputers which have real-time capability are called microcontrollers. Nowadays they are typically integrated on a chip and are not, as in the past, designed as discrete components on the printed-circuit board. This is possible due to the fact that highly complex systems can be integrated on a chip thanks to modern technologies.

For future applications it will no longer be sufficient to have just one CPU, since the clock frequency cannot be increased in any way the user likes and this also results in very high current inputs. For this reason, microcontrollers will come in variants containing more than one CPU. For series 2023 Bosch offers a system with 35 computer cores – 10 main cores, 12 digital signal processor cores, 10 cores in the timer, two cores in the peripherals, and one core in the security module.

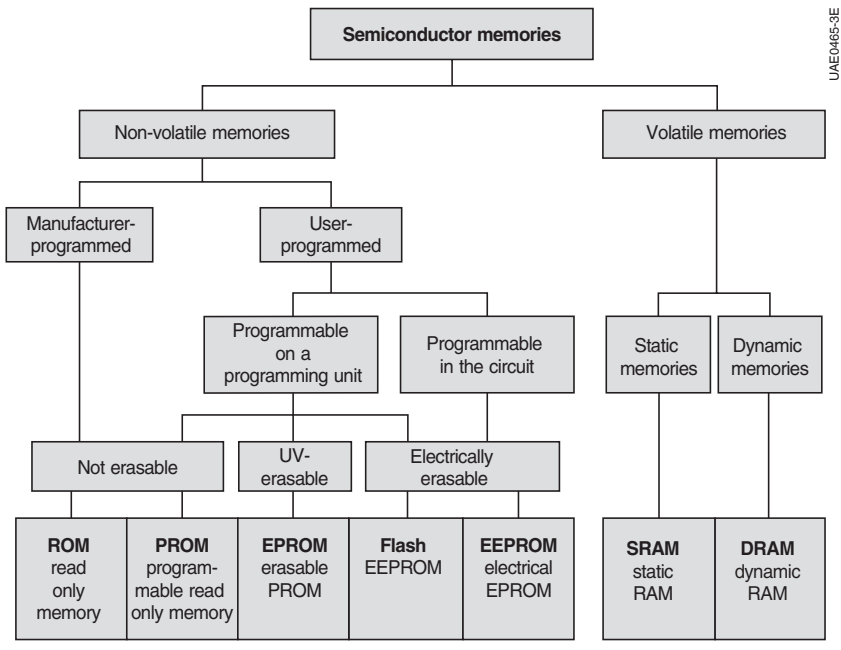
The microcontrollers which are used in the automotive industry differ from standard microcontrollers on various points.
– Temperature range: Junction temperature from –40 to 165 °C.
– Failure rate: Less than 1 ppm (one failure per one million components) – compared with 100 to 200 ppm for PCs.
– Service life: This is current specified at 40,000 hours in active operation (this corresponds in the case of a PC that is switched on for eight hours a day to an operating period of approx. 14 years).
– Significantly longer availability: Whereas no new microcontrollers have to be subsequently delivered for cellular phones and PCs after a production cycle of 1 – 3 years, complex projects in the automotive field start series production only after 3 – 5 years development, after which they remain in series production for a period of 15 years and are then subsequently delivered for a further 15 years.

Types of microprocessor unit
There is no clear definition which determines whether a component is termed an MPU or an MCU on the basis of its properties. A sensible technical distinction is to make a distinction based on the type of application.

MPU
Such a computer core is optimized for the support of non-real-time functions like virtual memory management and the use of other virtualization mechanisms like Hypervisor to support operating systems like Adaptive Autosar or Linux. With such MPUs interfaces such as PCI (Peripheral Component Interconnect, a bus system for connection peripherals such as for example Ethernet switches and a computer core) or USB (Universal Serial Bus, a bus system for connecting different devices from the segment of entertainment electronics) are very often supported. The architecture is optimized for bandwidth – in this way plannable tasks can be processed at very high speed.

MCU
The microcontroller unit is designed in such a way that it can satisfy “hard real-time requirements” (reaction to input signals or setting of output signals in the µs range). Properties like virtual memory management and fast reaction times to external events are absent (because the applications in part exclude themselves – high frequency and virtualization as for MPU with fast reaction to events as for MCU). Because this architecture is optimized for short latencies, very large memories close to the core are required, and not externally as for the MPU.

Semiconductor memories



Memory principle

Data storage comprises the following operations: recording (writing), permanent storage (data storage in the narrow sense), retrieval, and output (reading) of information. Figure 4 provides an overview of the different memory types. The memory operates by exploiting physical properties that facilitate unambiguous production and recognition of two opposed states (binary information). In semiconductor memories the states produced are either "more conductive" and "less conductive" or "charged" and "discharged". A technology in frequent use today is the flash memory. Memories operating according to this principle are electrically programmable and erasable.

New memory types will also be used in the future. The FRAM (Ferroelectric Random Access Memory) with the ferroelectric memory principle, the MRAM (Magnetoresistive Random Access Memory) with the magnetic effect as the memory principle, and the PCM (Phase Change Memory) utilizes as its memory effect the change of state of a material from crystalline to amorphous and the associated change in resistance. MRAMs and PCMs have the potential to supersede the flash memories (non-volatile but slow) and RAMs (fast but volatile) used today, since they retain their data after the power supply is switched off and also have very short access times (to be introduced in engine management from 2023 onwards).

A major advantage of MRAMs and PCMs is that the bits can be individually reprogrammed and the cells do not have to be jointly erased as with the flash EPROM. This facilitates faster programming, which is advantageous for field updates outside the workshop and in the manufacturing process at the vehicle manufacturer. Another advantage is that the reprogramming of individual bits is possible in the application. Because the running times of

Figure 4: Overview of semiconductor memories

the devices is getting ever longer and the technologies are getting ever smaller, the memory cells contain much less charge and therefore individual bits could lose the stored information in the event of long running times and high temperatures. In modern microcontrollers with structures of under 90 nm there are two remedial measures to counter this phenomenon:

– Reprogramming: Mechanism to ensure that cells which lose charge have sufficient charge again – the storage cell is supplied with additional charge.
– ECC (Error Correction Code): Unlike reprogramming, in this case additional bits are stored in the memory matrix and erroneous bits are corrected with the information from these bits – customary here are two bit error detection and single bit error correction for 64 bit memory areas via additional bits (customary as today for flash and RAM in technologies under 90 nm) to correct the erroneous bits.

Only static memories (SRAMs) are used for ECUs which operate at internal temperatures of more than 110 °C. Unlike dynamic memories (DRAMs), SRAMs do not lose charge and do not have to be refreshed during operation in the ms time range. SRAMs keep their charge as long as the storage cell is connected to the supply voltage.

Program and data memory

The microcontroller requires a program – the software – for the calculations. It is stored in a non-volatile program memory. The CPU reads out the values, interprets them as commands, and executes these commands in order.

Variant-specific data (individual data, characteristic curves and program maps) are additionally stored in this memory. The software can be adapted to different vehicle variants (e.g., different ignition maps) with these data.

The software requires a read/write memory to store variable data (variables) such as for example computing values.

Flash memory

The flash EPROM has superseded the conventional EPROM erasable with UV light (Erasable Programmable Read Only Memory) as the program memory. It is electrically erasable so that the ECU can be reprogrammed in the service workshop without it having to be opened. The ECU is connected via a serial interface to the reprogramming station.

RAM

All the variable data calculated in the software are stored in the RAM (Random Access Memory, i.e., in a read/write memory). Modern 40 nm microcontrollers contain up to eight MByte RAM – therefore there is no need for an external memory module. Newer technologies will additionally feature a HyperRAM interface to make an external RAM available for the application.

The RAM loses the entire data stock when the ECU is disconnected from the supply voltage; it is therefore a volatile memory. Parts of the RAM can be permanently supplied with voltage to prevent adaptation values learned during vehicle operation from being lost when the ignition is switched off. These values are however lost when the battery is disconnected. Therefore this option is only very rarely used today and the adaptation values are written to the non-volatile EEPROM.

EEPROM

Data that change in vehicle operation and which must not be lost when the battery is disconnected (e.g., important adaptation values, codes for the immobilizer) must be stored in a non-volatile memory (e.g., EEPROM).

It is also possible to use separately erasable areas of the flash EPROM as a non-volatile data memory for these data. An EEPROM is emulated in the flash (in separate areas – outside the program and data memory) for this purpose. The current data in each case are written to the end of a table, which gradually fills the blocks of the flash area. The old data can then be completely erased with the block. This ensures that the correct data are in the memory even when the supply voltage is disconnected.

Monitoring module
A monitoring module is required for safety-relevant systems. This is effected by a logic circuit in the voltage regulator (e.g., for engine-management systems) or in a separate integrated circuit (e.g., for transmission management). The monitoring module can also be effected by a separate computer.

The microcontroller and the monitoring module use a "question-and-answer game" to monitor each other. When a fault is detected, the ECU of both is rendered safe independently of each other – in the case of engine management for example by the deactivation of torque-relevant output stages (examples: ignition and fuel injection; deactivating these outputs means that the engine cannot provide any power).

Voltage regulator
The electronic components in the ECU need a stable voltage of 5 V. Some applications also require further voltage values, e.g., 3.3 V. The voltage regulator maintains the battery voltage, which can be 6 to 16 V depending on the battery state and load, at these constant values. Suppressor circuits suppress high interference voltages from the vehicle electrical system.

The voltage regulator contains an enabling logic which ensures that the voltages run up under defined conditions and then enable resets. This ensures that the microcontroller runs up under defined conditions after the supply voltage is switched on.

ASIC chips
ASIC chips are application-specific integrated circuits. They are designed and produced in accordance with the specification of ECU development. Integrating a large number of functions in an IC reduces the space requirement, reduces manufacturing costs and increases operational reliability.

Thus, for example, the power supply for the ECU and several power output stages with the associated diagnostic circuits can be integrated on one chip. An example of this is the "U-chip", which features on one IC a power supply, the monitoring module, serial interface drivers and output stages, and an H-bridge with diagnostics.

Another function of an ASIC module is, for example, to relieve the load on the microcontroller or to make additional hardware available (e.g., additional input and output channels for static signals and for PWM signals).

An ASIC can be used in the gasoline-engine-management system for knock control which boosts the signals supplied by the knock sensors, filters them via a bandpass, rectifies them, and integrates them via a specified crank-angle window. The microcontroller then only has to read out the integrated voltage value at the end of the window. However, in newer ECU generations the knock-sensor signals are detected directly by the microcontroller via high-speed analog-digital converters (ADCs).

Special ASICs are also used to operate, evaluate and diagnose λ sensors. They activate the sensors with defined signals, evaluate currents, voltages and temperature with great precision, and convert these signals for the microcontroller into digital input signals.

ASICs are also used to activate fuel injectors for high-pressure fuel injection. A defined current curve can thus be set.

For special applications ASICs with several output stages and H-bridges are available which also contain a diagnosis function and can be activated via a serial bus.

Communication
ECU-internal communication with the ASICs is effected via SPI (Serial Peripheral Interface) or via MSC (Micro Second Channel).

Data which do not require a high bit rate (e.g., fault-memory data stored in the EEPROM) are also serially transferred over only one data line.

In this way, the ECUs can also send data for calculations (e.g., wheel speed, steering angle, battery voltage, drive torque, selected gear, engine speed) to other ECUs if they are connected to these via a multitude of communication buses.

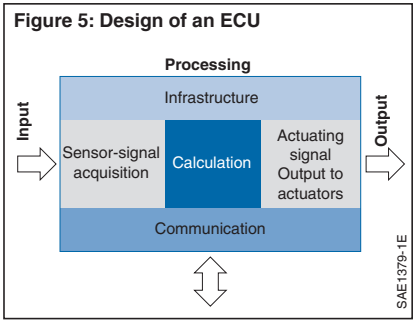
The buses which are mostly used in vehicles are:
– CAN (with the subvariants CAN, CAN_FD and CAN_XL): for some devices up to 20 CAN buses to one ECU – data transfer currently at 1 MBaud, in future up to 15 MBaud.
– LIN: up to 18 LIN buses for the connection of sensors with low bandwidths.
– FlexRay: currently at 10 MBaud, will be replaced in future by a special Ethernet variant.
– Ethernet: at various speeds also up to 2.5 GBaud bandwidth.
– PSI5: for sensors also with return channel for avoiding sensor tuning.

In the case of tuning often the weakest link of a chain is attacked – if the engine control unit is more difficulty to tune, the modification of input signals is used to achieve higher engine power. 30 years ago the crankshaft-signal connector was connected with a 180 ° offset to achieve a more retarded ignition with regard to TDC (cylinder top dead center) and thus more engine power – with the drawback of influencing the engine's service life. Today, microcontrollers are switched into the signal lines, which relay to the engine control unit for example a driver's request for more power (via pedal-travel sensor or air mass) according to the table stored in the microcontroller – e.g., 10 % more with the same input data.

Data processing

Architecture

The engine control unit operates according to the classic IPO principle (Input – Processing – Output). It can be subdivided into three main blocks (Figure 5):
– input circuits for sensor-signal acquisition,
– computer for calculating the actuating signals,
– output stages with the power electronics for activating the actuators.



Sensors and actuators form as the peripherals the interface between the vehicle and the ECU as processing unit. In addition, there are bidirectional communication data buses (e.g., CAN bus), via which information is exchanged with other ECUs or sensors [4].

Input signals

Control elements and sensors form an interface between the vehicle and the ECU. The electrical signals are supplied to the ECU via the wiring harness and connectors. Sensors can have analog or digital interfaces.

Analog interface
Analog input signals can assume any value (e.g., voltage value) within a certain range. Examples of physical variables which are available as analog measured values are the coolant and intake-air temperatures, the intake-manifold pressure, the intake air mass, the battery voltage, and also the hydraulic pressure in the braking system. The analog voltage output by the sensors is relayed to the ECU. The analog value is converted by an analog-digital converter (ADC) in the microcontroller or in an interface module into a digital value. A typical resolution of the converters integrated in the microcontroller is 10 bits. For a reference voltage of 5 V a resolution of approximately 5 mV is obtained with these 2^{10} = 1,024 stages.

Figure 5: Design of an ECU

Digital interface
Digital input signals have just two states "High" (logic 1) and "Low" (logic 0). They can be evaluated directly by the ECU. Examples of digital signals are switching signals of control elements, speed signals from a Hall-effect sensor (for measuring wheel speed or engine speed), or static signals from a Hall-effect sensor (e.g., position sensor in the transmission).

Sensor signals via communication interface
In future sensors which detect analog quantities will increasingly incorporate additional electronics which digitize the analog voltage locally and output the measured value via a standardized digital interface (see Integrated sensors). Examples of these interfaces are SENT (Single Edge Nibble Transmission) and LIN (Local Interconnect Network), whereby data can be transmitted bidirectionally (see LIN). They enable sensors from different manufacturers to be connected to ECUs.

Signal conditioning

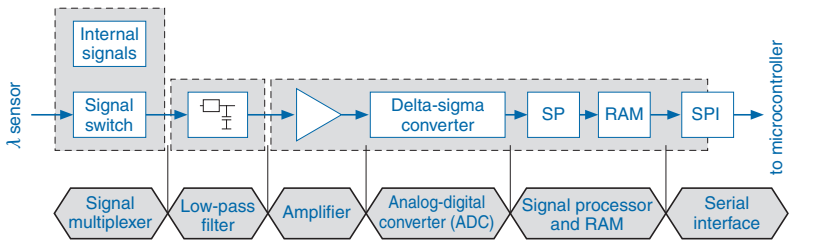
Adapter circuits
Each sensor has a specific input. The input signals are limited by suppressor circuits to permissible voltage levels. Filters remove most of the superimposed noise from the useful signals and limit the bandwidth (sampling theorem); the useful signals are then amplified or attentuated if necessary to the microcontroller's permissible input voltage (0 to 5 V).

Signal conditioning in the sensor
Depending on the sensor's integration level, signal conditioning can take place in part or entirely in the sensor already. The sensor signals digitized in the evaluation electronics are then output via a communication interface; further special signal conditioning in the ECU is not necessary.

Signal conditioning with ASICs
For some sensors, e.g., λ sensors, special modules (ASICs) are required which assume the complex tasks of activating and evaluating these sensors. These ASICs activate the sensors with defined signals, evaluate currents, voltages and temperature with great precision, and convert these signals for the microcontroller into digital input signals. The entire signal path (Figure 6) is achieved with a single ASIC.

Flexible input module
The market in the passenger-car sector is characterized by an increasing number of variants and niche applications to round off the manufacturers' product lines (for instance convertibles, roadsters, etc.). In the commercial-vehicle sector there has always been a very large number of special applications, for example bituminous finishers, complete beet harvesters, and other special machines. These often have special sensors; however, owing to the low quantities involved, it is not economical to create and maintain hardware variants. The trend is therefore towards software-configurable input circuits (Figure 7). The module L9966 used by Bosch (FlexIn ST Microelectronics) has for example 15 freely configurable inputs, which can be configured as analog input, resistance-measurement input, digital input, SENT (bus interface) or input for switching-type λ sensors. Furthermore, switchable current sources can be configured as pull-up or pull-down for each input.

Figure 6: Signal path for evaluating λ sensors



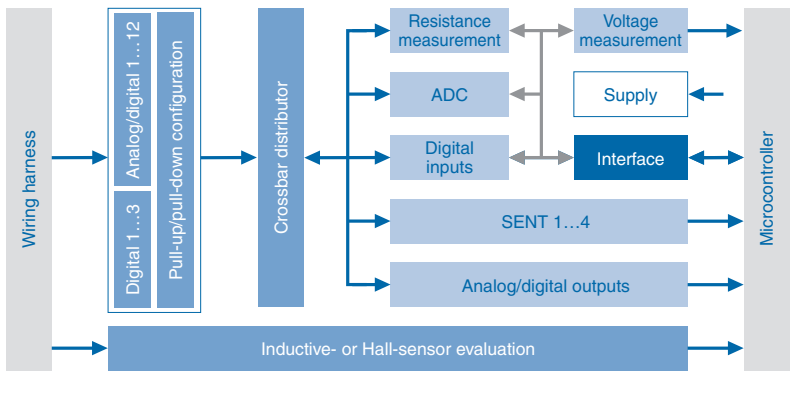


Figure 7: Block diagram of a software-configurable input circuit

Signal processing
The ECU is the control center for the functional sequences of an electronic system. The control algorithms run in the microcontroller. The input signals provided by the sensors and the interfaces to other systems for example via the CAN bus serve as input variables. They are checked for plausibility again in the microcontroller. The algorithms are processed with the aid of the ECU program (software). The ECU program is stored in the read-only memory (e.g., flash EPROM), the calculated intermediate values are stored in the data memory (RAM). The software calculates the output signals to activate the actuators.

Output signals
Different actuators are activated by the ECU via appropriate output stages on the basis of the data processed in the microcontroller. These actuators differ in their power demand and in how they are activated.

The output-stage modules in the ECU have a number of individually activated output stages which supply sufficient power to activate the actuators.

Signal types
Switching signals
Switching signals are used to switch actuators on and off, depending on the current operating point (e.g., fuel injectors, ignition coils). Consumers with high currents to be switched (e.g., engine fans) are switched via relays or with output stages directly on the assembly.

PWM signals
Digital output signals can be output as a PWM signal (pulse width modulation) with constant frequency and variable on-time. Actuators such as the exhaust-gas recirculation valve, the throttle valve or the charge-pressure actuator can, depending on this variable on-time, be moved into specified operating positions.

Application-specific output stages
Application-specific output stages are then used if special current and voltage curves for activating the actuators are needed which cannot be realized with standard output stages.

An example of such is the activation of high-pressure fuel injectors for gasoline direct injection (see High-pressure fuel injector) or for common-rail injectors (see Injectors). The actuators are activated by complex output-stage modules with integrated control logic and analog signal conditioning. These modules deliver a high voltage during switch-on, producing a high making current and thus a fast breaking operation. The system is then regulated back to a lower holding current.

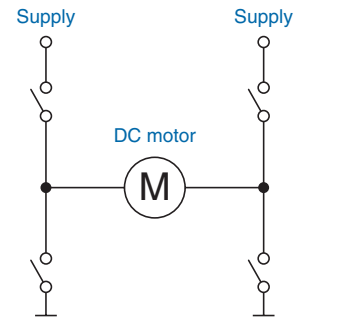
Flexible programmable output module
Increased flexibility is also called for in the area of output drivers in order to cover different applications with one hardware variant. One solution is the flexible programmable output module DGDI-S from Bosch (originally for Diesel-Gasoline-Direct-Injection Solenoid, but not also for other applications, Figure 8). This module has four microprogrammable sequencers, seven high-side and eight low-side FET drivers, and six current measurements. It can be reconfigured by software for use for example for injectors, solenoid valves, H-bridges or BLDC motors (brushless DC motors). Consequently, it is no longer necessary to have all the inputs and outputs permanently defined already at the start of ECU development. Adaptation to the concrete application can be performed later by means of a software or data-record modification.

Switching variants
There are different switching variants for activating the actuators. Low-side output stages control inductive and ohmic loads which are connected to the battery voltage (e.g., valves, relays, ignition coils). High-side output stages switch consumers which are connected to ground. DC motors are activated via bridge-type output stages (Figure 9); here, both connections of the motor are switched by the ECU. This makes it possible to reverse the direction of rotation (e.g., for power-window drives, activation of the throttle valve).

Self-protection function
The output stages are protected against short-circuits to ground, against short-circuits to battery voltage, and against being destroyed due to electrical or thermal overload. These malfunctions and interrupted lines are detected as faults by the output-stage IC and signaled to the microcontroller via a serial interface.

Communication interfaces
The ECU has one or more communication interfaces for communicating with other electronic systems. In this way, for example, the driving speed can be sent by driving-dynamics control to all the systems that need this signal (e.g., the instrument cluster for displaying the driving speed). The signals therefore only have to be calculated one in the ECU network. Data transfer is effected via bus systems (see Automotive networking, buses in the vehicle).

Figure 9: H-bridge for activating a DC motor



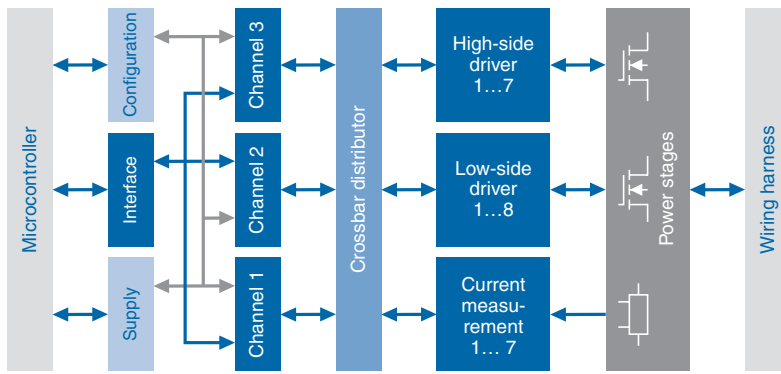


Figure 8: Flexible programmable output module DGDI-S

Assembly and connection technology

Circuit-board technology

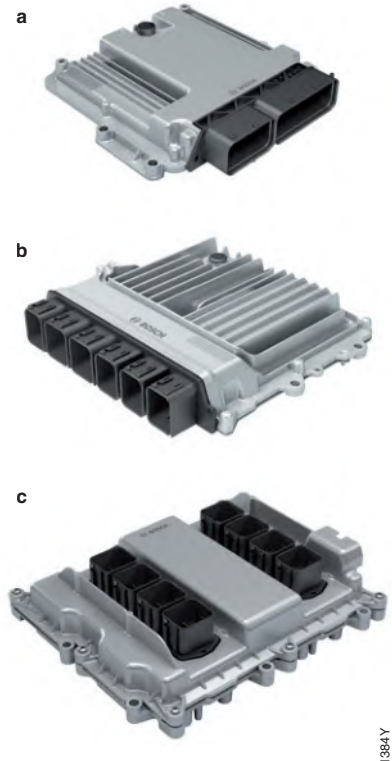
Engine control units (Figure 10) are typically manufactured in accordance with circuit-board technology using circuit-board materials with four to eight layers. The housing consists for example of a base/cover combination of diecast aluminum and deep-drawn aluminum sheet which are screwed or bonded to each other. A membrane impervious to water is used for pressure equalization. As a result, an atmospheric-pressure sensor can be installed in the ECU which for engine-management purposes enables the injected fuel quantity also to be corrected on an air-pressure-dependent, i.e., altitude-dependent, basis.

Hybrid control units

In special cases, especially where there are extreme temperature requirements, thick-film hybrid circuit-boards are used. This technology involves the application of both integrated and discrete components on ceramic substrates.

Plug-in connections

A customary plug-in connection for example for engine management in passenger-car applications has around 200 contacts, split into a number of compartments. In commercial-vehicle applications a number of connectors are also placed next to each other on the cover, making possible many more contacts (Figure 10).



Small ECUs (e.g., a sensor control unit) as a rule have one plug-in connection with one compartment and few contacts.

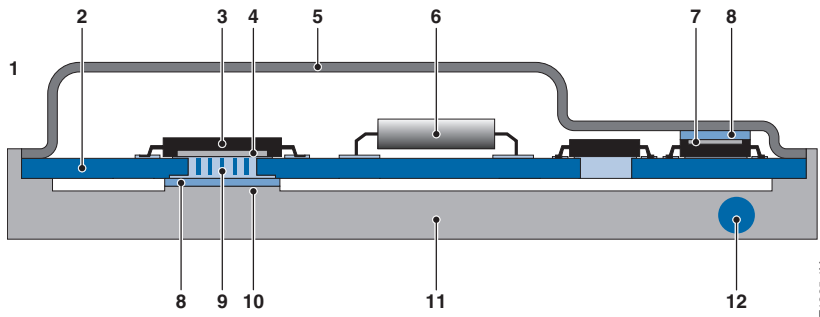
Cooling

Heat dissipation is particularly important for the electronics in a vehicle's engine compartment (e.g., engine control unit, driving-dynamics control ECU). At ambient temperatures of up to 125 °C in the engine compartment the ECU's power loss, which can range from 30 to 70 W, must be dissipated outwards. There are

Figure 10: Examples of ECUs for diesel-engine control systems

a) Passenger-car ECU for body mounting (154 plug-in contacts),
b) ECU for passenger cars and light commercial vehicles (228 plug-in contacts),
c) Commercial-vehicle ECU for engine mounting for up to eight cylinders, diesel or natural-gas operation (336 plug-in contacts).

for this purpose special means of discharging heat from its point of origin outwards.



The left side of Figure 11 depicts the cooling of an IC (integrated circuit). Heat is dissipated to the printed-circuited board by the cooling surface situated below the IC (slug-down). Feedthroughs, which direct the heat to the underside of the printed-circuit board, pass through the printed-circuit board. The housing base is raised at this point so that the distance to the printed-circuit board is so small that it can be bridged with heat transfer compound.

The far right side of Figure 11 depicts the converse path. A component dissipates its heat via the cooling surface resting on it (slug-up) and the heat transfer compound upwards to the housing cover. It is shaped in such a way that the distance to the component is as small as possible. Heat dissipation from the housing to the surrounding area can be effected by way of heat radiation, heat conduction, and active heat transfer (forced convection).

Heat dissipation via the surface can be additionally boosted by cooling fins on the surface and additional movement of the air (e.g., with an external fan). To provide cooling by heat conduction, the ECU is mounted on a thermal conductor with as wide an area as possible (e.g., vehicle body).

Active heat transfer means that cooling ducts through which a cooling medium (e.g., fuel) flows are integrated in the ECU housing. Aside from the physical properties of the cooling medium, the magnitude of the heat flow is dependent on the coolant temperature, the flow rate, and the duct length.

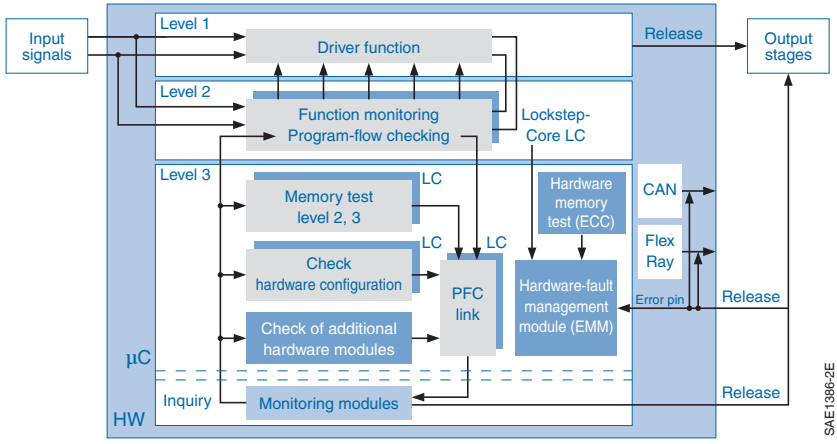
9 Feedthrough, in the p.c.b. under slug-down components for improved heat conduction through the p.c.b., 10 Cooling bank, 11 Housing base, 12 Fuel duct for cooling the ECU.

Software

To be able to support different electric and electronic architectures that are in a state of transition, it is necessary to isolate the application software from the hardware as far as possible. The solution comes in the form of standardized basic software (BSW) and standard interfaces for all the electronic vehicle functions. Generally, the basic software is defined as the hardware-dependent software, i.e., software components for example for microcontroller peripherals, drivers for application interfaces, diagnostics, communication, operating system, and system control.



Using the worldwide AUTOSAR standard (Automotive Open System Architecture [5], see Software engineering) ensures a high degree of software reusability and exchangeability. AUTOSAR takes into consideration the complete vehicle system, not just an individual ECU.

Application

ECUs are, as described above, structurally always very similar (Input – Processing – Output). The specific control required for the respective application is performed by the program executed in the microcontroller. This program consists of an executable program code and a data part (individual characteristics, characteristic curves, and program maps), the so-called application data. The entire program is stored in the read-only memory, designed in ECUs as a flash memory. To satisfy the different requirements for controlling for example a driving engine and the statutory provisions for exhaust-gas emissions and diagnostics, it is essential to change and optimize the application data.

Whereas roughly 100 to 1,000 application data were sufficient for the first generations of ECUs for engine management, today several 10,000 are required. The process of optimizing application data is called “application of ECUs”. The work necessary for this is carried out on test benches and in test vehicles and requires specially prepared engine control units.

Figure 12: ECU-software levels and hardware-based monitoring module

Functional safety

As the complexity of electronic components in vehicles constantly increases, so too does the potential for malfunctions. If a safety-relevant component is affected by such a malfunction, people may come to harm in the worst cases [3]. The engine control unit uses hardware and software functions to monitor itself continuously for malfunctions. Three software levels and a hardware-based monitoring module are implemented for this purpose (Figure 12).

The level 1 software contains the desired application functions. These check the plausibility of input signals supplied by different sensors and thereby blank out invalid sensors and implement appropriate substitute reactions. The level 2 software calculates in parallel in an independent computer core parts of the application software in a redundant, independent implementation (e.g., generation of torque or triggering the starter). The output stages are enabled only when both levels arrive at the same result. The level 3 software checks hardware-related faults (e.g., damaged memories).

On the hardware level the ECU has a monitoring module. Microcontroller and monitoring module monitor each other by way of a "question-and-answer game" (for example solving a computing task, the monitoring module specifies a number which must be incremented by the microcontroller). If a fault is detected, both can initiate appropriate substitute functions independently of one another.

The effectiveness of the switch-off paths of levels 2 and 3 and of the monitoring module is checked each time the ECU is switched on.

EOL programming

The large number of vehicle variants with different control programs and data records calls for a procedure for reducing the ECU types required by the vehicle manufacturer. To this end the complete memory area of the flash EPROM can be programmed with the ECU program and the variant-specific data record at the end of vehicle production with EOL programming (End of Line). Data transfer is effected via the communication interface.

Alternatively, to reduce the variant diversity in the memory, it is possible to store several data variants which are then selected by means of coding at the end of line. This coding is stored in the EEPROM.

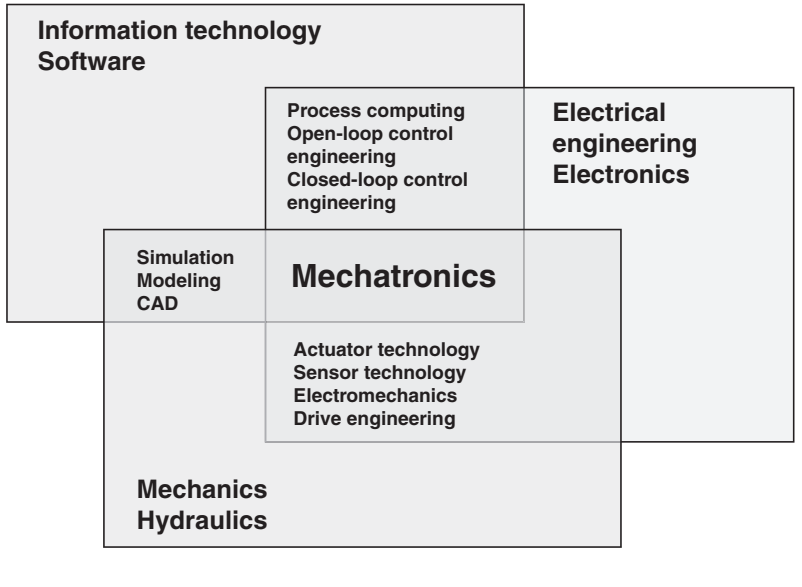
Mechatronics

Mechatronic systems and components

Definition

The term “mechatronics” is a compound derived from the words mechanisms and electronics, where electronics means “hardware” and “software”, and mechanisms is the generic term for the disciplines of “mechanical engineering” and “hydraulics”. It is not a question of replacing mechanical engineering by “electronification”, but of developing a synergistic approach and design methodology (Figure 1). The aim is to achieve a synergistic optimization of mechanical engineering, electronic hardware and software in order to project more functions at low cost, less weight and installation space, and better quality.

A crucial factor governing the success of a mechatronic approach to solving problems is to regard the two previously separate disciplines as a single entity.



Application

Mechatronic systems and components are now used in practically all aspects of the automobile today, starting with engine management and fuel injection for gasoline and diesel engines, transmission-shift control, and electrical and thermal energy management, through to a wide variety of braking and vehicle-dynamic systems. It even includes communication and information systems, with many different requirements when it comes to operability. Besides systems and components, mechatronics are also playing an increasingly vital role in the field of micromechanics.

Examples at system level

A general trend is emerging in the advanced development of systems for fully automated vehicle handling and guidance: In future, mechanical systems will be replaced to an increasing extent by “x-by-wire” systems. One system that has been

Figure 1: Interactions of mechatronics

in existence for quite some time is "drive-by-wire", i.e. electronic throttle control. "Brake-by-wire" is replacing the mechanical and hydraulic link between the brake pedal and the wheel brake. Sensors detect the driver's brake command and transmit this information to an electronic control unit. The unit then generates the required braking effect at the wheels by means of actuators.

A possible option for implementing "brake-by-wire" is the electrohydraulic braking system (SBC, Sensotronic Brake Control). When the brake is operated or in the event of stabilization interventions by driving-dynamics control, the SBC ECU calculates the desired setpoint brake pressures at the individual wheels. Since the unit calculates the required braking pressures separately for each wheel and detects the actual values separately, it can also regulate the braking pressure to each wheel via the wheel-pressure modulators. The four pressure modulators each consist of an inlet and an outlet valve controlled by electronic output stages which together produce a finely metered pressure regulation.

In the common-rail system, pressure generation and fuel injection are separated from each other. A high-pressure accumulator, i.e. the common rail, stores constantly the fuel pressure required for each of the engine's operating states. A solenoid-valve-controlled injector with integrated nozzle assumes the function of injecting the fuel directly into the combustion chamber of each cylinder. The engine electronics constantly request data on accelerator-pedal position, rotational speed, operating temperature, fresh-air intake flow, and rail pressure in order to optimize the control of fuel metering as a function of the operating conditions.

Examples at component level

Fuel injectors are crucial components in determining future potential of diesel-engine technology. Common-rail injectors are an excellent example of the fact that an extremely high degree of functionality and, ultimately, customer utility can only be achieved by controlling all the physical domains (electrodynamics, mechanical engineering, fluid dynamics) to which these components are subjected.

In-vehicle CD drives are exposed to particularly tough conditions. Besides wide temperature ranges, they must withstand extreme vibrations that have a critical impact on such precision-engineered systems. The drives are usually equipped with a spring-damper system to isolate the playback unit from vibrations that occur when the vehicle is moving. Any considerations to reduce the weight and installation space of CD drives immediately raise questions concerning these spring-damper systems. If the damper system is eliminated from a CD drive, the main focus is on designing a mechanical system with zero clearances and producing additional reinforcement for the focus and tracking controllers at high frequencies. Only by considering both measures from a mechatronic viewpoint is it possible to achieve an optimized vibration-proof solution for an automotive environment. Besides weight savings of about 15 %, the installation height has also been reduced by about 20 %.

The new mechatronic approach for electrically driven coolant motors is based on brushless, electronically commutated DC motors. Initially, they are more expensive (motor with electronics) than previous motors equipped with brushes. However, the overall optimization approach has a positive tradeoff: Brushless DC motors can be used as "wet rotors" with a much simpler design. This reduces the number of single parts by roughly 60 %. Taking the aggregate view, the sturdier design has double the service life, almost half the weight, about 40 % less the overall length, while maintaining costs at a comparable level.

Examples in the field of micromechanics

Another area of applications for mechatronics is the field of micromechanical sensors, with noteworthy examples such as hot-film air-mass meters and yaw-rate sensors.

The design of microsystems also requires an interdisciplinary approach owing to the close interaction between the subsystems involving individual disciplines such as mechanical engineering, electrostatics, fluid dynamics (where necessary), and electronics.

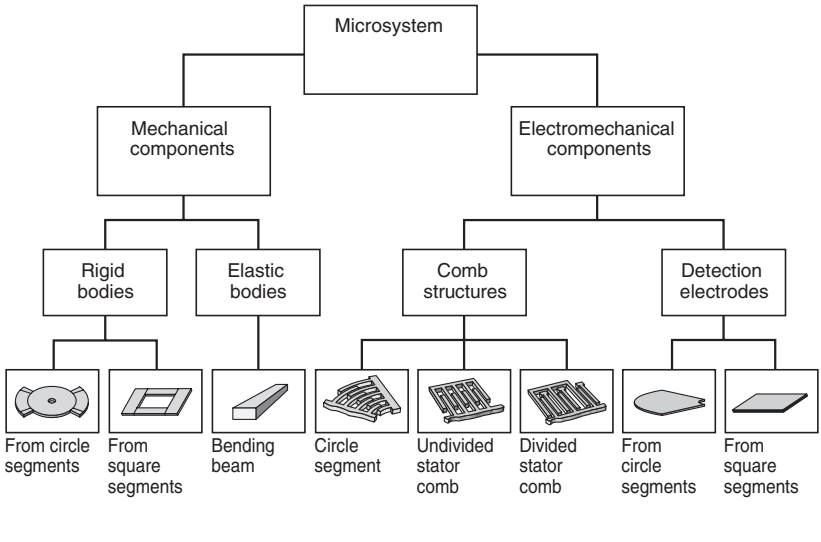
Development methodology

Simulation

The special challenges that designers face when developing mechatronic systems are the ever shorter development times and the increasing complexity of the systems. At the same time it is vital to ensure that the developments will result in useful products.

Complex mechatronic systems consist of a large number of components from a wide range of physical domains: hydraulics, mechanical engineering, and electronics. The interaction between these domains is a decisive factor governing the function and performance of the overall system. Simulation models are required to review key design decisions, especially in the early development stages when there is no prototype available.

Basic issues can often be clarified by producing relatively simple models of the components. If more detail is required, more refined component models are needed. The detailed models focus mainly on a specific physical domain.



As a result, there are detailed hydraulic models of common-rail injectors. They are simulated using special programs whose algorithms are matched precisely to the hydraulic systems. For example, the requirements here would be to take cavitation phenomena into consideration.

Detailed models are also needed to design the power electronics for activating the injectors. Again, this involves the use of simulation tools which must be developed specifically to design electronic circuits.

Tools that are specially designed for this specific part of the overall system are also required to develop and simulate the control-unit software which controls the high-pressure pump and power electronics using signals from the sensors.

As the components in the overall system interact with each other, it is not sufficient to consider specific detailed models of the components in isolation. The optimum solution is also to take into account the models of other system components. In most cases, these components can be portrayed by much simpler models. For

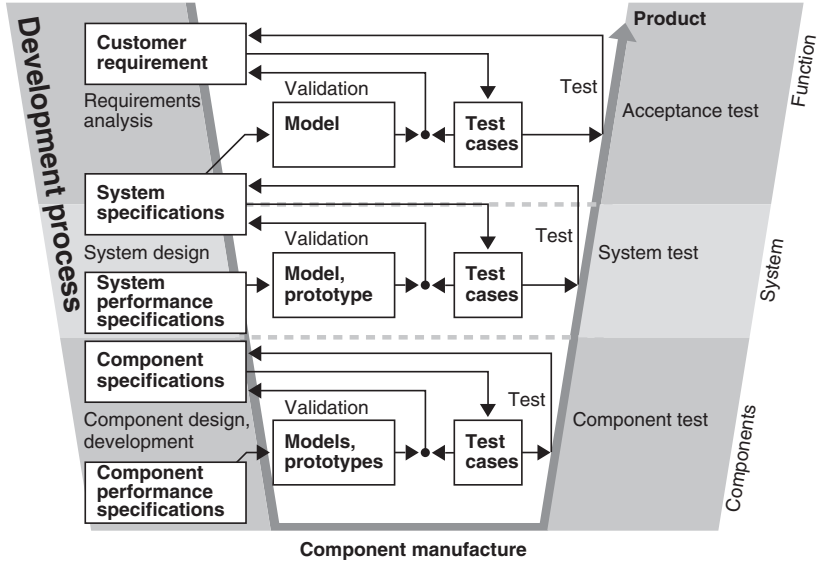
Figure 2: Model library for a micromechanical yaw-rate sensor

example, a system simulation focused on hydraulics only requires a simple model of the power electronics.

The application of various domain-specific simulation tools during the design of mechatronic systems is only efficient if there is some sort of support for exchanging models and parameters between the simulation tools. The direct exchange of models is highly problematic due to the specific languages used for describing the models of each of the tools.

However, an analysis of the typical components in mechatronic systems shows that they can be composed of a few simple elements specific to the domains. These standard elements include, for example:

– in hydraulics: restrictor, valve, or pipe,
– in electronics: resistor, capacitor, or transistor,
– in mechanical engineering: mass with friction, transmission, or clutch (accordingly for micromechanics).



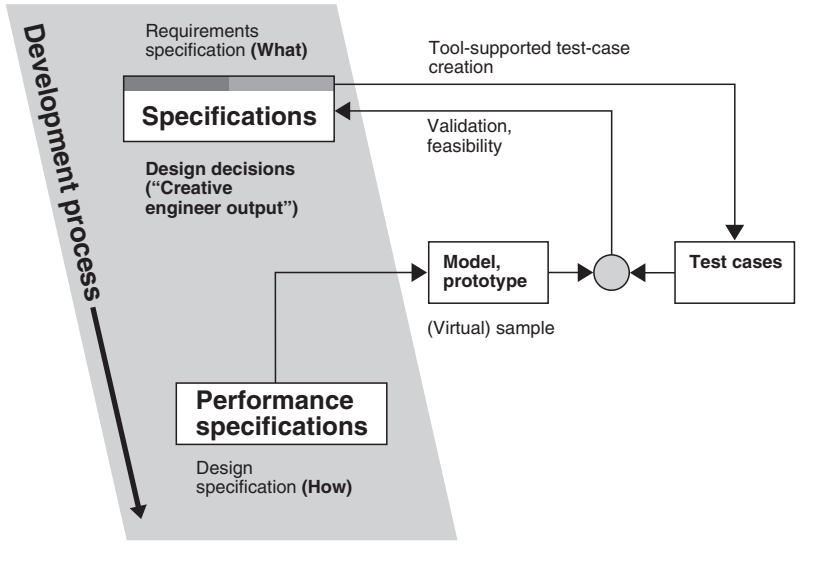
The preferable solution is that these elements should be stored in a central standard model library (Figure 2) that is also decentrally accessible to product development. The kernel of the standard model library is a documentation of all the standard elements. For each element, this comprises:

– a textual description of the physical behavior,
– the physical equations, parameters (e.g. conductivity or permeability), and state variables (e.g. current, voltage, magnetic flux, pressure),
– a description of the associated interfaces.

V model

The relationships between the different phases of product development are illustrated in the V model (Figure 3): from requirements analysis through drafting, development, implementation, and testing through to system introduction of the

Figure 3: General overview of V model



product. A project passes through three "top-down" levels during the development stage:
– customer-specific functions,
– system, and
– components.

A requirements specification ("what") must first be produced at each level in the form of specifications (Figure 4). This is then used to produce the design specifications based on design decisions (the actual creative engineering output). The performance specifications describe "how" a requirement can be met. The performance specs form the basis for a model description which allows a review (i.e. validation) of the correctness of each design stage together with previously defined test cases. This procedure passes through each of three stages, and, depending on the technologies applied, for each of the associated domains (mechanical engineering, hydraulics, fluid dynamics, electrics and electronics, software).

Recursions at each of the design levels shorten the development stages significantly. Simulations, rapid prototyping, and simultaneous engineering are tools that allow rapid verification, and they create the conditions for shortening product cycles.

Figure 4: Recursion methodology at one level

Outlook

The driving force behind mechatronics is the continuous progress in microelectronics. Mechatronics benefits from computer technology in the form of ever more powerful integrated computers in standard applications. Accordingly, there is a huge potential for further increases in safety and comfort in motor vehicles, accompanied by further reductions in pollutant emissions and fuel consumption. On the other hand, engineers face new challenges in mastering the new technologies for these systems.

Even in the event of a fault, future "X-by-wire" systems must continue to be capable of fulfilling a prescribed functionality without reverting to a mechanical or hydraulic fallback level. The condition for their implementation is a high-reliability and high-availability mechatronic architecture which requires a "simple" proof of safety. This affects both single components as well as energy and signal transmissions.

Besides "x-by-wire" systems, driver-assistance systems and their related man-machine interfaces are another field in which significant progress can be achieved for users and automotive manufacturers by the systematic implementation of mechatronic systems.

The design approaches of mechatronic systems should strive toward continuity in several aspects:

- Vertical: "Top-down" from system simulation, with the objective of overall optimization, through to finite-element simulation to achieve a detailed understanding, and "bottom-up" design engineering from component testing through to system testing.
- Horizontal: "Simultaneous engineering" across several disciplines in order to deal with all product-related aspects at the same time.
- Across corporate boundaries: The concept of a "virtual sample" is approaching gradually step by step.

Another challenge is training in order to further an interdisciplinary mindset and develop suitable DE processes and forms of organization and communication.

Automotive software engineering

Motivation

Aim of development
Any development has the aim of creating a new function or improving an existing function of the vehicle. Such functions bring about an added value for the user of the vehicle (e.g. occupants, mechanics in the workshop or haulage contractors), compliance with statutory requirements, simplified maintenance, or improved development or manufacturing efficiency. Technical implementation can be mechanical, hydraulic, electrical or electronic. Often it is combinations of these technologies, where electronics increasingly plays a key role in the realization of many innovations in a motor vehicle. Thanks to the use of electrics, electronics and software – the logical core of systems – "intelligent" functions of the drive, the chassis and the rest of the vehicle are cost-effectively realized.

Virtually all vehicle functions in all vehicle classes are now electronically controlled or monitored. Ongoing advances in the technology and performance of electronics hardware allow the realization of many new, more powerful functions through the use of software. The various electronic systems are being increasingly cross-linked in the vehicle. Efforts are pursuing cross-linking vehicles to each other and with the environment (e.g. Internet).

Software requirements
The specific requirements of the software are highly varied. Many systems for the engine and for driving safety must operate with "real-time capability", i.e. the response of the control operation must keep pace with the physical process. When very fast physical processes are being controlled, such as for example engine management or driving-dynamics control, the calculation must therefore be made very quickly. Even the requirements with regard to reliability are high in many fields. This is particularly true of safety-relevant functions. The software and the electronics are monitored by complex diagnostics.

The software is used across the many variants of a vehicle or even across model series. It must then be adaptable to the corresponding destination system. It contains calibration parameters and program maps for this purpose. These amount to several 10,000 per vehicle. These manipulated variables are dependent on each other in many ways. In addition, a functionality is distributed beyond multiple systems or control units more and more frequently.

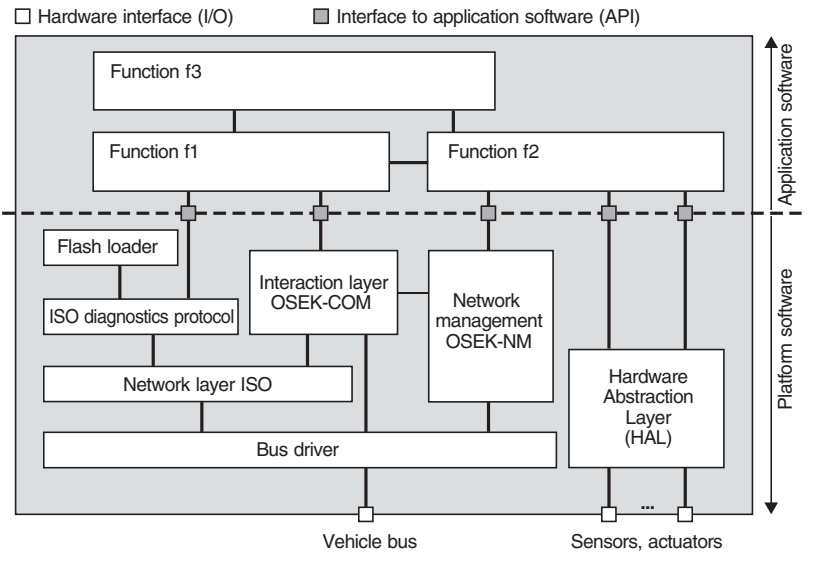
The software is for the most part developed specially for the corresponding applications and is integrated into the entire system. It is called "embedded software". The many functions are often developed and further developed over a long period of time in many locations around the world. Because spare parts must remain available even after the production of a particular vehicle has come to an end, the electronics in the vehicle must have a relatively long life cycle of up to 30 years.

For cost reasons, ECUs often contain microcontrollers with limited computing power and limited memory space. This requires optimization measures in software development to reduce the hardware resources required.

The characteristic features of software differ depending on the field of application. While the software for the drivetrain is extensive, the emphasis is on real-time performance in the chassis applications. In safety and comfort and convenience applications, the emphasis is on efficiency, i.e. the consumption of resources, and in multimedia applications large volumes of data must be processed in a short period of time.

The complexity resulting from these requirements and features must be economically mastered in a cooperation of development between vehicle manufacturers and suppliers.

Design of software in motor vehicles



The software in a motor vehicle is made up of many components. A distinction is essentially made, as is the case with a PC, between the "perceptible functions" of the software, the application software and platform software partly dependent on the hardware (Figure 1). The interaction between all the functions is defined in the architecture. Different views can be adopted here. The static view describes hierarchically the function groups, the signals and the distribution of the resources. On the other hand, the functional view describes the signal progression through the different functions. The dynamic, i.e. time-dependent view, considers the time response in the execution of the various tasks. Standards have already been introduced at an early stage to ensure the interaction between and further development of the individual components. The most important standards are explained in the following.

Important standards for software in motor vehicles

Bodies/committees

The "Association for Standardization of Automation and Measuring Systems" (ASAM) is a standardization body in the automotive industry for data models, interfaces and syntax specifications [5]. The ASAM developed different standards for connecting an ECU to a computer or a data-entry terminal. The standard ASAM-MCD1 (MCD stands for Measurement, Calibration and Diagnosis) supports different data transport protocols for this purpose. By using ASAM-MCD2 specifications, the binary data in the ECU can be addressed and the relevant quantities can at the same time be displayed in connected tools as physical values and processed. The standard ASAM-MCD3 also permits an automation of such processes, for example for the automatic calibration of data records. Further ASAM standards cover, for example, the exchange of functional descriptions and data.

Figure 1: Main component parts of the static software architecture for microcontrollers and standardized software components

The FlexRay Consortium developed the specification for the FlexRay field bus for open and closed-loop control in the automobile field. Thanks to high transfer rates with predefined bus arbitration and a fault-tolerant design it is particularly suitable for use in active safety systems and in the drivetrain (see FlexRay).

The International Electrotechnical Commission (IEC) is an international standardization body in the fields of electrical engineering and electronics [6]. The IEC offers three evaluation systems with which conformity to the international standards can be verified. The IEC works in close cooperation with the International Organization for Standardization (ISO) [7], the International Telecommunication Union (ITU) and numerous standardization bodies (including the Institute of Electrical and Electronics Engineers, IEEE) [8].

The Motor Industry Software Reliability Association (MISRA) is an organization in the automotive industry that devises rules for the reliable development and application of software in vehicle systems [9]. The most widely known is the programming standard MISRA-C, which was developed by the MISRA. It prescribes programming rules for reliable programming in the programming language C. The purpose of this standard is to avoid runtime errors due to unreliable C constructs and structural weaknesses due to misunderstandings between programmers, and to safeguard the validity of expressions. Many rules can be automatically checked and taken into account in the generation of codes.

The Society of Automotive Engineers (SAE) is an international science and technology organization operating in the field of mobility technology [10]. It sets among other things standards for the automotive industry and promotes the exchange of knowledge and ideas.

The standardization body "Open Systems and their Interfaces for the Electronics in Motor Vehicles" (Offene Systeme und deren Schnittstellen für die Elektronik im Kraftfahrzeug, or OSEK) came about from a project by the German automotive industry. Later came the "Vehicle Distributed Executive" (VDX) initiative of the French automotive industry. Standardizations of basic-software components are established under the term OSEK/VDX in the following fields [11]:

- Communication (data exchange within and between ECUs)
- Operating system (real-time execution of ECU software and basic services for other OSEK/VDX modules)
- Network management (configuration and monitoring).

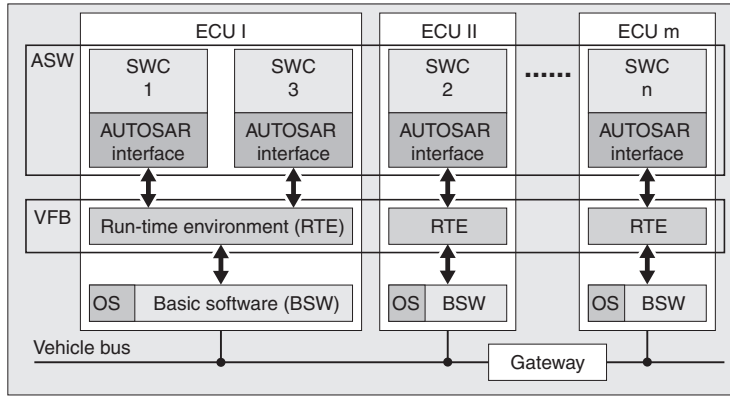
The Japan Automotive Software Platform and Architecture (JasPar) is an initiative for reducing costs and developing technology in automotive electronics. It encourages Japanese companies to develop jointly non-competition-relevant technologies such as network solutions, service functions and basic software. JasPar works in close cooperation with AUTOSAR and FlexRay.

AUTOSAR

AUTOSAR (Automotive Open System Architecture) [12] is a development partnership of vehicle manufacturers, ECU manufacturers and manufacturers of development tools, ECU basic software and microcontrollers. The aim of AUTOSAR is to simplify the exchange of software on different ECUs. To this end, a standardized software architecture has been devised with standardized description and configuration formats for embedded software in automobiles. AUTOSAR defines methods for describing software in vehicles which ensure that software components can be reused, exchanged, scaled and integrated. AUTOSAR is becoming accepted by an increasing number of automakers.

Crucial to AUTOSAR is a logical distribution into ECU-specific basic software (BSW) and ECU-independent application software (ASW) and their connection via the virtual function bus system (VFB) (Figure 2). This virtual function bus also connects software components implemented in different ECUs. In this way, these can be shifted between different ECUs without changes having to be made in the affected software components themselves. This can be useful in optimizing computing power, memory requirements or communication load.

The functional software components (SWC) are strictly separated from each other and from the basic software. They typically contain specific control algorithms executed at run time, the “runnable entities”. They communicate via the AUTOSAR interface with other functions and the ECU Interfaces. These interfaces (API) are defined in SWC XML descriptions.



The run-time environment (RTE) provides the communication services between the functional software components and the corresponding basic software on the ECU. The RTE is tailored to the specific ECU and the application. It can be generated to a large extent automatically from the interface requirements.

The basic software contains the ECU-specific program parts, such as the communication interfaces, diagnostics and memory management. The basic software also contains the service layer. This software combines software components for general service functions (SRV), communication (COM) and the operating system partly dependent on the ECU used (OS) [4, 11]. The latter is based on the OSEK/VDX OS. In this field, the resources of the ECU are subdivided and managed so as to arrive at optimal network support, memory management, diagnostics, etc.

The hardware used is encapsulated in two layers based on each other. Abstraction of the microprocessor (Micro-Controller Abstraction Layer, MCAL) with direct access to the interface modules of the ECU continues in a further layer (ECU Abstraction). “Complex Device Drivers” (CDD) facilitate direct access to microcontroller resources for applications with special functionality and timing requirements. They are also an integral part of the basic software such that the application software can be developed independently of the hardware, even when the services of the complex device drivers are required.

In addition to the ECU architecture, the development methods are also standardized in part by AUTOSAR. This relates, above all, to the structure and the dependencies of the different work products (e.g. files). These are needed in order to generate from the different software component descriptions executable programs for the respective ECUs.

Figure 2: AUTOSAR architecture
ECU Electronic control unit, ASW Application software, SWC Software components, VFB Virtual function bus, RTE Run-time environment, BSW Basic software, OS Operating system.

Diagnostic standards
Vehicle-specific systems for diagnostics for vehicle development and production and for workshops prove to be high-maintenance, cost-intensive and inflexible. They tie the manufacturers to suppliers and prevent simple data communication in the case of cross-company cooperations. Some diagnostic standards have therefore been developed (e.g. [13] and [14]).

The Automotive Electronics working group (ASAM-AE) [5] has devised three specifications for data-based (i.e. software-based) vehicle diagnostics which are published as international standards in the ISO 22900 standard group [15]:
– Interface between run-time environment and communication hardware (MCD-1D and PDU-API, ISO 22900).
– ODX standard for exchange of diagnostic data, e.g. for supplying the workshop tester with data (MCD-2D, ISO 22901, [16]).
– Object-oriented programming interface (MCD-3D, ISO 22900) for diagnostic applications, such as e.g. prompted troubleshooting.

The MCD-1D standard takes into consideration existing standard tools such as, for example, devices for flashing ECUs.

Requirements with regard to an exchange format, the "Open Test Sequence Exchange Format" (OTX), are currently being defined within the framework of an ISO draft in order to create, use and exchange diagnostic sequences.

The development process

The focal point of software development is the depiction of the logical system architecture in a concrete software system with all programs and data. Here, the entire processor-controlled system of the vehicle is considered. Particular importance is attached to a clear separation of specification, design and implementation. Specification of the software functions is performed on the physical level, while design and implementation of programs and data are geared towards the specific microcontroller.

In order to satisfy the above-mentioned requirements in the development of software in automobiles, the defined sequences (processes) are, in addition to the technology and the tools, an integral part of development.

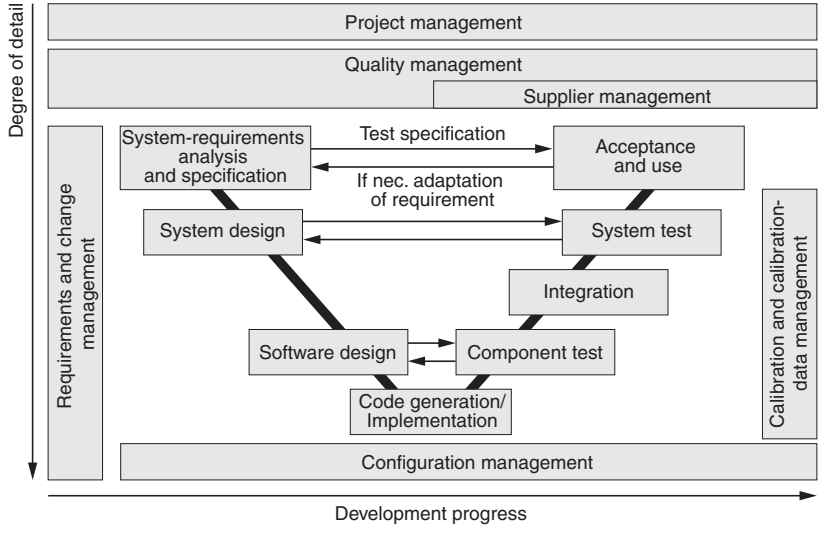
Process description models
Numerous more or less complicated models are used to describe the workflows in software development. They serve to make the sequences transparent, to compare them, to identify problem areas, and to verify conformity in accordance with defined standards. They were, however, not originally conceived to improve directly the quality of the software itself, to increase efficiency or to eliminate systematic faults in the sequences. Process description models are therefore only partly suitable. The common V model will be described here by way of example.

Principle of the V model
The V-shaped representation of the development sequence described here is used in many variations and degrees of detail. The "V model" of the federation for planning and implementing IT projects of central government in Germany [17] will not be described here.

The V model divides the process steps associated directly with development along a V, where the x-axis depicts the development progress and the y-axis the depth, i.e. the degree of detail, of the corresponding process step (Figure 3). A process step can be described by the required input variables, the procedure, the methods, the roles, the tools, the quality criteria, and the output variables. The process steps defined on the left arm are verified on the right arm. These steps can also run several times or be divided.

In the extended V model, accompanying processes such as, for example, request, change, project and quality management, can be considered.

Process evaluation models



Process evaluation models provide, in addition to a pure description of the tasks and sequences, information on the maturity and the quality of the processes. Work steps can thus be compared, evaluated and certified. In this way, it is also possible to identify process gaps which impact, for example, on the product quality or the costs. However, the information on the quality of the processes does not provide a complete picture of the quality of the products themselves here either. The three most important process evaluation models will be described here.

ISO 9000 and ISO/TS 16949

The process-oriented EN ISO 9000 standard series [18] and following stipulates the requirements with regard to a quality management system. The focus here is on the interactions and the interfaces. The original emphasis was on production and the customer interfaces.

The ISO/TS 16949 technical specification [19] was devised in the North American and European automotive industries and standardizes requirements relating to quality management systems. The aim of the standard is to improve effectively system and process quality in order to increase customer satisfaction, to identify failures and risks in the production process and in the supply chain, to eliminate their causes, and to check the effectiveness of the corrective and preventive ac-

Figure 3: Extended V model

tions taken. The core of the specification is not the discovery, but rather the avoidance of failures.

Compliance with ISO 9000 and ISO/TS 16949 can be verified by certification.

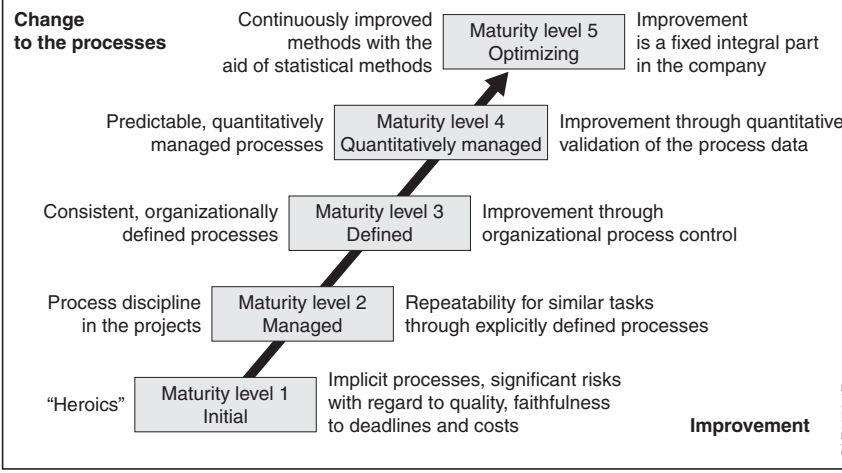
CMMI

"Capability Maturity Model Integration" (CMMI) is a model for evaluating and systematically improving development organizations and their processes [20] which was originally developed by the Software Engineering Institute (SEI). It describes a collection of requirements with regard to the processes and their dependencies (Figure 4). CMMI offers a framework, the implementation of which calls for a business-oriented interpretation and organization of content. It describes what has to be done. The organization must shape the "how" appropriately. The content of CMMI is based on essential industry "best practices". CMMI provides a procedure for process improvement created in the longer term from the path of organization development through to learning organization.

CMMI has much in common in terms of content with ISO 9000 and ISO TS 16949. In this context, CMMI has a higher degree of detail, while ISO 9000 and ISO TS 16949 cover a wider range of application.

CMMI distinguishes between five maturity levels (ML) for an organization unit (Figs. 4, 5). Different process areas are considered, depending on the maturity

Figure 4: CMMI process overview
ML Maturity level



Category	Process areas
Process management	ML3 Organizational process focus (OPF) ML3 Organizational process definition (OPD) ML3 Organizational training (OT) ML4 Organizational process performance (OPP) ML5 Organizational innovation & deployment (OID)
Project management	ML2 Project planning (PP) ML2 Project monitoring and control (PMC) ML2 Supplier agreement management (SAM) ML3 Integrated project management (IPM) ML3 Risk management (RSKM) ML3 Quantitative project management (IPM)
Engineering	ML2 Requirements management (REQM) ML3 Requirements development (RD) ML3 Technical solution (TS) ML3 Product integration (PI) ML3 Verification (VER) ML3 Validation (VAL)
Support processes	ML2 Configuration management (CM) ML2 Process and product quality assurance (PPQA) ML2 Measurement and analysis (MA) ML5 Cause analysis and rectification (CAR) ML3 Decision analysis and resolution (DAR)

Process areas

Elementary management and support processes (ML2)	Engineering processes (ML3)
Organization processes and further management processes (ML3)	"High-maturity" processes (ML4 and ML5)

SAE1177-2E

Figure 5: CMMI maturity level

level. A maturity level is reached when all the corresponding process areas are mastered and verified by an assessment. To reach a higher maturity level, the process areas of the maturity levels underneath must also be verified again.

CMMI is used as an improvement and evaluation model for development organizations and offers good support for organization-wide process optimization and auditing of suppliers.

Automotive SPICE

SPICE stands for "Software Process Improvement and Capability Determination". Automotive SPICE [21] is a motor-vehicle-specific variant of the international ISO/IEC 15504 standard (processes in the life cycle of software, [22]). It is a model for project-specific evaluation of software development processes and concentrates, like CMMI, on the requirements for systematic development. The model content of Automotive SPICE and of CMMI is therefore very similar. Automotive SPICE concentrates more on the requirements level and affords less scope for the business-oriented interpretation of requirements. Automotive SPICE focuses (currently) only on the software and only on individual projects. In contrast, the ranges of application of CMMI go further, comprising development activities and services of all kinds and their direction through the organization. Automotive SPICE is used by motor-vehicle manufacturers as an evaluation model for software projects of suppliers.

The process assessments are carried out using the two-dimensional reference and assessment model. The "process dimension" serves to identify and select the processes to be analyzed in the assessment, the "maturity-level dimension" on the other hand serves to determine and evaluate their respective capability. The maturity-level dimension consists of the six maturity-level stages "incomplete", "performed", "controlled", "established", "predictable" and "optimizing".

Quality assurance in software development

As with any technical product, numerous tools for quality assurance are also used on software. In contrast to mechanics and electrics, quality assurance plays a lesser role in the manufacture of software, since software is relatively easy to reproduce. Important emphases are the overall functionality of the system, the quality standards, mastery of complexity, and application. Because the software in a motor vehicle also includes safety-relevant systems such as, for example, driving-dynamics and driver-assistance systems, the verifiability of quality plays an important role. Even the economic representation of the aimed-for software quality, especially in complex systems, is very important.

ISO 26262

Based on the IEC 61508 standard [23], the ISO 26262 standard [24] has been introduced by the automotive industry for drafting safety-related electric and electronic systems in motor vehicles. This comprises requirements relating to both the product and the development process, and thus comprises conception, planning, development, implementation, startup, maintenance, modification, shutdown and uninstallation both of the safety-relevant system itself and of the safety-related (risk-reducing) systems. The standard designates these phases in their entirety as the "entire safety life cycle". The products are subdivided into Safety Integrity Level SIL 1 through SIL 4 (ISO 61508) and Automotive SIL, ASIL A through ASIL D (ISO 26262). SIL 1 and ASIL A are the lowest, SIL 4 and ASIL D the highest safety integrity level.

Workflows of software development in motor vehicles

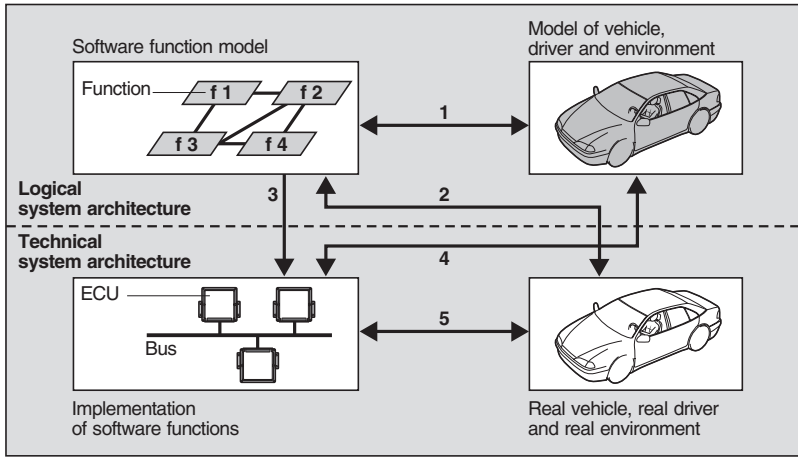
Interdisciplinary cooperation in development (e.g. between drive and electronics development), distributed development (e.g. between supplier and vehicle manufacturer or at different development locations) and the long life cycles of the software elements call for a common and holistic understanding of the tasks involved. For example, when designing the open-loop and closed-loop control functions of a vehicle, it is also necessary to maintain an overview of overall reliability and safety requirements, as well as the aspects of software realization. To meet these challenges, model-based development has established itself in many fields of application (Figure 6).

Model-based development

Model-based development distinguishes between two areas. The logical system architecture comprises and describes the virtual area of the models, while the technical system architecture contains the real ECUs and vehicles. The "logical system architecture" is gray in the figures and the "technical system architecture" is white. This procedure is described in terms of open-loop and closed-loop control functions, but is also suitable for general realization of functions – for example, for monitoring and diagnostic functions.

A graphics-based function model considers all system components and can be used as the basis for a general understanding. In software development, the use of model-based development methods, with notations such as block diagrams or finite state machines, is replacing written software specifications to an increasing extent. This method of modeling software functions has still other advantages. If the specification model is formally described, i.e. unambiguously and without leeway for interpretation, as a mathematical function, the specification can be executed on a computer in a simulation, and tested quickly and realistically in the vehicle itself by means of "rapid control prototyping". Inconsistencies can also be uncovered more easily.

Methods of automated code generation can be used to implement the specified function models as software components for ECUs. The function models, therefore, need to contain additional software design information. These may include optimization measures, depending on the product characteristics required by the electronic system. Automated code generation also ensures that the code has consistent quality characteristics.



In the next step, virtual environment models, which are supplemented if necessary by real components such as injectors, simulate the environment of the ECUs, facilitating "In-the-loop tests" in the laboratory. Compared to test-bench and road tests, this increases flexibility and enhances test depth, thereby making test cases easier to reproduce.

The calibration of the software functions in the electronic system must consider the vehicle-specific settings, for example, parameters stored in the form of characteristic values, characteristic curves, and characteristic maps of these functions. In many cases, this matching does not take place until a later stage in the development process, frequently directly in the vehicle while the systems are running. The trend, however, is increasingly towards an earlier preliminary data feed; i.e. starting in the early development phases the most realistic calibration data possible is determined using models or empirical values. Because of the multitude of calibration variables and the mutual dependence, the calibration requires suitable procedures and tools, because in the end the quality of the calibration engineering, i.e. the exact adaptation of the software to the vehicle, decides the extent to which the potential of the software is utilized.

Efforts to shift development steps ahead are increasing, i.e. in the realm of simulated (virtual) environment, to detect faults early and save on expensive test hardware and experimental vehicles

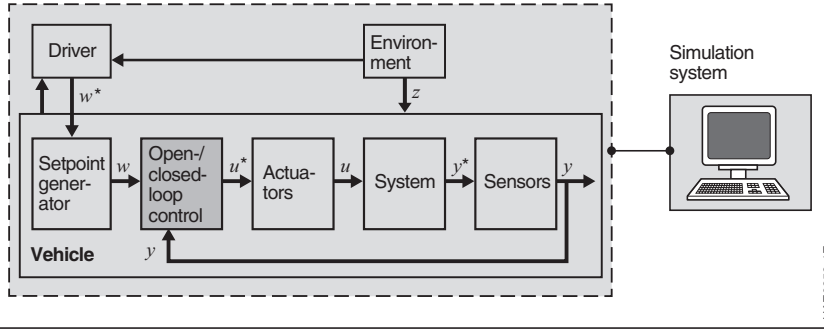
Figure 6: Development steps in the model-based development of software functions

Step 1: Modeling and simulation of the software functions for the ECU and of the vehicle, driver and the environment on the computer (software functions are all the functional program parts of the software),
Step 2: Rapid control prototyping of the software functions in the real vehicle,
Step 3: Implementation of the software functions in the real vehicle,
Step 4: Integration and testing of the ECUs with In-the-Loop test systems, laboratory assemblies and test benches,
Step 5: Testing and calibration of the software functions and of the ECUs in the vehicle.

(front loading). High-performance simulation tools and virtual ECU environments make this possible.

Function and ECU networks
This procedure can also be applied to the development of function networks and ECU networks. In these cases, however, additional aspects are introduced, such as:
– combinations of modeled, virtual, and functions already realized in ECU code, and
– combinations of modeled, virtual, and realized mechanical components and hardware.

It is useful, therefore, to distinguish between functions at an abstract level, and technical realization at a more concrete level. The concept of a separate abstract and concrete approach can be applied to all vehicle components, the driver, and the environment.



Modeling and simulation of software functions

Modeling
Block diagrams should be used where possible to model open-loop and closed-loop control systems. These diagrams use blocks to represent the response of components, and arrows represent the flow of signals between the blocks (Figure 7). As most of the systems are multivariable systems, all signals are generally in vector form. These are classified into:
– measurement or feedback variables y,
– open- or closed-loop control output variables u^*,
– reference or setpoint variables w,
– driver setpoint values w^*,
– open- or closed-loop control variables y^*,
– manipulated variables u,
– disturbance values z.

The blocks are classified into:
– open-or closed-loop control,
– models of actuators,
– system model,
– models of setpoint generators and sensors, and
– model of the driver and the environment.

The driver can influence the functions of the open- or closed-loop controller by defining setpoint values. All components for entering setpoint values for the driver (for example, switches or pedals), are known as setpoint generators. Sensors, in contrast,

Figure 7: Modeling with block diagrams and simulation

record signals from the plant. A model of this type can be executed on a simulation system (for example, a PC), thus allowing it to be analyzed in more detail.

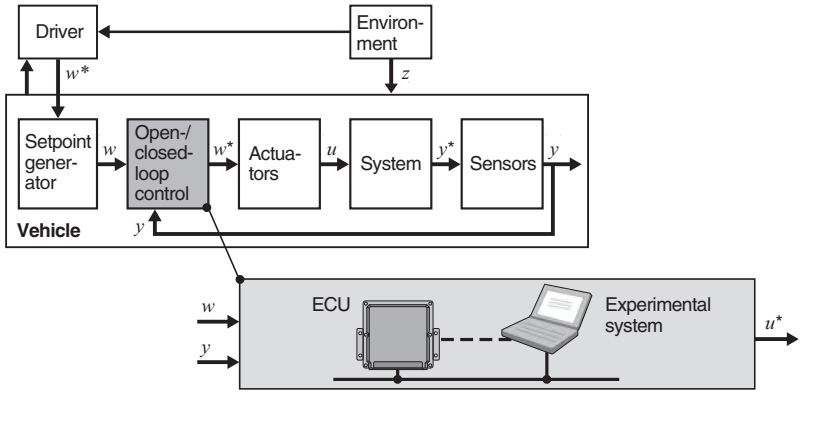
Rapid control prototyping of software functions

Rapid control prototyping in this context includes all methods for the early implementation of specifications of open-loop and closed-loop control functions in the real vehicle. To allow this, the modeled open- or closed-loop control functions must be implemented in the test. Experimental systems can be used as an implementation platform for the software parts of the open- and closed-loop control functions (Figure 8).

The experimental systems are connected to the setpoint generators, sensors and actuators, as well as the other vehicle ECUs that belong to the overall system. The interfaces to the real vehicle mean that the software functions implemented in the experimental system – and in the ECU – take into account real-time requirements.

Real-time computer systems with considerably higher computing power are usually deployed as ECUs in experimental systems. PCs are increasingly being used as the processor core for this task. This allows the model of a software function to be automatically converted from a specification into an implementable model using a rapid control prototyping tool that is subject to standardized rules. The specified behavior can then be modeled as accurately as possible.

Experimental systems with a modular structure can be configured specifically for the application, for example, in terms of the required interfaces for input and output signals. The overall system is designed for deployment in the vehicle, and is operated using a computer, e.g. a PC. This allows the testing of software function specifications directly in the vehicle at an early stage. The specifications can then be changed as required.



When using experimental systems, there is a choice between bypass and fullpass applications.

Bypass or fullpass applications

Bypass applications are mainly used if only a few software functions are under development, and an ECU with tried-and-true basic functionality is available – for example, from a previous project.

Bypass applications are also suitable if the sensor and actuator functions of an ECU are very complex, and supporting them requires significant effort on the part of the experimental system (for example, in the case of engine ECUs).

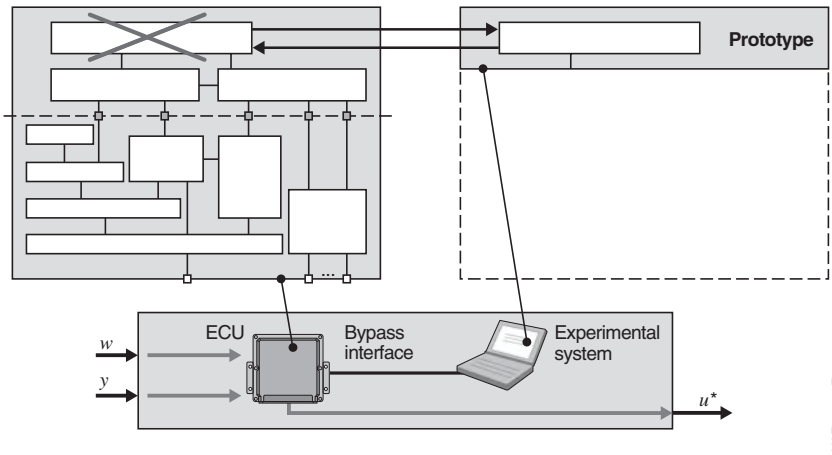
Figure 8: Rapid control prototyping for software functions in the real vehicle

Fullpass applications are more suitable if an ECU of this type is not available, if additional setpoint generators, sensors, and actuators also need to be tested, and if the scope of the ECU is of manageable complexity.

It is also possible to combine a bypass of individual software parts and a fullpass of the entire software. This has the advantage of increased flexibility.

Bypass applications

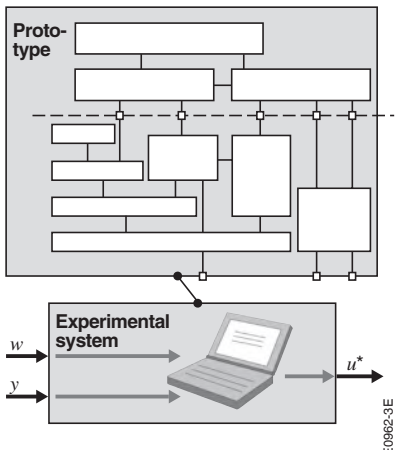
Bypass development is suitable for early testing of an additional or modified software function of an ECU in the vehicle. The new or modified software function is defined by a model and run on the experimental system. This requires an ECU that can run the basic functionality of the software system, support all the necessary desired-value generators, sensors, and actuators, and provide a bypass interface to the experimental system. The new or modified software function is developed using a rapid control prototyping tool. It is then run on the experimental system (Figure 9).



This approach is also suitable for further developments to existing ECU functions. In this case, the existing functions in the ECU are still used, but they are modified to the extent that the input values are sent via the bypass interface, and the output values from the newly developed bypass function are used. The required software modifications to the ECU are called the bypass hooks. These can also be used in previously compiled software with modern development tools. For the essential synchronization of functional computing between the ECU and the experimental system, a procedure is normally adopted in which the ECU triggers computation of the bypass function on the experimental system via a control flow interface. The ECU monitors the output values of the bypass function for plausibility.

The bypass can also be effected via the vehicle bus (e.g. CAN). Even direct access to the CPU of the ECU via the microcontroller interfaces is possible by means of an emulator probe.

Fullpass calibration

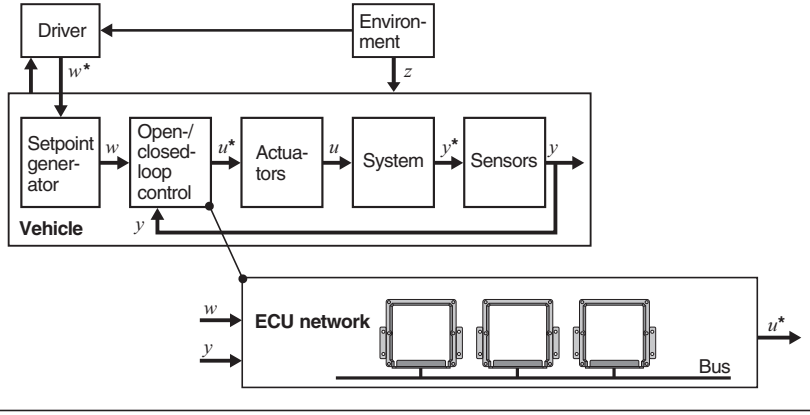


If a completely new function is to be tested in the vehicle, and an ECU with a bypass interface is not available, the test can be carried out using a “fullpass” development. In this case, the experimental system must support all the setpoint generators, sensors, and actuator interfaces for the function. The real-time behavior of the function must also be defined and guaranteed by the experimental system (Figure 10). In general, this is performed by a real-time operating system on the fullpass computer.

Figure 9: Prototype development with bypass system

Virtual prototyping
In the case of complex systems, it is advantageous to test functions as early as possible. One possibility is offered by virtual prototyping. Here the prototype is tested on a virtual environment model. The operating system of the later ECU (e.g. RTA) runs on the experimental system. This enables the time response of the later software to be considered as well.

Figure 10: Prototype development with fullpass system



Design and implementation of software functions

Based on the specification of data, the functional behavior and the real-time behavior of a software function, all the technical details of the ECU network, the implemented microcontroller, and the software architecture must be taken into account at the design stage. The final implementation of the software functions can then be defined and executed on the basis of software components (Figure 11).

In addition to decisions regarding the design and behavior of a software function, that takes the time and discrete-related functions of the microcontrollers into consideration, an implementation includes design decisions regarding real-time behavior, distribution and integration of microcontrollers and ECUs, and reliability and safety requirements of the electronic systems. All requirements for electronic systems and vehicles from the production and service viewpoints must also be taken into account (for example, monitoring and diagnostics concepts, the parameterization of software functions, or software updates for ECUs in the field).

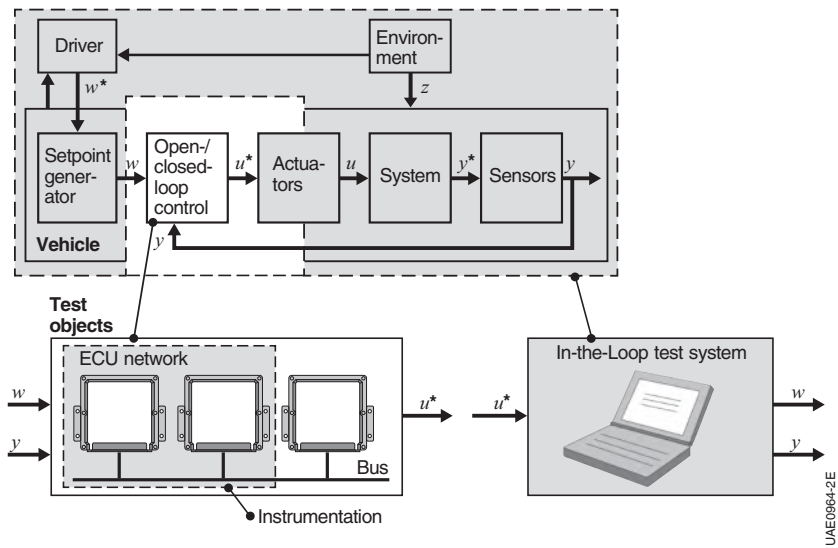
Generation of the code and of the accompanying data (e.g. data for documentation, variant management or preliminary data feed of the calibration) is often performed automatically in accordance with established standards.

Figure 11: Realization of open-loop and closed-loop control functions using an ECU network

Integration and testing of software and ECUs

Requirements

Prototype vehicles are often only available in limited numbers. It means that a component supplier often does not have a complete or up-to-date integration and test environment for the components supplied. Restrictions in the test environment can sometimes limit the possible test steps. For this reason, the environment models often serve as the basis for test systems and test benches in the integration and test phase.



Component integration is a synchronization point for all the individual component developments involved. The integration test, system test, and acceptance test cannot be carried out until all the components are available. For ECUs, this means that the software functions can only be tested when all the components in a vehicle system are available (ECUs, setpoint generators, sensors, actuators, and system). The use of In-the-Loop test systems in the laboratory allows early verifications on ECUs in a virtual test environment in the absence of actual peripheral components (Figure 12).

This allows tests to be performed and automated under reproducible laboratory conditions with a high level of flexibility. In contrast to tests on the test bench or in the real vehicle, the full, unrestricted range of operating states can be tested (for example, an engine ECU can be tested at all load and rpm situations). Vehicle wear and failure situations are easy to simulate, and allow testing of the monitoring, diagnostic, and safety functions of the ECU. Component tolerances (for example, in setpoint generators, sensors, and actuators) can be simulated to allow a verification of the robustness of open-loop and closed-loop control functions.

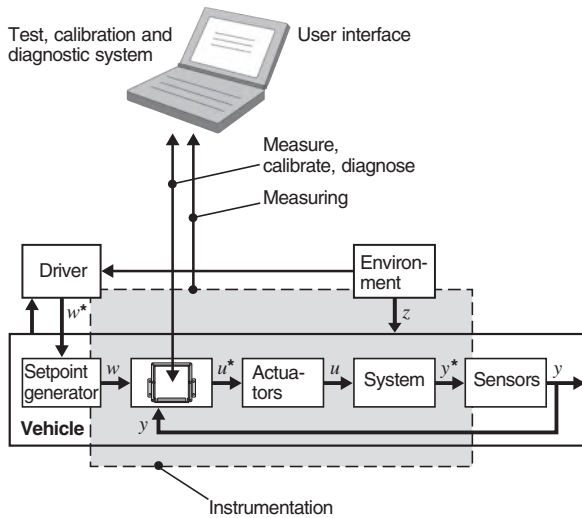
A significant benefit is also the great test depth which can be achieved through automation. This enables, for example, as many fault types as possible and their combinations to be tested under exactly reproducible conditions and documented by means of a failure log.

This procedure can also be applied to testing actual setpoint generators, sensors, and actuators. The interfaces of the

Figure 12: Integration and testing of ECUs with an In-the-Loop test system

test system need to be modified accordingly. Any intermediate steps can also be incorporated into the procedure.

A structure as illustrated in Figure 12 depicts the ECUs in the form of a black box. The behavior of the ECU functions can only be assessed on the basis of the input and output signals w, y and u^*. This "black-box view" is sufficient for simple software functions. But testing more complicated functions requires the integration of a measurement procedure for internal ECU intermediate variables. This type of measuring technique is also known as instrumentation. The testing of diagnostic functions also requires access to the fault memory via the ECU diagnostics interface, and this requires the integration of a measurement and diagnostics system.



In-the-Loop test systems

In-the-Loop is a test procedure in which an embedded electronic system is connected via interfaces to a real (e.g. sensors, actuators) or virtual environment (mathematical models). The reaction of the system is analyzed and played back to the system. Depending on the type of test specimens, a distinction is made between the following test systems:

- In the case of Model-in-the-Loop (MiL), the function model of the software is tested. The model runs on a development computer.
- In the case of Software-in-the-Loop (SiL) the software code is tested. It runs on a development computer.
- In the case of Function-in-the-Loop (FiL), the software code is also tested. However, in contrast to SiL, this runs on the destination hardware. Coupling between the software and the environment model is performed by means of hooks and an emulator probe.
- In the case of Hardware-in-the-Loop (HiL), the complete ECU is tested by means of the input and output interfaces (I/O). Combinations of FiL and HiL are also used. PCs are increasingly being used as simulation computers.

In-the-Loop test systems can be used to validate and further develop software and hardware.

Figure 13: Integration and testing of ECUs in the real vehicle

Calibration of software functions

Procedure

Each electronically controlled vehicle system can only then develop its capability when it is optimally adapted to the respective vehicle type. In order for software functions to be used in as many vehicle variants as possible, these contain variable parameters. Adapting these parameters to the corresponding vehicle variant and for every operating condition (e.g. cold running, extreme heat or altitude) is known as calibration. To reach the desired level of functionality in the complete vehicle, a multitude of characteristic values, characteristic curves and program maps – the calibration data – must be applied.

Most changes to the vehicle require a change to the calibration. An example here: The λ oxygen sensor in the exhaust-gas system measures the residual oxygen in the exhaust gas. The fuel quantity actually injected can be determined on the basis of this signal. In this way, it is possible to adapt the activation parameters in the engine ECU exactly on a continuous basis. Changes to the exhaust-gas system which result in a change to the exhaust-gas back pressure at the point where the λ sensor is installed (e.g. altered exhaust manifold, particulate filter) must be adapted. If this is not done, this will result in a deterioration in consumption and emissions.

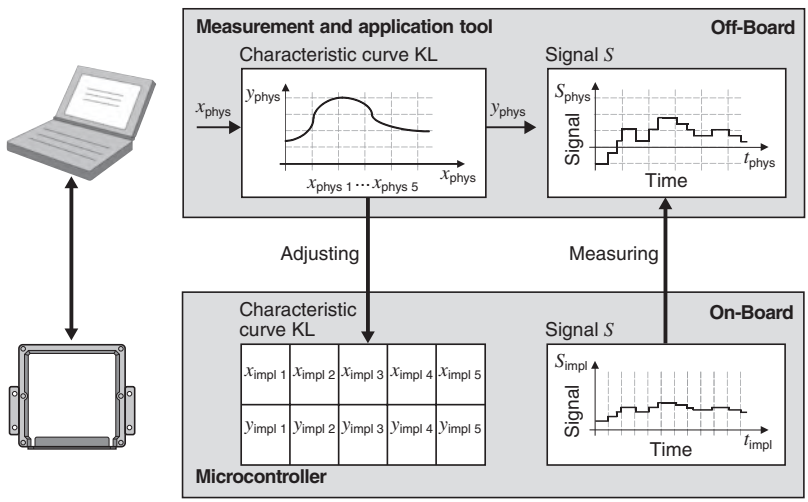
Variant management can be simplified in development, production and service by separating program and data statuses. The program status contains, for example, all the information on the variables to be applied and their limit values and correlations, while the data status contains the variables actually applied.

Calibration takes place in the laboratory on engine and vehicle test benches during vehicle tests and under real environmental conditions on test tracks. In addition to a measurement and diagnostic system, a calibration system is often required to calibrate internal ECU parameters (such as characteristic curves and program maps). On completion of calibration, the determined data are comprehensively checked. These values are then stored in the read-only memory (EPROM or flash) of the series ECU.

The parameter values must be variable during calibration. A calibration system, therefore, consists of one or more ECUs with a suitable interface to a measurement and calibration tool (Figure 14). In addition to their deployment in vehicles, measurement, calibration and diagnostic systems can also be used in in-the-loop test systems and on test benches. It is being applied more and more often in a virtual environment. Here, high-performance tools assist in finding the trade-off (optimal compromise of the calibration data).

Changes to the parameter values, for instance to the values of a characteristic curve, are supported in the calibration tool by editors. Alternatively, these operate on the implementation level (i.e. with the applied values) or on the physical specification level. Accordingly, the measurement tool converts recorded values into a physical representation or an implementation representation. Figure 14 shows an example of the physical and the implementation levels for a characteristic curve and a recorded measurement signal.

When working with calibration systems, it is usually possible to choose between offline and online calibration.



Offline calibration
In offline calibration, the execution of open-loop control, closed-loop control, and monitoring functions, i.e. of the "drive program", are interrupted to modify or adjust parameter values. Offline application therefore leads to many restrictions. In particular when deployed on test benches and during in-vehicle testing, it always causes an interruption to the test-bench or road test.

Online calibration
In online calibration, the parameter values can be adjusted while the microcontrollers are executing the software functions. It is, therefore, possible to adjust parameter values while executing open-loop control, closed-loop control, and monitoring functions at the same time, and hence during regular use at the test bench or in vehicle.

Online calibration places higher demands on the stability of the open-loop control, closed-loop control, and monitoring functions, since the driving schedule must remain stable during all adjustment procedures if exceptions occur, for example, if the distribution of interpolation points in characteristic curves fails to rise monotonically for short periods of time. Online calibration is suitable for long-term modification of less dynamic parameters (for example, tuning of engine control functions on the engine test bench).

For applying more dynamic functions or safety-critical functions (for example, setting the software functions of an ABS system for braking maneuvers during a test drive), the settings are not adjusted during actual braking maneuvers. In this case, online calibration can still save time by avoiding any interruptions in the program execution, thus reducing the interval between two test drives.

Outlook

New vehicle functions and technologies will continue to lead to an increase in the scope of software in motor vehicles – even in the low price segment. In the process, the number of ECUs stays the same in many vehicles. As a consequence, the scope of functions of some ECUs is continuing to increase. In all, the system limits between the different ECUs are disappearing more and more, such as, for example, in the management of a hybrid drive. The electronics in motor vehicles are thus becoming ever more complex – including beyond an individual vehicle. The economic mastery of complexity is therefore certainly a key element in future automotive software engineering and the associated development environments.

Another trend is the increasing virtualization of development. Virtualization involves integrating parts of later development steps, such as testing and calibration, into the earlier development phases such that the function models can be optimally tested in-the-loop and fed with data on a preliminary basis early on. In this way, failures are detected earlier, support is provided for distributed development and bottlenecks shortly before series startup are avoided.

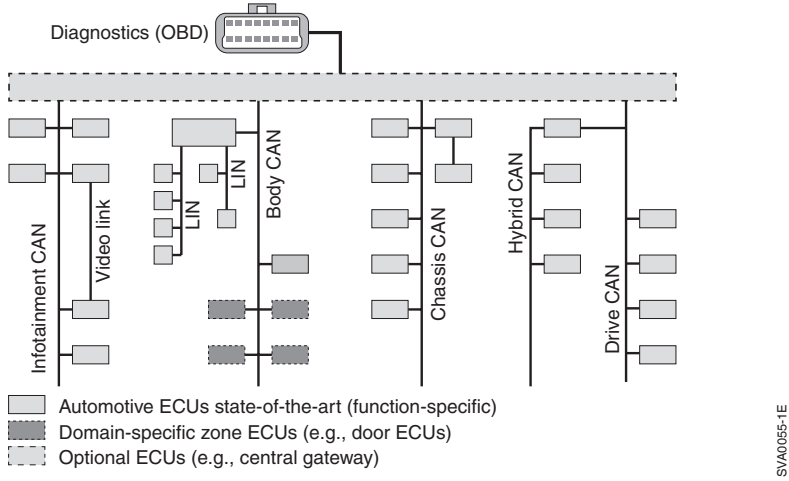
Architecture of electronic systems

General

Owing to the increasing demand for safety, comfort, entertainment, and environmental protection, electronic systems in motor vehicles realize an increasing number of functions and are characterized by a high level of networking and complexity. Optimized processes, methods, and tools of system architecture are required to keep on top of this structure in the future too.

History



Over the many decades of automobile history, there has been a manageable number of electrical systems in motor vehicles: ignition, lighting, windshield wipers, horn, fuel gage, various indicator lamps, and a vehicle radio. Semiconductors were used initially – except in vehicle radios – only for rectification (direct-current generator replaced by alternator from approximately 1963) and then later for electronic control (transistorized ignition from 1965).

Certain in-vehicle functions were realizable with electromechanical means or with discrete electronic components either not at all or only with disproportionately high complexity. Thus, for example, the first electronic antilock braking system (ABS) had already been developed in 1970, but was never ready for series production on account of its size, weight and cost. By the mid-1970s the development of integrated circuits for a broad range of applications had also reached and revolutionized automotive engineering.

One of the first instances of the networking of electronic systems came about during the development of the traction control system (TCS). This networking was initially realized by purely mechanical means. The throttle valve in the air-intake system of the internal-combustion engine was fitted with a device which could be activated directly by the traction control system. It was not discernible to the engine management whether the driver or the traction control system was moving the throttle valve.

The next stage involved the realization of an electronic connection to the engine control unit via a PWM interface (pulse-width modulation) to improve dynamic response. This could be used to transfer

Figure 1: ECU interconnection in a modern mid-size vehicle

the signal to the engine control unit for reducing the drive torque. This was then implemented in the form of an air-supply throttling, an injection blank-out or an ignition- angle adjustment.

On account of the ever more stringent exhaust-emission regulations the possibilities represented up until that point of coupling between the traction control system and the engine management were no longer sufficient. What was now required was to transmit to the engine management how a reduction of the drive torque requested by the traction control system is effected in the air, fuel or ignition path. It was therefore necessary to come up with a more powerful interface via which a desired torque and a dynamic-response request could be transmitted from the traction control system to the engine management. By contrast, the actual torque, the engine speed and the current setting reserve were to be transmitted to the TCS control unit. It proved complex and expensive in terms of the number of cables required to transfer these different data via discrete and, for example, pulse-width-modulated interfaces. The CAN bus system (Controller Area Network) was introduced in 1991 as an alternative to discrete cabling. In this way, the foundations for the modern networking of systems in motor vehicles were laid.

Technology of the present day

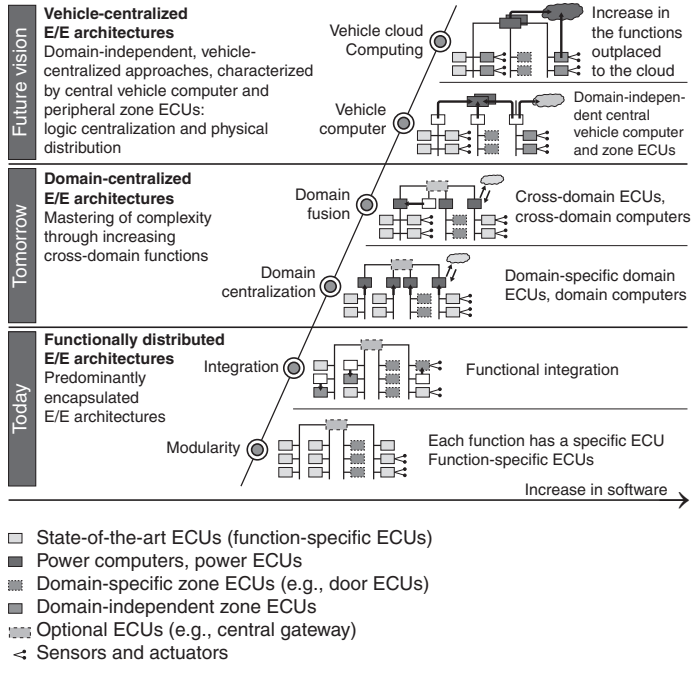
In today's vehicles, virtually all the ECUs are networked directly or indirectly (e.g. via gateways) with each other (Figure 1).Gateways facilitate the exchange of data between different communication systems and beyond vehicle limits (connection to radio systems and the Internet). Networking goes to some extent so far that 60 or more ECUs communicate via several CAN or CAN FD bus systems (CAN with Flexible Data-Rate) and further communication systems, such as FlexRay, MOST (Media Oriented Systems Transport) or LIN (Local Interconnect Network), with each other. Aside from the classic communication systems, Ethernet is also used for various vehicle functions which require a large bandwidth. This is the case for example with a 360° camera for automatic park assist, which enables the driver among other things to have a bird's-eye view of the vehicle for example in the infotainment-system display.

Because of the powerful networking between the ECUs, some new performance features can even be achieved completely without additional hardware, i.e. purely by means of data communication and software. An example of this is the tire-pressure monitoring system (TPMS). Since the end of 2014 a tire-pressure monitoring system has been mandatory in all vehicles. There are two ways of realizing such a system: firstly as an indirect solution and secondly as a direct solution. The indirect solution uses the wheel-speed sensors of driving-dynamics control (Electronic Stability Control, ESC) and thus does not require any further hardware. As soon as a wheel loses air, the wheel diameter decreases, as a result of which the wheel must turn more quickly and consequently the air loss can be determined by means of an algorithm.

Also classed as state-of-the-art are numerous Advanced Driver Assistance Systems (ADAS). For example, the car manufacturers offer functions such as Adaptive Cruise Control (ACC), Lane Keeping Support, or the combination of adaptive cruise control and lane keeping support known as Integrated Cruise Assist (ICA), and many others. All this can be realized with a matching E/E architecture with suitable sensors, such as for example a video camera, radar sensors, and ultrasonic sensors.

Development trends

The increasing number of electronic and electrical components in modern vehicles and the constantly increasing complexity necessitate a continuous further development and constant technological advances in E/E architectures. For this reason, E/E architectures of vehicles have in the past obviously changed with regard to the communication technologies and also in their systemic manifestation. Further developments will also be constantly identifiable in the future. The following text will examine the evolution of E/E architectures and provide an outlook of future developments and trends (Figure 2).



Distributed E/E architectures – modularity and integration
The picture of the first E/E architectures and their comparably lower level of complexity was initially characterized by their strong modularity (Figure 2, bottom third). Logic functions were distributed to many individual ECUs – function-specific ECUs – in the vehicle such that virtually every function had its own ECU with performed the function. In the ensuing period, with the sharp increase in functions, new functions were frequently integrated in ECUs that already existed in the vehicle. The reasons for this in particular are the rapidly growing number of ECUs and the associated rising costs. An example of functional integration is the integration of a parking-assist function in the "Body Control Module", which is essentially responsible for controlling and monitoring the functions and components of the body electronics (e.g. light-actuator technology, door-actuator technology).

For the reasons mentioned this stage of development of the E/E architectures is called "Functionally distributed E/E architectures" (Figure 2).

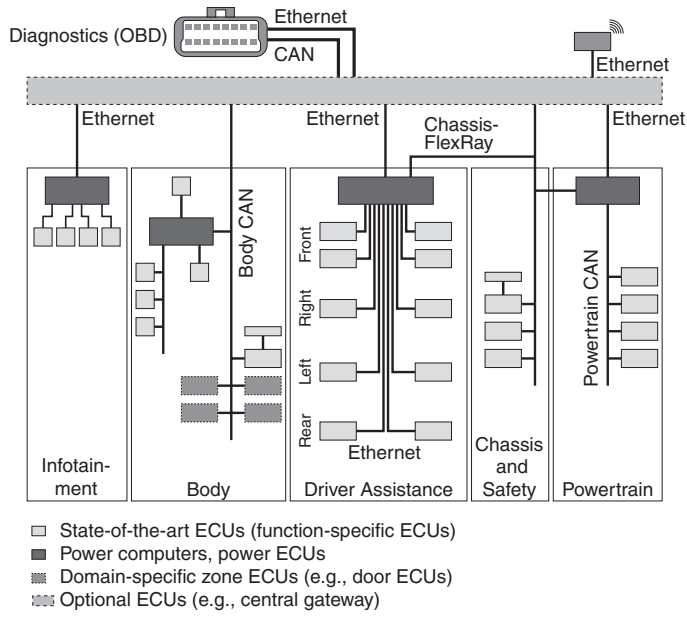
Domain-centralized E/E architectures
In the ensuing step – the domain-centralized and cross-domain-centralized E/E architectures – not only do the number of electronic and electrical components and the number of functions continue to rise sharply, but also increasingly the dependencies of the functions within the individual domains (Figure 2, middle third). The term "domain" refers to the grouping of similar functions. Typical domains are shown in Figure 3.

Furthermore, the interfaces and dependencies between the domains increase sharply. This development is already

Figure 2: Bosch E/E architecture roadmap

clearly discernible in today's vehicle architectures and will take on an ever more significant role in future. An example of this is the cross-domain function "Vehicle Motion Control", which will be described in more detail later. Thus, in this case, sensors, actuators, and functions from the "Powertrain" and "Chassis and Safety" domains interact directly with each other.

In other words, increasingly vehicle-wide functions extending over a number of domains stand out. The associated strong logic interaction and networking as well as the resulting dependencies give rise from a functional perspective to a centralization. This means that, instead of the originally modularly distributed arrangements, increasingly functions are being bundled into domain ECUs, domain computers, or event into cross-domain ECUs or cross-domain computers.



Therefore the term used for the E/E architectures of tomorrow is "Functionally domain-centralized E/E architectures" (Figure 3).

Vehicle-centralized E/E architectures

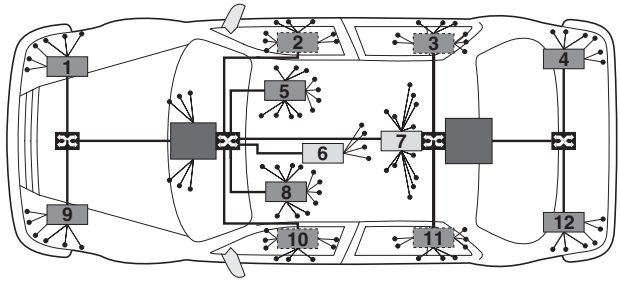
If one takes a further look into the future, the vehicle is in particular characterized by a high degree of automation, networked systems – vehicle-internal and vehicle-external – and by multimedia and infotainment applications. These vehicle properties impose the highest demands on the E/E architecture and on the communication network. In this way, requirements with regard to maximum permissible latencies or the number of hops (path from one network node to the next) acquire ever greater importance. This constitutes a huge challenge for classic E/E architectures. For this reason, the trend is towards functional centralization (Figure 2, top third).

If all the logic were to be brought together on a powerful central vehicle computer, an ideal state would be achieved for example with regard to the mentioned latency requirements and the number of hops. All the functional interfaces would then be located within this central vehicle

Figure 3: Schematic diagram of a functionally domain-centralized E/E architecture

computer. This is the basic idea behind centralized E/E architectures, consisting of a central vehicle computer which with extremely high computing capacity constitutes a vehicle-wide functional control system and a number of zone ECUs. While a large part of the complex logic of the highly automated and comfortable vehicle of the future will therefore be realized in the central vehicle computer, the peripheral zone ECUs function from a communication standpoint as gateways and from an energy standpoint as supplying and driving elements for the vehicle sensor and actuator technologies. In order to guarantee the high communication demand and hence the high bandwidths, technologies such as Ethernet will in future take up greater shares of the communication network and entail new concepts (Figure 4).

Furthermore, even outplacements of logic elements to the back end – the so-called cloud – are conceivable in order to be able to calculate cross-vehicle information and algorithms, for example the calculation of traffic forecasts, not locally but centrally and to make available a number of vehicles or vehicle fleets.



The following section describes using highly automated driving functions how these bring an influence to bear on the E/E architectures in modern vehicles.

Effect of highly automated driving functions on the E/E architecture

Nowadays car manufacturers increasingly advertise with driver-assistance functions which make it easier for drivers to negotiate road traffic safely and comfortably. As good as all the functions that can be bought today by the end customer are assistance functions in which the driver is supported but not replaced. This is to change in the near future. Car manufacturers and suppliers are meticulously developing highly automated driving functions to further relieve the load on drivers. A distinction is made here between assisted (driver has to monitor) and piloted (driver does not have to monitor) driving. The German car industry has in a panel of experts come up with a uniform understanding of the stages of automation [1].

Starting at Stage 0, in which the driver exclusively assumes longitudinal and lateral control of the vehicle, right up to Stage 5, in which the system can automatically manage all situations during driving and a driver is no longer required (Table 1). The factors driving the development of highly automated driving are, aside from greater road safety, above all increasing comfort and convenience and more time which the driver can use for other activities. Activities like for example writing e-mails, surfing the Internet, and many more are then possible while driving.

For highly automated driving to be possible at all, it needs a powerful and reliable E/E architecture. The following section will address which E/E architecture blocks and which adaptations are required for this.

E/E architecture blocks

To realize a powerful and reliable E/E architecture, certain E/E architecture blocks are needed. These include among others communication, the vehicle electrical system, the sensor and actuator set, and performant ECUs. For highly automated driving functions it is important that parts of these E/E architecture blocks are always available. This gives rise to high safety requirements, which can only be satisfied by fallback levels (redundancies) in the event of a fault. Such concepts are also called fault-tolerant. Here, redundancy can refer to communication, the vehicle electrical system, and the software and the hardware.

The E/E architecture blocks and corresponding fallback levels are described in the following.

Fault-tolerant communication network

Highly automated driving functions in vehicles must ensure that required information is always available between two components. For example, it must always be possible for the brake and the steering to receive the necessary information as to whether the vehicle hast to be braked or steered. Redundant communication can be used to satisfy this safety requirement. A distinction is made here between a

Table 1: Degree of automation acc. to VDA (source: VDA)

Stage	Degree of automation	Description	
		Driver	Automation
0	Only driver	Driver constantly performs longitudinal and lateral control	No intervening vehicle system active
1	Assisted	Driver constantly performs longitudinal or lateral control	System assumes the other function in each case
2	Partially automated	Driver must constantly monitor the system	System assumes longitudinal and lateral control in a specific application
3	Highly automated	Driver must constantly monitor the system Driver must potentially be in a position to take over	System assumes longitudinal and lateral control in a specific application System identifies system limits and prompts the driver to take over with a sufficient time reserve
4	Fully automated	No driver required in the specific application	System can automatically manage all situations in the specific application
5	Driverless		System can automatically manage all situations throughout the entire journey No driver required

variety of topologies: ring, star, bus, and fully meshed topology (Figure 5, see also Networking in motor vehicles).

Fault-tolerant vehicle electrical system
Like the communication network, the vehicle electrical system must also have a fault-tolerant design. The vehicle electrical system can be divided into three elements (Figure 6): storage elements (e.g. battery), coupling elements (e.g. DC/DC converter), and source elements (e.g. alternator).

To enable the vehicle to still be controlled accordingly in the event of a fault, the safety-related components, which for example implement the braking and steering functions, are supplied by two completely independent storage devices. These two storage devices are in the event of a fault separated via a coupling element, meaning that the fault is encapsulated and consequently the fault is prevented from spreading to the other supply channel. On account of the redundant actuator technology, in this case the safety-related functions like braking and steering continue to be available – for a limited time at least – for a transition to a safe state, even if a supply channel fails.

Sensor redundancy concept
An important influencing factor for highly automated driving is the vehicle environment. This is detected by a variety of sensors such as radar, lidar, camera, and ultrasonic sensors. GPS and inertial sensors are also used to pinpoint the vehicle position. In combination it is possible to determine both what is situated around the vehicle and where the vehicle itself is situated.

A redundant sensor set can also be realized with the basis of the redundant communication network and the redundant vehicle electrical system. It is import-

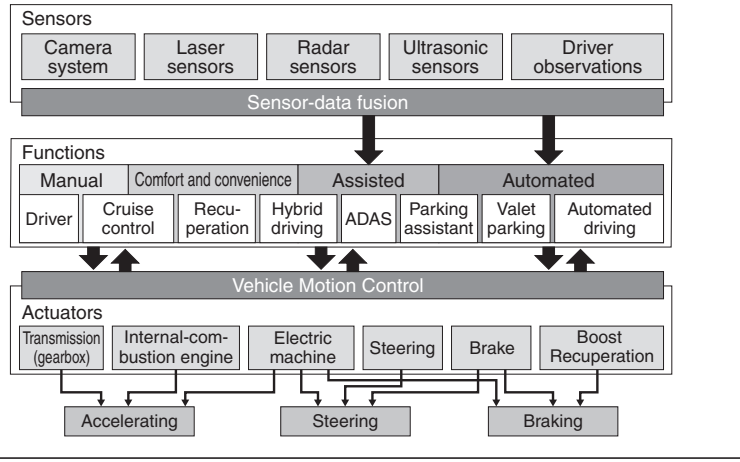
S Starter,
G Alternator.

ant here that a field of view (FoV) is always covered by different sensor principles so that the environment can be reliably detected in all situations. For example, the sensors should be split between the two supply channels in such a way that the field of view is covered during normal operation by sensors A, B, C, and D, in fault scenario I (fault on supply channel 1) by sensors B and C, and in fault scenario II (fault on supply channel 2) by sensors A and D. Which sensor principles, sensor combinations, and sensor distributions are ideal to be able to detect the environment in all situations is currently the object of development.

Performant ECUs



The vehicle environment and the vehicle position are elementary information for highly automated driving. The sensor data obtained are fused in performant ECUs into an environment model. A lot of computing capacity is required for this processing operation. Fault tolerance is important here so that the sensor-data fusion can also be computed in the event of a fault. Among others, for example, either a fault-tolerant ECU (e.g. two boards in one housing) or a combination of two ECUs with one main path and one substitute path can be used.

To be able to deliver this computing capacity at all, automotive electronics will in future increasingly turn to other disciplines, for example consumer electronics. This will also involve the use of microprocessors in addition to automotive-certified microcontrollers.

Vehicle Motion Control

Irrespective of whether assisted or highly automated driving is now employed when the driver wants to go from A to B, a "Vehicle Motion Control" (VMC) [2] (Figure 7) is always demanded. This VMC assumes

Figure 7: Vehicle Motion Control (source: [2])

lateral and longitudinal control of the vehicle without permanent monitoring by the driver by coordinating and monitoring access to actuators (brake, steering, and drive). The environment model from the sensor-data fusion serves as the input for deriving an adequate driving decision.

Actuator redundancy concept
Highly automated driving functions such as highway pilot require a redundant brake and steering in the network of actuators which are coordinated by VMC. Redundant braking capability is provided here for example by the combination of a vacuum-independent, electromechanical brake booster and driving-dynamics control (ESC) (source [2]). Furthermore, fault-tolerant steerability for example is provided by electric steering in which all the components are redundantly designed (among others power supply, communication, windings, logic, etc.).

E/E architectures for highly automated driving
For the various highly automated driving functions such as for example traffic-jam pilot or highway pilot the previously mentioned E/E architecture blocks are required to realize a powerful and reliable E/E architecture. The described stages of the degree of automation can be used to subdivide the driving functions and derive appropriate requirements with regard to the E/E architectures. Reference is made here once again to the importance of the redundant design of the individual E/E architecture blocks for highly automated driving functions which do not require monitoring by the driver.

Development of E/E architectures

Definition of "E/E architecture"
As the amount of electronics and networking in the vehicle increases, so too the demand for powerful development processes and their description methods for the architecture of electrical and electronic systems increases.

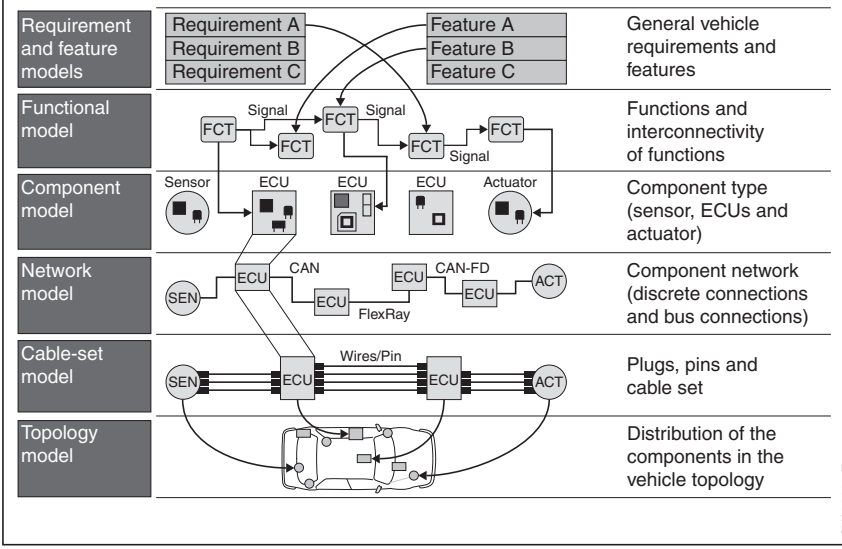
The term "architecture" generally refers to the art of building. In the construction industry, the architect designs a building by drawing up plans for the different views and contractual work based on the client's wishes and boundary conditions. A plan abstracts the reality with regard to a particular aspect (e.g. geometric conditions or electric cabling). The building can finally be erected on the basis of the plans of all the necessary aspects.

When carried over to a motor vehicle, this is referred to as the "E/E architecture". "E/E" denotes the electrical and electronic aspects of the motor vehicle. The "plans" of the E/E architect are referred to in the following with the general term of "model".

Car manufacturers and their suppliers have different views on how many models of which type are needed to describe completely the electrical and electronic systems in the vehicle. The models presented in the following have proven successful in practice and are a necessary framework for describing the E/E scope.

The term architecture is often used in the literature and in publications to denote the models themselves. Here, a clear distinction is made between work operation (architecture development) and presentation of the result (model).

Models of E/E architecture
The models of E/E architecture reflect the results of the different integration aspects of the electronic systems in the vehicle (Figure 8). These aspects are usually dealt with simultaneously because E/E architecture development in the concept phase of a vehicle addresses both the geometry (the "body structure") and new systems which are to be implemented in the vehicle. In the course of vehicle development, the situation may for instance arise where an electronic system in the



chosen technology cannot be integrated into the available space. Compromises must be found in this case.

Feature and requirement models
Feature model
The feature model defines which performance features (features, fixed term in E/E architecture) the vehicle is to have later. These performance features are vehicle properties which can be experienced by the driver and the passengers – thus for example ACC Stop and Go (see Adaptive Cruise Control). The vehicle scope is defined with the feature model. All further models can be derived and developed on the basis of the features.

Requirement model
All the necessary vehicle requirements are set out in the requirement model. These put the features in concrete terms and serve as an input variable for the functional model. Here, for example, the ACC feature can be put in concrete terms with regard to the driving speed. Because the Stop-and-Go variant of ACC is involved, the lower limit of the speed range must be 0 km/h. The upper limit differs from car manufacturer to car manufacturer (e.g. 130 km/h). If the feature for example were not a Stop-and-Go ACC variant, the speed range could be 30 to 200 km/h.

Functional model
Functional models are the preliminary stage of concrete technical systems. They describe the logic functions which are needed to realize the required performance features without going into their concrete technology. Thus the functional architecture is independent of the technical architecture. It is thereby possible to develop features optimally and without technical restrictions. For the example of ACC Stop-and-Go (Figure 9) this entails a breakdown into logic functions such as:
– Sensor technology,
– Longitudinal control of braking deceleration,
– Longitudinal control of acceleration,
– Actuator technology.

Figure 8: Models of E/E architecture
FCT Function, ECU Electronic Control Unit, SEN Sensor, ACT Actuator.

Component model

Technology model

The technology model describes what technical realization is used for the specified transfer elements without already combining these into modules, such as electronic control units (ECUs). "Technology blocks" are created.

Thus, signal filtering can be realized with discrete components by means of a digital circuit or filter software on a microcontroller. Even a controller function can be executed with a discrete electronic circuit or a microcontroller. Voltage stabilization can be achieved by either a smoothing capacitor or a DC/DC converter.

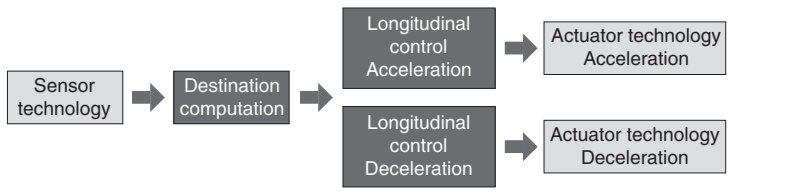
The decision as to a technical implementation is influenced not only by the function, but also by further criteria such as costs, weight, scalability, etc. Before the technology blocks are combined into modules in the form of ECUs, the first step is to look for synergy with the further technology blocks to be integrated. A technological active chain is created (Figure 10). If a specific sensor technology is available, for example, for an active-chain link whose signal is required by another active chain, this will also be used. This occurs even if this sensor is overspecified for the additional user, i.e. there are lower requirements, for example, of the available signal range or of the accuracy.

It is nevertheless important to store the original requirement in a database as this synergy may no longer be present in another vehicle. The automotive industry usually uses the nomenclature according to DIN EN 60617 [3] to describe the hardware.

Node model

The links of the technological active chains are combined into groups at different locations, the "nodes". Here, strict adherence to the optimum cost and further criteria (e.g. latencies) is maintained in relation to integrating the technology blocks. Thus, attempts are made, for example, to integrate the software parts of several technological active chains on a common microcontroller. Sensor information is used jointly wherever possible and actuators are activated by different functions. For example the ACC and ESC functions activate the brake actuator.

Figure 9: Functional model ACC



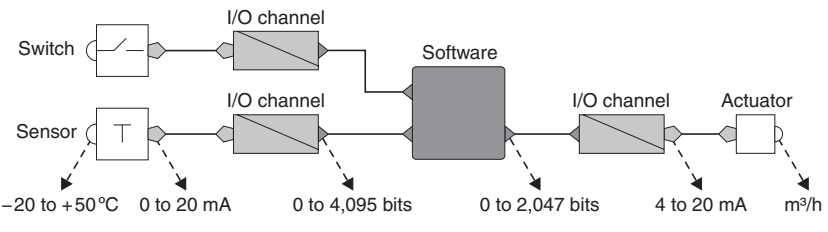


Figure 10: Example of a technological active chain

Hardware model of the electronic component
This model represents the structure of the electronic hardware of an individual ECU. It is created by allocating specific electronic components from the technological active chains to an electronic module in a node. An ECU is therefore, generally speaking, a collecting point for electronic components of different systems, an "integration platform".

Software for controlling different systems from different sources (car manufacturers or their suppliers) is integrated on the microcontrollers located in the ECU. By networking the ECUs, it is possible to implement complex distributed functions which utilize sensors and actuators from different installation locations in the vehicle.

During development, initially customary circuit diagrams will be used for the electrical or electronic parts of the ECU. Then the ECU mechanics and the design and connection technology will be established. E/E-architecture development is confined to a very rough representation in the early concept phase.

Software model of the electronic component
The AUTOSAR standard defines the structuring of software close to hardware level and its interface to the application functions and establishes interfaces between application functions. AUTOSAR additionally defines standardized exchange formats which are supported by popular modeling tools (see AUTOSAR).

Typically, a distinction is made between basic and application software. Blocks of basic software are, for example, device-driver software, communication software, operating system, and hardware abstraction.

Network model
Network model of communication
Because all the technology blocks of a vehicle have been allocated to ECUs in the previous steps, a network of these ECUs is now in place with their communication relationships. The network model of communication represents all the ECUs in the motor vehicle which have bus communication and are thus directly or indirectly networked with each other (see for example Figure 1).

Each signal which is exchanged between two or more ECUs is assigned to a suitable bus system. AUTOSAR defines for this purpose standardized exchange formats which enable bus communication to be described.

Network model of energy supply
The allocation of the technology blocks to ECUs and sensor and actuator modules has also given rise to a network of electrical loads/consumers which requires a suitable energy supply. On the one hand, it is important to fuse individual electric circuits so that a short-circuit does not affect the entire network. On the other hand, not all circuits should be supplied with electrical energy in each operating state. The principle of "terminals" was therefore introduced for this purpose. Thus, for example, terminal 15 is only supplied with electrical energy when the ignition is switched on. The assignment of the individual terminals to ECUs follows the "terminal concept". Among others, the different vehicle states (e.g. driving, parking, loading, etc.) are required as input for the terminal concept. For example, parts of the energy management and the wake-up and go-to-sleep sequences of the ECUs are realized in the network by means of hardware.

The electrical circuit diagram (Figure 11) shows the electrical networking and fusing of the individual modules without the installation position being taken into consideration. Here the colors of the cables (not shown in the figure) and the matching with a terminal or fuse can be seen. The terminal designations follow the conventions in DIN 72552 [4].

The positive pole of the supply voltage is usually featured in the top half of the representation while the negative pole (ground) is featured in the bottom half.

Cable-set and topology models
This model groups electrical and electronic modules in a specific location in the vehicle (Figure 12). In this way, the connecting cables between the ECUs and the energy-supply leads of the electrical

loads/consumers are brought together in cable looms. This creates the cable set. Here many different boundary conditions must be observed, such as for example:
– the manufacturing concept (one-part or multi-part cable set),
– the loom cross-sections (flexibility),
– the electromagnetic compatibility (EMC),
– the heat dissipation,
– the weight,
– the costs (e.g. of copper),
– and the structure of the cable set in the vehicle.

The topology describes the possible routing paths in the body, such as for example the H structure, which consists of two main connections from the front end to the rear end of the vehicle and a cross cable (crossing) from the left to the right side of the vehicle.

Two-dimensional models are usually sufficient in the concept phase of a vehicle; detailed three-dimensional models are used in the later development phase.

E/E architecture development process
The E/E architecture development process links the individual draft stages with each other on a logic and time basis and provides quality criteria at the beginning and the end of a draft stage. The individual draft stages are described below.

Requirement management
The requirements decisively determine the decisions of the E/E architect. It is advisable and common to distinguish between functional and non-functional requirements. Functional requirements refer to the desired performance features, the features, which can be used in the vehicle. Non-functional requirements refer to the technical solution and are therefore also known as draft restrictions.

Such a restriction can be, for example, the space available in the center console for installing ECUs. Another restriction can be the maximum permissible heat dissipation in a location which influences the power electronics positioned there.

Thus, for example, the audio amplifier in vehicles is frequently installed in the luggage-compartment area since the heat in the vehicle passenger compartment cannot be adequately dissipated.

Once the documentation of the functional and non-functional requirements has been completed, the actual development of the E/E architectures begins.

Development of E/E architectures

The development of the E/E architecture can follow two paths: The bottom-up approach, which starts out from existing components, and the top-down approach, which features the implementation of all the previously described modeling steps starting out from the functional and non-functional requirements.

In the bottom-up approach the creation of the E/E architecture starts out from the functionality of existing components and this is supplemented additionally by function and communication aspects. This approach is typically chosen for the creation of E/E architectures of successor generations to existing vehicle platforms or if cost restrictions necessitate the use of cost-effective components already existing on the market.

The top-down approach focuses on the function complexity and is typically chosen for creating E/E architectures of new vehicle platforms. In addition, the functional model will in future play an increasingly more important role, particularly to be able to realize cross-domain features. The functional model will be developed independently of the further technical implementation of the E/E architecture.

The use of E/E concept tools allows an exchange of data with development partners for electronic components or for the cable set.

Evaluation of models

The following must be observed for all approaches: During the transition from one model hierarchy to the next (e.g. from the functional model to the technology model), a list of evaluation criteria (e.g. reuse or testability) is compared with a portfolio of specimen solutions (e.g. bus technologies). Evaluation of the specimen solutions using the criteria allows a solution to take shape on the basis of the purely functional requirements and irrefutable boundary conditions ("MUST criteria").

An alternative procedure consists in comparing a reference solution (e.g. the previous networking model) using the evaluation criteria with alternative solutions. This does indeed deliver fast results, but possibly not the global optimum.

Because the evaluation criteria are generally weighted differently by the car manufacturers, the electronic systems of the vehicles sometimes differ considerably from each other.

E/E architecture development tools

Ideally a tool is used for architecture modeling which can represent and network with each other the different models and model levels of the E/E architecture work. Fully connected documentation is created in this way. This enables the different disciplines involved in the development process to come on board at the relevant points. It should furthermore be possible to record the modeling properties numerically in order to be able to provide them with an evaluation.

Different E/E architecture development tools have in the meantime come onto the market which enable architecture modeling to be performed on a tool-assisted basis. An important point is the standardization of the models and their data formats. Only this facilitates competition between the tool manufacturers and opens up to the different disciplines involved the opportunity of joining the process at different points.

Summary and outlook

As a result of the ever increasing scope and the increasing networking of electronic systems, it is necessary to use suitable processes, methods and tools in E/E architecture development. E/E architecture development has established itself as an independent area of responsibility in the automotive industry and has a decisive influence in the development of new vehicles. It is thereby possible also to render further features in the automobile. These include for example highly automated driving functions like highway pilot or wireless software and firmware updates via the air interface ("over the air"). It is possible through new approaches in E/E architecture development to deliver powerful and reliable E/E architectures in the future as well. If the procedures described in this publication are consistently applied and developed further, the increasing complexity in motor vehicles will also be manageable in the future and will continue to make significant contributions to improving traffic flow, traffic safety, driving comfort, and economical fuel utilization.

Vehicle communication networks

Bus systems

Networks for data communication, also known as bus systems or protocols, are widely used in today's motor vehicles. Various components such as sensors, actuators or ECUs – the nodes or network users – are connected to each other via a single channel (Figure 1). A wealth of data, also known as messages, telegrams, packets or frames, is exchanged via this channel. For example, the driving speed is determined in the Electronic Stability Program (ESC) and transferred to all the other ECUs which are networked as nodes in the bus system.

Advantages of bus systems
Compared with conventional cabling, in which the transmitter and receiver of information are each connected by separate lines, bus systems offer significant advantages:
– The costs of materials for the cables are lower (which offsets the higher costs for the electronics).
– The space required and the weight of the cabling are lower.
– The number of plugs susceptible to faults is lower, thus fewer failures occur in total.
– Data can be distributed to various receivers; for example, the signals of a sensor can be used by several systems.
– All the systems in the vehicle which are connected via the bus can be reached from one access point. This provides for simpler diagnostics and the configuration of all the ECUs at the end of the line.
– The performance of calculations can be distributed to different ECUs.
– Analog sensor signals must be digitized for data processing. The sensor signals can be conditioned directly in the sensor, the information is then disseminated via the bus.

Figure 1: Automotive networking
Schematic representation of nodes and data lines.

2 Data line,
3 Node (network user).

Requirements of buses

General requirements

In order to be able to be used in vehicles, buses must satisfy typical requirements. A bus must use a transmission process which has control over the propagation times, attenuations and reflections of the signals for cables up to 40 m long with which typically all the parts of the vehicle are reached. A network must be able to connect several dozen users in the process.

A bus must be able to withstand the rough ambient conditions in the vehicle with regard to temperature, vibrations and electromagnetic interference.

Because vehicles are produced in high numbers, even small savings potentials in the cost of the bus hardware of the individual vehicle must be utilized in the design of the bus. It must equally be noted that there are several competing manufacturers of bus components.

There is a large number of equipment variants of a vehicle type which must be covered by a basic configuration of the bus. The additional installation of an optional extra must not affect the other vehicle systems.

The performance of the bus must be clearly defined in a public standard in order to have a benchmark against which components can be verified. This ensures that verified components of different suppliers function together in a single network.

Special requirements

Different systems in the motor vehicle have different requirements and therefore necessitate the use of different buses. The required data transfer rate (data rate) very much depends on the application. It ranges from a few bit/s for switching the lights, through engine management with a few 100 kbit/s, right through to video applications with several Mbit/s.

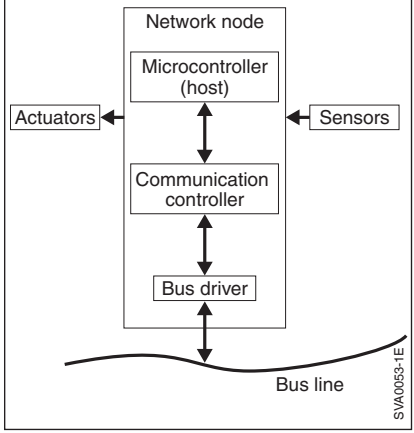
For systems in which a failure or a delayed execution of a function is safety-relevant (e.g., airbag, electric power steering), a maximum duration for the delay of data transfer – the length of time between the sending of a telegram and actual reception (latency) – must be guaranteed in all cases. When the time response of the bus is defined and reproducible at all times, this is referred to as determinism. In this way, transfer times for messages, in particular, are already known in the design phase.

For safety systems such as electric power steering it must be verified that everything has been done in terms of state-of-the-art technology to avoid flaws/faults in design and to ensure correct functioning under all permissible boundary conditions.

Transfer malfunctions which inevitably occur during operation must be detected and dealt with for the relevant application.

Technical principles

Components of a bus



In order for a network to function as planned, calculations must be carried out constantly in every node. This is performed for the most part by a special piece of hardware (Figure 2), the "communication controller". This removes the load from the actual computer (host), which can also perform this function – although less efficiently. The communication controller can be implemented as a separate semiconductor component; in the case of many microcontrollers, however, communication controllers for some buses are already integrated.

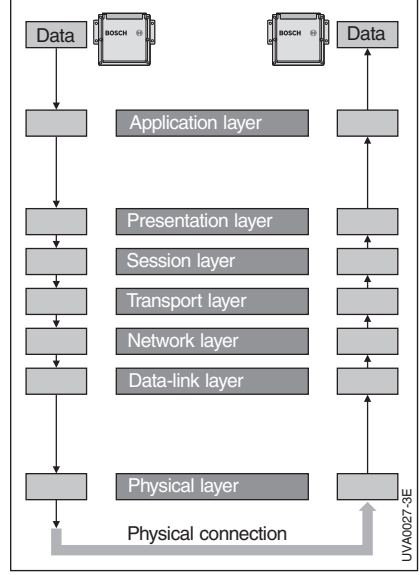
A further component, the bus driver or transceiver, converts the signal which it receives from the communication controller into the physical signal on the bus line (e.g., voltage level). It converts data received on the bus line and forwards them to the communication controller.

Communication protocol

Data transfer between the nodes is established in the communication protocol. These agreements relate to the syntax, semantics, and synchronization of communication. The syntax determines which character strings may be used for communication, the semantics define the correct use of syntactically correct constructs.

Figure 2: Hardware of a node (network user)

OSI reference model



The ISO (International Standardization Organization) developed the OSI reference model (Open Systems Interconnection), which is often used as the basis for describing and comparing communications protocols. In this model, the function of a data-communication system is broken down into different hierarchical layers which each use the functions made available by a different layer. The OSI reference model is an aid to structuring conceptually the function of a communication system. However, finding efficient solutions is not necessarily supported by observing this model.

Seven layers are defined (Figure 3), but many protocols are only defined on one part thereof. The upper layers in the OSI reference model (application layer, presentation layer and session layer) are for the most part not served by motor-vehicle buses.

Physical layer

The physical layerdefines the physical properties of the transmission medium (e.g., voltage level or shape of plugs). In

Figure 3: OSI reference model

motor vehicles for the most part, electromagnetic signals in the kHz to MHz range are used on special cables and optical fibers (physical connection, Figure 3). Radio of different frequencies or the joint use of cables already provided with electrical power for supply purposes are technologies which have not yet been tested in large batches.

The most widely used method is, because of the low costs involved, transmission by cable, particularly as a voltage difference on twisted two-wire cables, with or without shielding against radiation, or on single-wire cables with a voltage reference to ground.

Optical fibers made from plastic or glass fibers (for the infrared spectral range) are used above all wherever high data rates are needed. They are insensitive to electromagnetic radiation (e.g., by the ignition system), but are costly to lay and their resistance to aging has not yet been adequately assured.

The physical possibilities of the medium also limit the types of encoding of a bit. With optical media, there are the two states “light” and “no light”, which offer encoding by means of amplitude (brightness).

Electrical voltage signals on a cable offer different possibilities for representing bits. The simplest and usual method used in motor-vehicle buses is encoding in which each bit is assigned a voltage value (amplitude modulation) which is applied for the entire bit duration (NRZ, Non Return to Zero). In contrast, with Manchester encoding the level changes during a bit length from 0 to 1 (corresponding to the encoding of 0) or from 1 to 0 (corresponding to the encoding of 0).

Because the signal level can remain constant over several bit lengths with NRZ encoding, additional measures are required to safeguard synchronization. With bit stuffing a complementary bit is inserted after a defined number of equal bit values; the receiver filters this bit out again.

In the case of bus systems with a high data rate, open cable ends must, if necessary, be terminated by terminating resistors in order to prevent reflections from disrupting the signal shape.

Data-link layer
The data-link layer effects the correct transport of data between neighboring nodes. Data bits are arranged into frames. By adding further bits such as checksums or numberings, it is possible to detect or even correct errors that occur during transfer. Alternatively, an error can be rectified by requesting a new transfer.

Network layer
If not every node is directly connected with every other, a route must be found for the data which passes through intermediate stations. The search for a route is also called routing and includes different characteristics of the transmission paths (particularly bandwidth) and the intermediate stations, also called routers.

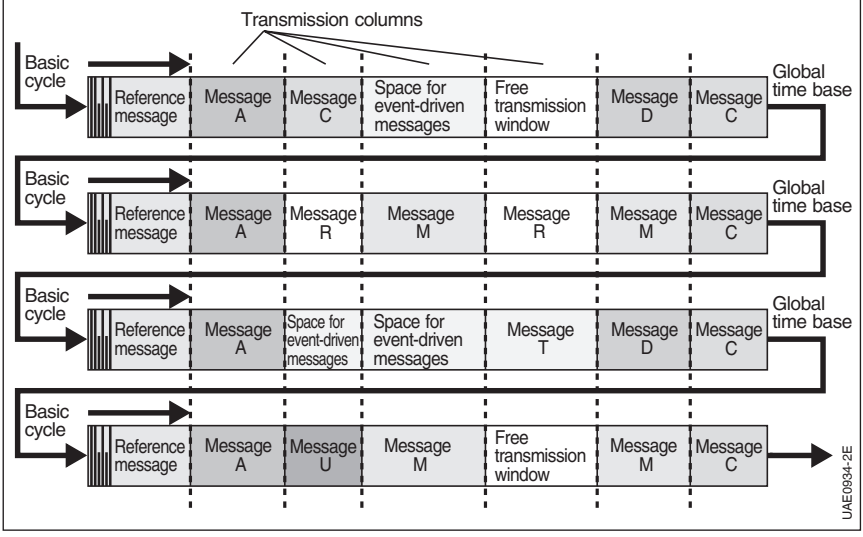
Transport layer
The transport layer’s functions include disassembling large data packets and reassembling them at the receiver, which the parts potentially reach via different routes at different times, or if transmission errors occur ensuring that a packet is transmitted again. The transport layer also serves to hide the properties of the transmission path from the application and to offer services independently.

Data frame
Data are usually transmitted as fixed-structure packets (frames), which, as well as the actual content – the user data – also contain control and test data such as source, destination, priority and check bits to protect against corruption.

Data rate
The data rate is a measure of the speed at which the individual bits are transferred. It is given as the number of bits per second. This produces the derived units such as kbit/s and MByte/s (1 byte = 8 bits).

The gross data rate takes into account all the transferred bits, while the net data rate takes into account only the user data. A measure of the efficiency of a bus system is the ratio of net data rate to gross data rate.

Access methods
A central function of a network to which several users have access at the same time is the administration of the token in order to avoid conflicts. This is known in buses as arbitration. It should be borne in mind here how urgently a message has to be transported. Different mechanisms are circulated.



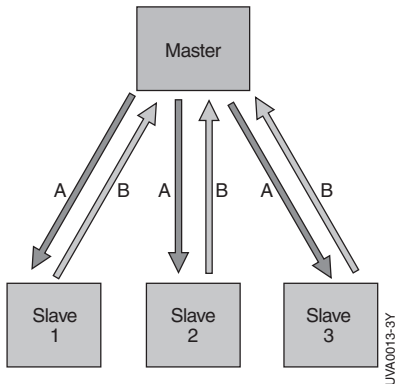
Time control
With time-controlled buses, conflict-free access is possible whereby each node receives permanently allocated times (slots, columns) for its emissions. These recurring times are combined into cyclesand the cycles combined into the communication matrix (Figure 4). This mechanism is called TDMA (Time Division Multiple Access).

The latency is limited in the case of time control to a maximum length. The response behavior of the bus system must therefore be predicted with regard to time.

The messages (reference messages, Sync Frame) themselves are used to synchronize the clocks in the nodes. If there are numerous timing nodes (time master) in the network, the clocks are synchronized on the basis of the measured reception times with the expected reception times. The strict periodicity (determinism) makes it possible to quickly detect when a message fails to materialize, which is required particularly in safety-relevant systems such as electric-motor-operated steering.

In addition, the time-controlled approach promotes the possibility that several subsystems are developed independently

Figure 4: Communication matrix of a time-controlled bus (example: TTCAN)



of each other, because in this way the composabilityof the subsystems into predictable behavior of the overall system is supported. When each subsystem has its independent time slice, two nodes cannot disrupt each other by simultaneously occupying the bus.

Master-slave
A designated node (master) grants one of the other nodes (slave) limited access (Figure 5). In this way, it determines the communication frequency by interrogating its subordinate nodes. A slave responds only when it is addressed by the master. This method produces defined latencies.

However, some master-slave protocols permit a slave to register with the master in order to send a message.

Figure 5: Master-slave method
A Master inquiry,
B Slave response.

Multi-master
In a multi-master network, various nodes can access the bus automatically and send a message if the bus appears free. In other words, each node can perform the master role and all the nodes can equally start a message transfer. However, this also means that methods for identifying and dealing with access conflicts must be in place. This can be done, for example, by way of a decision phase with prioritization or a delayed resending.

The use of priority control prevents a bus conflict when several nodes want to occupy the bus at the same time. The network node which has a high priority or which would like to transmit a high-priority message asserts itself and sends its message first. When the line is free again, all the nodes which have to send messages – particularly the node that is waiting – start with a renewed attempt. Consequently a maximum value cannot be specified for the latency with this method.

The multi-master architecture has a positive effect on system availability because communication is not controlled by any single node, the failure of which would result in a total communication failure.

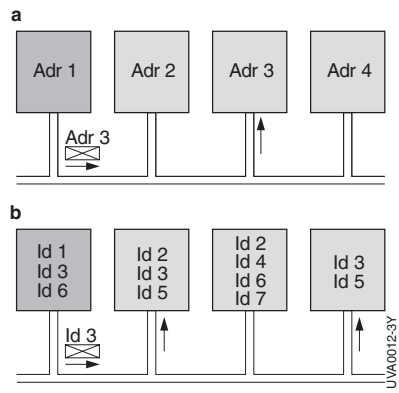
Token passing
The right of access is temporarily awarded to a node, which then passes it on to another node for a limited time. The controlled allocation of the right of access ensures that only one single node has right of access to the bus at a given time.

Forms of communication
The simplest form of communication is the 1:1 connection (point-to-point or unicast connection), in which one transmitter and one receiver are connected via a bus.

When a transmitter sends a telegram to several receivers without all the receivers processing this telegram, this is called a broadcast connection. In a multicast connection each receiver processes the telegram provided by the transmitter.

Addressing
In order for messages to be transferred via a network and their information to be evaluated, they contain, in addition to the user data (payload), information on the data transfer. This information can be contained explicitly in the transfer or stipulated implicitly. Addressing is required to ensure that a message arrives at the correct receiver. There are different methods of doing this.

User-oriented method
Data are exchanged here on the basis of node addresses (Figure 6a). The message transmitted by the sender contains, as well as the data to be transferred, the address of the destination node. All the receivers compare the transmitted receiver address with their own and only those receivers with the correct address evaluate the message. Messages can be directed to individual addressees, to groups (multicast) or to all the nodes in the network (broadcast).



Most conventional communication systems (e.g., Ethernet) operate in accordance with the principle of User addressing

Message-oriented method
With this method, it is not the receiver nodes but the messages themselves which are addressed (Figure 6b). A message is identified according to its content by a message identifier which was established in advance for this information type. With this method, the sender does not require any knowledge of the destination of the message, since each receiver node decides for itself whether to process the message. Several nodes can also accept and evaluate the message.

Most bus systems in the automotive field (e.g., CAN, FlexRay) operated according to the message-oriented method.

Transfer-oriented method
Even transfer features can be used to identify a message. If a message is always sent in a defined time slot, it can be identified using this item. For safeguarding purposes, this addressing is also combined in many cases with a message- or user-oriented addressing.

Figure 6: Addressing types

b) Message-oriented method.
Adr i, $i = 1…n$, address of nodes.
Id i, $i = 1…n$, message identifiers.

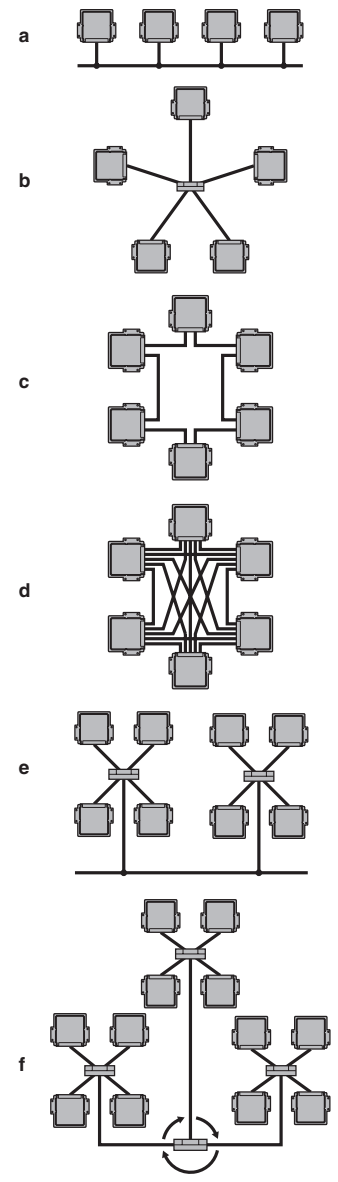
Network topology
A network topology refers to the structure of network nodes and connections. This shows which nodes are connected to each other, but not the details, such as the length of the connection for example. For different applications of communication networks, there are different requirements of the topology used.

Bus topology
This network topology is also referred to as a linear bus. The core element is a single cable, to which all the nodes are connected by way of short connecting cables (Figure 7a). In this topology, it is very easy to expand the network by additional users. Messages are sent out from the individual bus users and distributed to the entire bus.

If a node fails, the data expected from this node are not available to the other nodes in the network, but the remaining nodes can continue to exchange messages. However, a network with a bus topology will fail completely if the central cable has a fault (e.g., in the event of a cable break).

Star topology

The star topology consists of a central node (repeater, hub, star), to which all the other nodes are connected by way of individual connections (Figure 7b). A network with this topology can therefore be easily expanded if free connections are available at the central element.



Data are exchanged via the individual node connections with the central star, where a distinction is made between active and passive stars. The active star contains a computer which processes and forwards the data. The network's performance is significantly determined by the performance of this computer. The central node, however, does not necessarily have to have special control intelligence. A passive star only joins the bus lines of the network users.

If one node fails or a connecting cable to the central node is faulty, the remaining network continues to be operational. If, on the other hand, the central node fails, then the entire network is rendered inoperational.

Ring topology

In the ring topology, each node is connected to its two neighbors. This creates a closed ring (Figure 7c). In a ring, data are transferred in only one direction from one station to the next. The data are checked in each case after they are received. If they are not intended for this station, they are renewed (repeater function), amplified, and sent forward to the next station. The data to be transferred are forwarded in the ring, i.e., from one station to the next, until they reach their intended destination or arrive at the starting point again. When a message has passed through the complete ring, reception is acknowledged by all the nodes. Once one station in a single ring fails, data transfer is interrupted and the network fails completely.

Figure 7: Network topologies
a) Bus topology, b) Star topology,
c) Ring topology, d) Mesh topology,
e) Star-bus topology,
f) Star-ring topology.

Rings can also be structured in the shape of a double ring in which data are transferred in both directions. In this topology, the failure of one station or of a connection between two stations can be managed, since all the data continue to be transferred to all the operational stations in the ring.

Daisy-chain topology
The daisy-chain topology looks like the ring topology when a connection is removed. Here, the first component is connected directly to data-processing equipment (e.g., a computer). The subsequent components are connected to their preceding components (series-connection principle), thereby creating a chain. Messages thus pass through several nodes until the destination is reached.

Mesh topology
In a mesh topology, each node is connected to one or more further nodes (Figure 7d). In the event of the failure of a node or a connection, there are diversions along which the data can be routed. This network is therefore characterized by high failure tolerance. However, the costs of networking and transporting the messages are high.

Hybrid topologies
In hybrid topologies, different network topologies are connected. The following combinations are possible, for example:
– Star-bus topology: The hubs of various star networks are connected to each other as a linear bus (Figure 7e).
– Star-ring topology: The hubs of various star networks are connected to the main hub (Figure 7f). In this main hub, the hubs of the star networks are connected in a ring shape.

Coupling of bus systems
Depending on the requirement, different bus systems with different communication protocols are used in motor vehicles. Intermediate stations are required to be able to transfer messages from one bus system to the other.

Repeater
Similar buses are coupled via the repeater. The repeater compensates the attenuation on the lines; it therefore works as a booster. The communication traffic is transferred from one bus system to the other.

Gateway
The gateway processes the incoming data packets and generates from them the data packets for the bus system to be operated. The gateway thus converts the incoming data in order to send it with the required communication protocol.

Router
The router forwards to the other bus only those data which are needed by the ECUs connected to this bus (nodes).

Standby state
With a command the node can be switched to a power-saving standby state, the sleep mode, when no data exchange is required. Communication is deactivated in this state.

The node is returned to the normal operating state with a wake-up. The different bus systems apply their specific methods to control the sleep mode and the wake-up mode.

Transfer reliability
An important feature of buses, particularly if they are to be used in safety-relevant systems, is their ability to identify faults and, if necessary, to maintain limited operation. This includes the possibility of detecting the corruption of data. Electromagnetic radiation from the surroundings (e.g., from the ignition coil) on the cables may cause some bits to assume incorrect values at the receiver. These incidents can be identified by transferring check information in addition to the data.

The simplest case is an additional parity bit, which is used to detect whether the correct number of ones is even or uneven. A more elaborate method is the block-securing method (cyclic redundancy check, CRC), in which different levels of protection can be achieved with a selectable number of check bits. The transmitting node generates via the encoding rule the check information and thereby supplements the telegram to be sent. The receiver calculates from the received telegram the check information according to the same algorithm and compares it with the received value. A data-transfer error can be detected in this way.

One way of ensuring limited operation is to bypass failed lines and prevent blockage of the bus by faulty nodes.

It is ensured that an item of data sent out by a node, e.g., the vehicle speed, is available either to all the addressees in the network or to none (consistency). The situation where two nodes have different images of the speed value therefore cannot arise. For this purpose, a node signals that reception has failed or refrains from acknowledging correct reception (acknowledge). The other nodes then reject the data already correctly received by them.

Buses in motor vehicles

External buses connect ECUs, sensors, and actuators to each other. They run via a wiring harness and plug-in connections. Levels, bit rates, and impedances are precisely defined in order to ensure interoperability. Examples are CAN, FlexRay, and LIN. For a quick overview, these buses are frequently classified according to the scheme in Table 1.

Internal buses connect integrated circuits on the board. They are only used inside an ECU.

Table 1: Classification of bus systems

Class A	
Data transfer rates	Low data rates (up to 10 kbit/s)
Applications	Networking of actuators and sensors
Represented by	LIN, PSI5
Class B	
Data transfer rates	Medium data rates (up to 125 kbit/s)
Applications	Complex mechanisms for error handling Networking of control units in the comfort area
Represented by	Lowspeed-CAN (CAN-B)
Class C	
Data transfer rates	High data rates (up to 1 Mbit/s)
Applications	Real-time requirements Networking of control units in the drive and chassis area
Represented by	High-speed CAN (CAN-C)
Class C+	
Data transfer rates	Very high data rates (up to 10 Mbit/s)
Applications	Real-time requirements Networking of control units in the drive and chassis area
Represented by	FlexRay
Class D	
Data transfer rates	Very high data rates (from 10 Mbit/s)
Applications	Networking of control units in the areas of telematics and multimedia
Represented by	MOST, Ethernet

CAN

Overview

The CAN bus (Controller Area Network) has established itself as the standard since its first series introduction in motor vehicles in 1991. But it is also often used in automation technology. The major features are:

- Priority-controlled message transmission with non-destructive arbitration.
- Low costs through the use of a low-cost twisted two-wire cable and use of a simple protocol with low computing-power demand.
- A data-transfer rate up to 1 Mbit/s for the high-speed CAN (CAN-C) and up to 125 kbit/s for the low-speed CAN (CAN-B, lower expenditure for the hardware).
- High reliability of data transfer through recognition and signaling of sporadic faults and permanent faults and through network-wide consistency via Acknowledge.
- The multi-master principle.
- High availability by locating failed stations.
- Standardization in accordance with ISO 11898 [1].

Transfer system

Logic bus states and encoding

To communicate, the CAN bus uses the two states “dominant” and “recessive”, with which the information bits are transmitted. The dominant state represents “0”, the recessive “1”. The NRZ process (Non Return to Zero) is used as encoding for transmission, in which a zero state is not always returned to between two equal transfer states and, therefore, the time interval between two edges which is required for synchronization can become too great.

For the most part a two-wire cable with, depending on the ambient conditions, a non-twisted or twisted pair is used. The two bus lines are called CAN_H and CAN_L (Figure 1).

The two-wire cable facilitates a symmetrical data transfer, in which the bits are transferred via both bus lines using different voltages. This reduces sensitivity to common-mode interference, since interference affects both lines and can be filtered out by creating the difference (Figure 2).

The single-wire cable represents a way of lowering manufacturing costs by saving on the second cable. However, a common ground connection which assumes the function of the second cable must be available to all the bus users for this purpose. The single-wire version of the CAN bus is therefore only possible for a communication system with limited spatial reach. Data transfer on the single-wire cable is more susceptible to interference radiation, since it is not possible to filter out interference pulses as on the two-wire cable. A higher level signal on the bus line is therefore required. This in turn has a negative effect on the interference radiation. The edge steepness of the bus signals must therefore be reduced compared with the two-wire cable. This is associated with a lower data-transfer rate. For this reason, the single-wire cable is only used for the low-speed CAN in the area of body and comfort and convenience electronics. The single-wire solution is not described in the CAN specification.

There are also so-called fault tolerant transceivers, which communicate via a two-wire cable, but if a cable breaks continue operating as a single-wire system.

Voltage levels

High-speed and low-speed CANs use different voltage levels to transfer dominant and recessive states. The voltage levels of the low-speed CAN are shown in Figure 1a, those of the high-speed CAN in Figure 1b.

The high-speed CAN uses, in the recessive state on both lines, a nominal voltage of 2.5 V. In the dominant state, nominal voltages of 3.5 V and 1.5 V are applied to CAN_H and CAN_L respectively. In the low-speed CAN in the recessive state, a voltage of 0 V (max. 0.3 V) is applied to CAN_H and a voltage of 5 V (min. 4.7 V) is applied to CAN_L. In the dominant state, the voltage at CAN_H is min. 3.6 V and at CAN_L max. 1.4 V.

CAN_L CAN Low level.

Limits
It is important for the arbitration method in the case of CAN that all the nodes in the network see the bits of the message identification (frame identifier) simultaneously so that a node – while it is still transmitting a bit – sees whether another node is also transmitting. Delays result from the signal propagation time on the data bus and the processing times in the transceiver. The maximum permissible transfer rate is thus dependent on the overall length of the bus. ISO specifies 1 Mbit/s for 40 m. For longer lines, the possible transfer rate is roughly inversely proportional to the line length. Networks with a 1 km reach can be operated with 40 kbit/s.

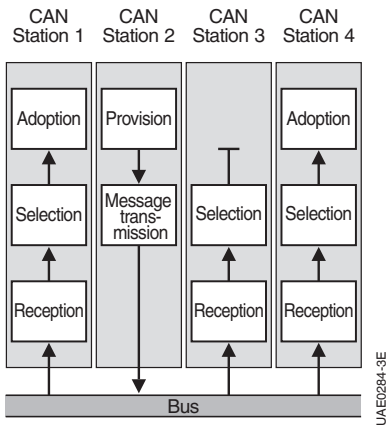
CAN protocol
Bus configuration
CAN operates according to the multimaster principle, in which a linear bus topology connects several nodes of equal priority rating.

Content-based addressing
CAN uses message-based addressing. This involves assigning a fixed identifier to each message. The identifier (ID) classifies the content of the message (e.g. engine speed). Each station processes only messages whose identifiers are stored in the list of messages to be accepted. This is called acceptance checking (Figure 3). Thus, the CAN requires no station addresses for data transmission, and the nodes are not involved in managing the system configuration. This facilitates adaptation to variations in equipment levels.

Logic bus states
The CAN protocol is based on two logic states: The bits are either “recessive” (logic 1) or “dominant” (logic 0). When at least one station transmits a dominant bit, it overwrites the recessive bits simultaneously sent by other stations.

Bus arbitration and priority assignments
Each station can begin transmitting a message as soon as the bus is unoccupied. When several stations start to transmit simultaneously, a “wired-and arbitration scheme” becomes active to resolve the resulting bus-access conflicts. The arbitration scheme ensures that the domi-

Figure 3: Addressing and acceptance checking
Station 2 sends, stations 1 and 4 receive the data.



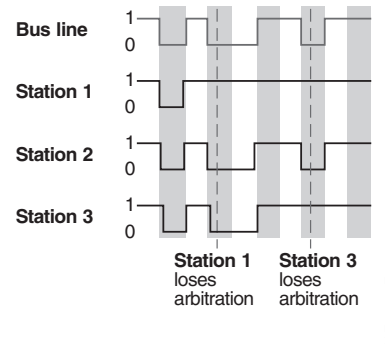


Figure 4: Bitwise arbitration
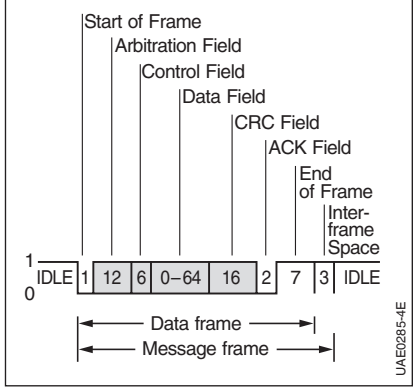
0 Dominant level,
1 Recessive level.
Station 2 gains first access (signal on the bus corresponds to signal from station 2).



nant bits transmitted by a station overwrite the recessive bits of other stations (Figure 4). Each station gives bit by bit – the highest significant bit first – the identifier of its message on the bus. During this arbitration phase (selection phase) each transmitting station compares the applied bus level with the actual level. Each station that transmits a recessive bit but observes a dominant bit loses arbitration. The station with the lowest identifier – i.e. with the highest priority – is assigned first access on the bus without having to repeat the message (non-destructive access control). Transmitters respond to failure to gain bus access by automatically switching to receive mode; they then repeat the transmission attempt as soon as the bus is free again.

Data frame and message format

The CAN supports two different message formats, which primarily differ with respect to the length of their identifiers. The standard format has 11 bits, while the extended format has 29 bits. Thus, the data frame to be transmitted contains a maximum of 130 bits (in the standard format) and 150 bits (in the extended format). This ensures minimum waiting time until the next transmission (which could be urgent). The data frame for the standard format consists of seven consecutive fields (Figure 5). The "Start of Frame" indicates the beginning of a message and synchronizes all nodes.

Figure 5: Data frame

The "Arbitration Field" consists of the message's identifier and an additional control bit. While this field is being transmitted, the transmitter accompanies the transmission of each bit with a check to ensure that no higher-priority message is being transmitted (which would cancel the access authorization). The control bit determines whether the message is classified under "data frame" or "remote frame".

The "Control Field" contains the code indicating the number of data bytes in the "Data Field".

The "Data Field" has an information content of between 0 and 8 bytes. A message of data length 0 can be used to synchronize distributed processes.

The "CRC Field" (Cyclic Redundancy Check) contains a checksum for detecting possible transmission interference.

The "Ack Field" contains the acknowledgement signals with which the receivers indicate the error-free receipt of messages.

The "End of Frame" marks the end of the message.

Then comes the "Interframe Space" to provide a separation from the next data frame.

Transmitter initiative

The transmitter will usually initiate a data transmission by sending a data frame. However, the receiver can also request data from the transmitter. This involves the receiver sending off a "Remote Frame". The "Data Frame" and the corresponding "Remote Frame" have the same identifier. They are distinguished by the bit that follows the identifier.

Error detection
The CAN incorporates a number of monitoring features for detecting errors. These include:
– 15-bit CRC: Each receiver compares the CRC sequence which it receives with the calculated sequence.
– Monitoring: Each transmitter reads its own transmitted message from the bus and compares each transmitted and scanned bit.
– Bit stuffing: Between “Start of Frame” and the end of the “CRC Field”, each “Data Frame” or “Remote Frame” may contain a maximum of five consecutive bits of the same polarity. The transmitter follows up a sequence of five bits of the same polarity by inserting a bit of the opposite polarity in the bitstream. The receivers eliminate these bits again as the messages arrive.
– Frame check: The CAN protocol contains several bit fields with a fixed format for verification by all stations.

Error handling
When a CAN controller detects an error, it aborts the current transmission by sending an error flag. An error flag consists of six dominant bits; it functions by deliberately violating the stuffing convention and the formats.

Fault confinement with local failure
Defective stations can severely impair the ability to process bus traffic. Therefore, the CAN controllers incorporate mechanisms which can distinguish between intermittent and permanent errors, and local station failures. This process is based on statistical evaluation of error conditions.

Implementations
The semiconductor manufacturers offer different implementations of CAN controllers which differ primarily in the extent to which they can store and manage messages. In this way, the host computer can be relieved of protocol-specific activities. A standard categorization is Basic CAN controllers, which have only a few message memories, and Full CAN controllers, in which there is room for all the messages necessary for an ECU.

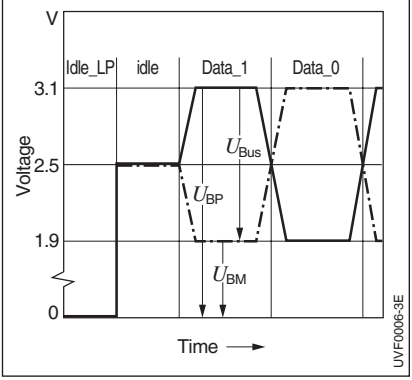
Standardization
The CAN has been standardized for data exchange in motor vehicles; for applications with a low transfer rate up to 125 kbit/s as ISO 11898-3 [1] and for applications with a high transfer rate over 125 kbit/s as ISO 11898-2 [1] and SAE J 1939 (truck and bus, [2]).

Time-triggered CAN
The extension of the CAN protocol to include the capability of operating in time-triggered mode is called “Time-Triggered CAN” (TTCAN). It is fully configurable with regard to the proportion of time-triggered to event-driven communication components, and is therefore fully compatible with CAN networks. TTCAN is standardized as ISO 11898-4 [1].

CAN with flexible data rate
CAN-FD extends CAN by a second bit rate and a wider data field. Unlike the nominal bit rate previously applicable to CAN, the data bit rate is not limited to 1 Mbit/s. The data bit rate acts exclusively on the data field within the data frame, whereas the nominal bit rate still acts on the control data.

In addition, CAN-FD increases the data field from 8 to up to 64 bytes. This also necessitates adaptations to the checksum so as not to compromise transmission reliability. CAN-FD is standardized as ISO 11898-7 [1].

FlexRay



Overview

FlexRay is a bus which was designed for control engineering in the automotive field. Particular attention was given in development to its suitability for use in active safety systems without a mechanical fallback level (X-by-Wire), where determinism and fault tolerance are required. Essentially, thanks to the high transfer rate of up to 20 Mbit/s for non-redundant transmissions, its use in the field of audio transmission or for highly compressed video transmission is also conceivable. The major features are:

– Time-triggered transmission with guaranteed latency,
– Possibility of event-driven transmission of information with prioritization,
– Transmission of information via one or two channels,
– High transfer rate of up to 10 Mbit/s, with parallel transfer via two channels up to 20 Mbit/s,
– Structure as a linear bus, in a star configuration or as a mixed form.

FlexRay is the first automotive communication standard to have been created in a consortium of vehicle manufacturers, suppliers and semiconductor manufacturers. It contains elements from TTCAN, Byteflight and other technologies. The specifications published by the FlexRay Consortium are today (only) available as ISO standard 17458 [3].

Figure 6: Bus states and voltages for FlexRay

Transmission media

The transmission medium used in a FlexRay system is a twisted-pair two-wire cable where both shielded and non-shielded cables can be used. Each FlexRay channel consists of two strands, Bus-Plus (BP) and Bus-Minus (BM). FlexRay uses NRZ (Non Return to Zero) for encoding.

The bus state is identified by measuring the voltage difference between Bus-Plus and Bus-Minus. Data transfer is thus less sensitive to external electromagnetic influences, since these act equally on both strands and cancel each other out in the difference.

When different voltages are applied to the two strands of a channel, four bus states can be assumed; these bus states are referred to as Idle_LP (LP, Low Power), Idle, Data_0, and Data_1 (Figure 6). Idle_LP is the state in which a low voltage between –200 mV and 200 mV (to ground) is applied to Bus-Plus and Bus-Minus. In the Idle state, a voltage of 2.5 V with a maximum difference of 30 mV is applied to BP and BM. In order to place the channel in the Data_0 state, at least one transmitting node must apply a negative differential voltage of –600 mV to the channel, for Data_1,600 mV, based on a mid-level of 2.5 mV.

Topologies

FlexRay networks can be structured as bus topologies and star topologies. Two stars can be cascaded – when signal delays are taken into consideration in the stars. Topologies in which several buses are connected to a star are also possible.

Because both channels of a FlexRay system can be structured independently of each other, it is possible for different topologies to be used for both channels. For example, one channel can be structured as an active star topology, the other as a bus topology.

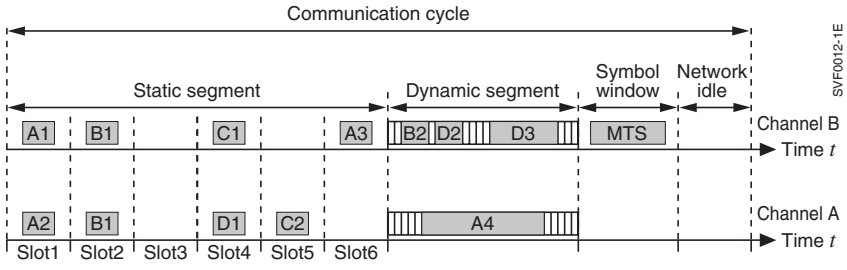
On account of the frequencies, which can be ten times those of CAN, it is necessary when designing a FlexRay network to ensure in all topologies in particular that parameters such as line length and terminating resistors are selected in such a way that signal distortions remain in the permissible range.

Bus access, time control

In order to achieve determinism, i.e. the guarantee of a maximum duration for the transmission of a message, communication is performed in the FlexRay bus on a time-controlled basis in cycles of constant duration. Each cycle first features a static segment which is divided into time slots of equal length (Figure 7). Each time slot is permanently assigned a maximum of one node which is permitted to transmit at this time.

This is followed by a dynamic segment in which bus access is regulated by the priority of messages. The split between the static and dynamic segments is freely configurable, but cannot be altered during operation. The same applies to the lengths of the time slots, which are configurable, but must remain constant during operation.

The "Symbol Window" can optionally be defined as the third element in the cycle. This can be used to transmit a single symbol. Symbols are provided to wake a network and to test functionalities.



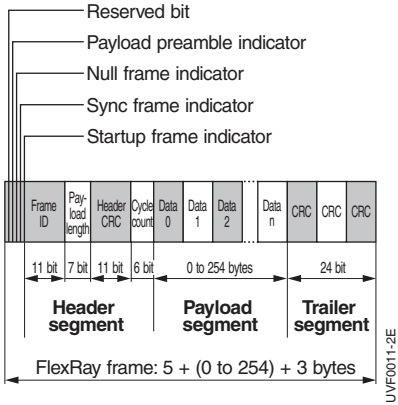
Synchronization

Each network node requires its own time generator, which it utilizes to decide the time for transmitting and to determine the duration of the bits. The internal time generators of several nodes may deviate from each other on account of temperature and voltage fluctuations and manufacturing tolerances. In a bus system such as FlexRay, which controls bus access via time slots, it is therefore necessary to ensure that the deviation of the clocks from one another remains within a permissible range through regular corrections. To this end, some nodes assume the role of time generators, to which the other nodes regularly synchronize their internal clocks. The procedure adapts both the zero points (offset) of the clocks and their rate. It can continue to operate even if individual nodes fail. To be able to make corrections, each cycle ends with a short phase (NIT, Network Idle Time) in which the zero point of the cycle can be shifted.

Thanks to this procedure a "global time" is provided in all the nodes; this time is given in macroticks. The synchronization mechanism causes the length of one macrotick to be the same on average in all the nodes.

When the network is switched on, a common conception of time on the part of all the nodes must first be established. The start-up process, which takes a little time, serves this purpose. Likewise, a node which intends to synchronize itself to a running network needs a period of time to be taken into consideration.

Figure 7: Time control for FlexRay (example)
A1 Node A transmits message 1,
A2 Node A transmits message 2,
MTS Media Test Symbol.



Arbitration in the dynamic segment
Messages can be given different priorities in the dynamic segment. The duration until a message is transmitted cannot be guaranteed for this. The priority is established by the frame ID, which may be allocated only once in the network. The messages are transmitted in the sequence of their frame ID. To this end, each node runs a counter (slot ID), which is increased when a message is received. If the slot ID assumes the value of the frame ID of a message ready in this node, it is transmitted. If the length of the dynamic segment is not sufficient for all the messages, the transmission process must be shifted to a later cycle.

The data frames in the dynamic segment can have different lengths. The limits of the dynamic slots on the two channels are independent of each other. Thus, there may be messages with different slot IDs on the channels at one time.

Data frame
FlexRay uses in both the static and dynamic segments the same data-frame format, which can be divided into the three sections of Header, Payload and Trailer (Figure 8).

Figure 8: Data frame

Header
The header comprises:
– The reserved bit for future protocol changes.
– The payload preamble indicator, which identifies whether the payload contains a network management vector.
– The null frame indicator, which identifies that the data have not been updated since the last cycle.
– The sync frame indicator, which signals that this data frame is to be used to synchronize the system.
– The startup frame indicator, which identifies that this frame is used in the network's start-up phase.
– The frame ID; this corresponds to the number of the slot in which the data frame is transmitted.
– The payload length which contains the size of the user data. For all the slots in the static segment this field always contains the same value. Data frames in the dynamic segment can have different lengths.
– The header CRC, which provides this part of the data frame with extra protection, because it is crucial to the time response.
– The cycle count; the number of the cycle in which the transmitting network node is located is transmitted in this field.

Payload
The user data which are processed further by the host are transmitted in the payload segment. For data frames in the static segment the first payload bytes can optionally be declared to the network management vector. The controllers or all the vectors received in the cycle and make them accessible to the host. For data frames in the dynamic segment the first payload bytes can optionally be declared to a 16-bit message ID. In both cases, subsequent handling is left to the software.

The user data have a maximum length of 254 bytes, which are transmitted in 2-byte words.

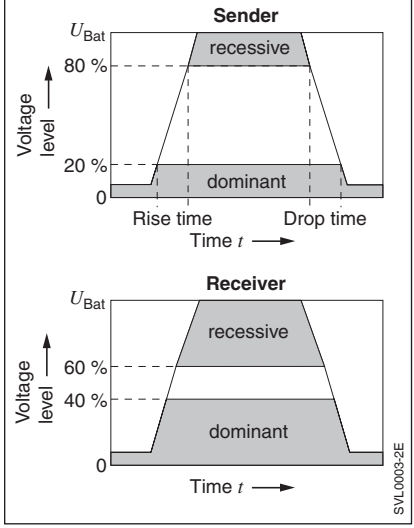
Trailer
The trailer contains a 24-bit checksum (frame CRC), which acts on the entire data frame.

Generating a frame bitstream
Before a node can transmit a data frame with the host's data, the data frame is converted into a "bitstream". To this end, the data frame is first deconstructed into individual bytes. A Transmission Start Sequence (TSS) of configurable bit length is inserted at the start of the data frame, followed by a bit Frame Start Sequence (FSS). Then an extended byte sequence is generated from the bytes of the data frame, where a two bit Byte Start Sequence (BSS) is inserted ahead of each frame byte.

To conclude the bitstream, a two bit Frame End Sequence (FES) is appended to the bitstream.

In the event that the data frame is in the dynamic segment, it is possible to append to the bitstream a further Dynamic Trailing Sequence (DTS) of configurable bit length. This prevents another node from starting its transmission via the channel early.

Operating modes
FlexRay can be placed in a mode in which the nodes need only minimal power and in which all the operations of the encoding and decoding process are stopped, but can be woken up by a signal on the bus line. Here, the bus driver is still capable of detecting special signals on the bus and then also of activating its host by means of a corresponding signal. Each node can transmit a wake-up.



LIN

Overview
The LIN bus (Local Interconnect Network) was designed to cover the communication requirements for Class A systems (see Table 1) with the most cost-effective hardware possible in the node. Typical applications are the door module with door lock, the power-window units, door-mirror adjustment, and air-conditioning system (transmission of signals from the control element, activation of the fresh-air blower).

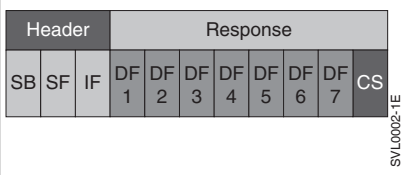
The current LIN specification can be accessed on the LIN Consortium website [4].

Important features of the LIN bus are:
– Single-master and multi-slave concepts,
– Low hardware costs on account of data transfer via non-shielded single-wire cable,
– Self-synchronization of the slaves even without a quartz oscillator,
– Communication in the form of very short messages,
– Transfer rate max. 20 kbit/s,
– Bus length up to 40 m and up to 16 nodes.

Figure 9: Voltage level on data line of LIN bus

Transfer system

The LIN bus is designed as a non-shielded single-wire cable. The bus level can assume two logic states. The dominant level corresponds to a voltage of approximately 0 V (ground) and represents logic 0. The recessive level corresponds to the battery voltage U_{batt} and represents the logic 1 state.



Because of the different design variations of the circuitry, the levels may be subject to differences. The definition of tolerances for transmitting and receiving in the field of the recessive and dominant levels ensures a stable data transfer. The tolerance bands are wider at the receiving end (Figure 9) so that valid signals can also be received in spite of interference radiation.

The transfer rate of the LIN bus is limited to 20 kbit/s. This is a compromise between the demand for high edge steepness to synchronize the slaves easily on the one hand and the demand for low edge steepness to improve EMC performance on the other. Recommended transfer rates are 2,400 bit/s, 9,600 bit/s and 19,200 Bit/s. The minimum permissible value for the transfer rate is 1 kbit/s.

The maximum number of nodes is not stipulated in the LIN specification. Theoretically, it is limited by the number of available content-related message identifiers. Line and node capacities and edge steepnesses limit the combination of length and node number of a LIN network; a maximum of 16 nodes is recommended.

The bus users are usually arranged in a linear bus topology; however, this topology is not explicitly prescribed.

Figure 10: LIN frame
SB Synch Break,
SF Synch Field,
IF Ident Field,
DF Data Field,
CS Checksum.

Bus access

In the LIN bus, access is provided on the basis of the master-slave access method. The network features a master, which initiates each message. The slave has the opportunity to respond. The messages are exchanged between the master and one, several or all the slaves.

The following relationships are possible during communication between master and slave:

– Message with slave response: The master transmits a message to one or more slaves and asks for data (e.g. switch states of measured values).
– Message with master instruction: The master issues control instructions to a slave (e.g. switching on a servomotor).
– Message for initialization: The master initiates a communication between two slaves.

LIN protocol

Data frame

The information on the LIN bus is embedded in a defined data frame (LIN frame) (Figure 10). A message initiated by the master begins with a header. The message field (response) contains different information depending on the type of message. If the master transmits control instructions for a slave, it describes the message field with the data to be utilized by the slave. In the event of a data request, the addressed slave describes the message field with the data requested by the master.

Header

The header is made up of the synchronization break (Synch Break), the synchronization field (Synch Field), and the identifier field (Ident Field).

Synchronization
A synchronization takes place at the start of each data frame to ensure a consistent data transfer between master and slaves. First the start of a data frame is clearly identified by the Synch Break. It consists of at least 13 consecutive dominant levels and one recessive level.

After the Synch Break, the master transmits the Synch Field, consisting of the bit sequence 01010101. The slaves thus have the opportunity to adapt themselves to the master's time base. The clock pulse of the master should not deviate from the nominal value by more than ±0.5%. The clock pulse of the slaves may deviate prior to synchronization by up to ±15% if the synchronization achieves a deviation of max. ±2% up to the end of the message. The slaves can thus be designed without an expensive quartz oscillator, for example with a cost-effective RC circuit.

Identifier
The third byte in the header is used as the LIN identifier. Similarly to the CAN bus, content-based addressing is used – the identifier therefore gives information about the content of a message. All the nodes connected to the bus decide on the basis of this information whether they intend to receive and process the message or ignore it (acceptance filtering).

Six of the eight bits of the identifier field determine the identifier itself, from which 64 possible identifiers (ID) are obtained. They have the following meanings:
– ID = 0–59: Transmission of signals,
– ID = 60: Master request for commands and diagnostics,
– ID = 61: Slave response to ID 60,
– ID = 62: Reserved for manufacturer-specific communication,
– ID = 63: Reserved for future expansions of the protocol.

Of the 64 possible messages, 32 may contain only two data bytes, 16 four data bytes, and the remaining 16 eight data bytes.

The last two bits in the Ident Field contain two checksums, with which the identifier is protected against transmission errors and resulting incorrect message allocations.

Data field
Transmission of the actual data begins after the master node has transmitted the header. The slaves identify from the transmitted identifier whether they are addressed and, if necessary, transmit back the response in the data field.

Several signals can be packed into a data frame. Here, each signal has exactly one generator, i.e. it is always described by the same network node. During operation it is not permitted to change the signal allocation to another generator, as would be possible in other time-controlled networks.

The data in the slave response are safeguarded by a checksum (CS).

LIN description file
The configuration of the LIN bus, i.e. the specification of network users, signals and data frames, is performed in the LIN description file. The LIN specification provides for a suitable configuration language for this purpose.

From the LIN description file, tools automatically generate program sections which are used to implement the master and slave functions in the ECUs located on the bus. The LIN description file thus serves to configure the entire LIN network. It is a common interface between the vehicle manufacturer and the suppliers of the master and slave modules.

Message scheduling
The scheduling table in the LIN description file determines the order and time frame in which the messages are transmitted. Frequently needed information is transmitted from time to time. When the table has been worked through, the master begins again with the first message. The sequence of processing can be altered depending on the operating state (e.g. diagnostics active or inactive, ignition on or off).

Thus, the transmission frame of each message is known. The deterministic performance is guaranteed by the fact that all the transmissions are initiated by the master in the case of master-slave access control.

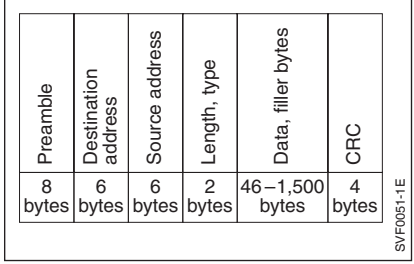
Network management
The nodes of a LIN network can be placed in sleep mode in order to minimize closed-circuit current. Sleep mode can be achieved in two ways. The master transmits the "Go to Sleep" command with the reserved identifier 60, or the slaves automatically go into sleep mode if there has been no data transfer on the bus for an extended period of time (four seconds). Both the master and the slaves can wake up the network again. The wake-up signal must be transmitted for this purpose. This consists of a data byte with the number 128 as content. After a break of 4 to 64 bit times (wake-up delimiter), all the nodes must be initialized and be able to respond to the master.

Ethernet

Overview
The term Ethernet refers to a family of buses in which the addressing, the format of the messages and access control are identical (laid down in IEEE 802, [5]). Ethernet and the Internet Protocol (IP) were developed for data communication between computers or peripherals which are locally separate and where, during operation, reconfigurations of the network through the addition of new users or the failure of users can occur. The Ethernet buses are identified by the following important features:
– The transfer rate is in the range of 10 Mbit/s up to 10 Gbit/s.
– Data transfer is possible via assorted media such as coaxial cable, twisted two-wire cable, radio or glass fiber.
– The technology involved is standardized and very widely used.
– Simple insertion and removal of nodes is possible.
– The time response in the case of real-time applications is not guaranteed.

Ethernet is used in series-production vehicles; e.g. in the BMW 7 Series, where it is used to input vehicle data at the end of production.

Transfer system
The Ethernet versions differ in terms of transfer rate, physical design of the channel, and encoding. Coaxial cables, twisted two-wire cables with one or more core pairs, optical fibers, radio paths, or even power-supply cables are specified as channels. Encoding differs accordingly.



Originally, coaxial cables in a bus topology were used as the medium. Here, the transceivers of the nodes were connected either directly or with T-pieces to the cable. Today, twisted two-wire cables are widely used. The transfer rates have been increased from initially 10 Mbit/s via the Fast Ethernet with 100 Mbit/s and the Gigabit Ethernet with 1,000 Mbit/s up to 10 Gbit/s.

Topology

The size of a network is limited by the fact that the signal propagation time between two nodes influences the arbitration process. This can be bypassed by subdividing into segments, which are connected by way of special components – hubs and switches. A hub functions as an amplifier which re-establishes the ideal signal shape of a bit if it has been corrupted by interference or dispersion on the transmission medium. A switch checks entire packets for correctness with regard to the checksum and directs packets without collision to another output if the destination address can be reached by this route. To this end, it must have the option of storing messages temporarily. As well as the costs involved in the hardware, a disadvantage when such elements are used is that the data stream is delayed. For this purpose, however, nodes with different data rates can be connected.

Today, networks are usually designed in such a way that each node is connected to the output of a switch, i.e. there is no direct connection between nodes. Switches themselves are in turn connected via a higher-level switch in such a way that a tree-shaped structure is created.

Figure 11: Frame format of Ethernet protocol

Ethernet protocol

Bus access

To transmit, a node checks whether there are signals on the bus. It starts to transmit when it deems the line to be clear. Because of the signal propagation time between two nodes, the situation may arise where two nodes deem the bus to be clear and start to transmit virtually simultaneously. The data frames transmitted in the process are destroyed. The nodes identify this, abort their transmission, and wait a certain amount of time – different for each node – until they begin with a new transmission attempt. This destruction of data frames reduces the effective transfer rate to a tolerable extent provided bus utilization is not too high.

This arbitration process limits the length of messages and the propagation time, i.e. the reach. There are no priorities among the messages. A maximum duration for transmission can, therefore, not be guaranteed.

Each node adopts from all the messages those which contain its own as the destination address for further processing.

Data frame

Figure 11 shows the slightly simplified structure of a data frame. The preamble is a periodic bit sequence (101010 – 1011) and thereby generates a signal to synchronize the receiver. Messages contain the address of their source and their destination. Each network card has a unique address. The receiving nodes compare the destination address with their own card address and accept the data frame if they match. With multicast and broadcast addresses, several receivers can also be addressed.

PSI5

Overview

The Peripheral Sensor Interface 5 (PSI5) is a digital interface published by the PSI Consortium ([6]) for sensor applications in motor vehicles and can be assigned by the application to Class A (see Table 1). The PSI5 is based on already existing interfaces for peripheral airbag sensors, but has been developed as an open standard which can be used and implemented at no extra charge. The technical characteristics mentioned in the following, the low implementation expenditure and the low additional costs compared with an analog sensor connection make the PSI5 an attractive option for sensor applications in motor vehicles too.

Transfer system

The PSI5 is a two-wire current interface in which the same lines are used to power the sensors and for Manchester-encoded data transfer. The bus master in the ECU modulates a voltage to the sensor for this purpose. Data transfers from the sensor to the ECU are effected by current modulation of the supply lines. In this way, high EMC robustness and low electromagnetic radiation are achieved. A wide range of supply currents for the sensors can be supported.

The different PSI5 operating modes define the topology and parameters of communication between ECU and sensors (Figure 12):

- Communication modes: The asynchronous mode can be used for a unidirectional point-to-point connection. In the three synchronous bus modes (parallel, universal or daisy-chain cabling) several sensors can communicate on a time-controlled basis with the bus master bidirectionally and using TDMA processes.
- Data-word width: The PSI5 supports a variable data-word width of 8, 10, 16, 20 or 24 bits.
- Error detection: This can be effected either with a parity bit with even parity or with three CRC checksum bits.
- Cycle times: These are specified in µs.
- Number of time slots per cycle.
- Data-transfer rate: As standard 125 kbit/s or optionally 189 kbit/s.

For example, the operating mode “PSI5-P10P-500/3L” denotes a parallel synchronous mode with ten bits per data word and parity bit for error detection. The data are transmitted every 500 µs with three time slots per cycle and a low bit rate.

Figure 12: Designation of PSI5 operating modes

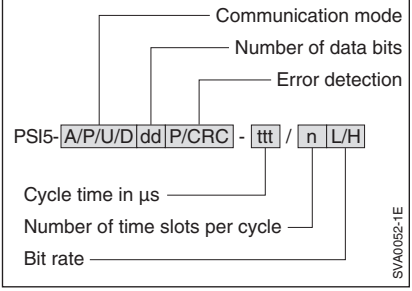
L Low (low bit rate),
H High (high bit rate).



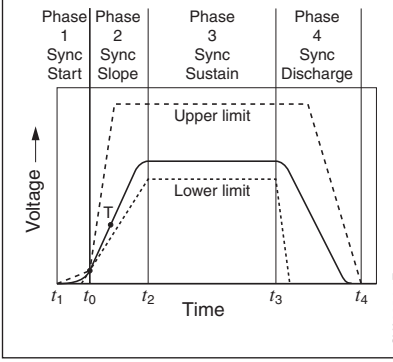


Figure 13: Synchronization signal of PSI5

T Trigger point.

During communication from sensor to ECU, a “low level” is represented by a normal (non-oscillating) current input of the sensor. A “high level” is generated by an increased current sink of the sensor (typically 26 mA). This current modulation is detected by the receiver in the ECU.

Each PSI5 data packet consists of N bits, in which there are in each case two start bits and one parity bit (or three CRC bits) and N–3 (or N–5) data bits. The data bits are transmitted with the least significant bit (LSB) first. Error detection with a parity bit is recommended for eight or ten bits, three CRC bits for longer data words.

In a PSI5 message, the data and value ranges have different meanings. One range serves to transmit the sensor output signals (≈ 94 %), one range the status and error messages (≈ 3 %), and one range the initialization data (≈ 3 %).

After each starting or undervoltage reset, the sensor conducts an internal initialization, after which the sensor is in an executable mode.

Whereas communication by the sensor with the ECU is effected with current signals, voltage modulation of the supply lines is used during communication by the ECU with the sensors. A logic 1 is represented by the synchronization signal, a logic 0 by the absence of the expected synchronization signal within the designated time slot. The synchronization signal consists of four voltage phases (Figure 13):

– Sync Start (nom. 3 µs, < 0.5 V),
– Sync Slope (nom. 7 µs, > 0.5 V),
– Sync Sustain (nom. 9 µs, > 3.5 V), and
– Sync Discharge (nom. 19 µs, < 3.5 V).

MOST

Overview

Application

The MOST bus (Media Oriented Systems Transport) was specially developed for the networking of multimedia applications in motor vehicles (infotainment bus). Alongside the classical entertainment functions such as radio receivers and CD players, infotainment systems also provide video functions (DVD and TV), navigation functions, and access to mobile communication and information. The MOST bus supports the logical networking of up to 64 devices and provides a fixed and reserved transmission bandwidth. MOST defines the protocol, the hardware, the software, and the system layers. MOST is jointly developed and standardized by automobile manufacturers and suppliers within the MOST Cooperation [7]. With a data rate of more than 10 Mbit/s, the MOST bus is a Class D bus system (see Table 1).

For data transfer, the MOST bus supports the following transmission channels:

- Control channel to transport control commands,
- Multimedia channel (synchronous channel) for the transmission of audio and video data,
- Package data channel (asynchronous channel), for example to transmit configuration data for a navigation system and to update software in control units.

Requirements

The transmission of multimedia data – both audio and video data – requires a high data rate and also synchronization of the data transfer between source and sink as well as between a number of sinks.

Transfer system

Physical layer

The MOST standard specifies both optical and electrical technologies of the physical layer (transmission layer). The optical transmission layer is widespread and currently uses fiber-optic cables (polymer optical fibers, POF) made of polymethyl methacrylate as its transfer medium. These have a 1 mm core diameter and are used in combination with LEDs and silicon photo diodes as receivers (see Optical fibers/waveguides).

The outstanding feature of MOST 50 is its suitability for the electrical transmission of data. This enables data transfer across unshielded, twisted copper cables (UTP, unshielded twisted pairs). Whereas MOST 25 technology has continued to develop in Europe for a many years and has become established in the Korean market, the Japanese market in particular prefers MOST 50, the second generation of the multimedia standard.

The identification number, for example in the case of MOST 25, stands for a transfer rate of approx. 25 Mbit/s. The exact data rate depends on the sampling rate that the system uses. With a sampling rate of 44.1 kHz, the MOST frame (data frame) is transferred 44,100 times per second; a frame length of 512 bits results in a data rate of 22.58 Mbit/s. For MOST 50, the same sampling rate results in double the data rate, as the frame is 1,024 bits long. Higher data rates of 150 MBit/s (MOST 150) are currently also available.

Special features of MOST 150

In addition to the higher bandwidth of 150 Mbit/s, MOST 150 contains an isochronous transport mechanism to transfer compressed data of HD videos efficiently. MPEG transport streams (MPEG, Moving Picture Experts Group) are transported directly here. With a corresponding MPEG4-based video codec, it is possible to transfer resolutions of up to 1,080 p (1,080 screen lines), as delivered by BluRay players for example. Alongside this, MOST 150 provides an Ethernet channel for the efficient transmission of IP package data (IP = internet protocol).

In contrast to the MAMAC protocol (MOST Asynchronous Medium Access Control) used in the case of MOST 25, the Ethernet channel is able to transfer Ethernet frames. The Ethernet channel transfers unmodified Ethernet data blocks, which means that software stacks and applications from the fields of consumer electronics and IT can be integrated seamlessly in vehicles with much shorter innovation cycles. TCP/IP stacks or protocols that use TCP/IP (TCP = Transmission Control Protocol) can thus communicate via MOST 150 without changes.

The MOST Network Interface Controller (NIC) is a hardware controller that is responsible for control of the physical layer and implements important transfer mechanisms.

Protocol

Data transfer

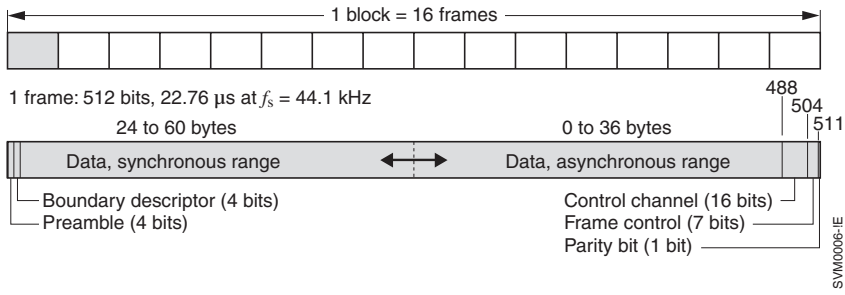
Data transfer on the MOST bus is organized in data frames that are created by the timing master with a fixed data rate and passed on by the devices in the ring.

Data frames

The timing master usually creates data frames with a clock rate of 44.1 kHz, more rarely also 48 kHz. The size of the data frames thus determines the bus speed of a MOST system. In the case of MOST 25, the size of a data frame is 512 bits (Figure 14). The synchronous and asynchronous areas of MOST 25 jointly use 60 bytes of the data frame. The division between the synchronous channels and the asynchronous channel is determined by the value of the boundary descriptors with a resolution of 4 bytes. The synchronous area must have at least 24 bytes (six stereo channels). This means that between 24 and 60 bytes are permitted for the synchronous area and between zero and 36 bytes are permitted for the asynchronous area. The preamble is used for synchronization; the parity bit is used to recognize bit errors.

Transmission of control messages

The control channel is used to signal device statuses and for the messages required for system administration. So that the control channel does not occupy too much bandwidth per frame, it has been distributed to 16 frames grouped to form a block. Each frame transports two bytes of the channel (Figure 14). In order to ensure recognition of the block start, the preamble of the first frame of a block bears a special bit pattern. In the case of MOST 25, the control channel has a gross bandwidth of 705.6 kbit/s.



Transmission of multimedia data

The synchronous channels are used for realtime communication of audio and video data, whereby the data interchange is controlled via the corresponding control commands on the control channel. A synchronous channel can be assigned a certain bandwidth, which occurs with a resolution of one byte of a data frame. A stereo audio channel with a resolution of 16 bits, for example, requires four bytes. In the case of MOST 25, depending on the value of the boundary descriptor, a maximum of 60 bytes are available for synchronous channels; this corresponds to 15 stereo audio channels.

Transmission of package data

Data are transferred packet-wise on the asynchronous channel. It is therefore suitable for the transmission of information that has no fixed data rate but requires high data rates at short notice. Examples are the transmission of track information of an MP3 player or a software update.

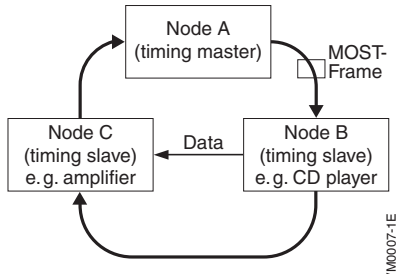


Figure 14: MOST frame structure

In the case of MOST 25, the asynchronous channel has a gross bandwidth of up to 12.7 MBit/s and it currently supports two modes: a slower 48-byte mode in which 48 bytes are available in each package for the net data transmission as well as a 1,014-byte mode that is more complex to implement. In order to ensure reliable transmission and flow control for the typically large asynchronous channel data volumes, an additional transport protocol (Data Link Protocol) is usually deployed; this is implemented in a driver layer at a higher level. This is either the MOST High Protocol (MHP), which has been specially developed for the MOST, or the common TCP/IP protocol that is placed on a corresponding adaptation layer called the MOST Asynchronous Medium Access Control (MAMAC).

Topology
MOST is organized in a ring structure (Figure 15). This is a point-to-multipoint data flow system (i.e. the streaming data have one source and a number of sinks) and all the devices therefore share a joint system frequency that they acquire from the data flow. The devices are thus in phase and can transfer all data synchronously. This makes mechanisms for signal buffering and signal processing superfluous. A certain device acts as "timing master" and generates the data frames used for data transfer and to which the other devices synchronize.

Figure 15: Ring structure of the MOST bus

Addressing
The devices are addressed on the MOST bus via a 16-bit address. Various types of addressing are available: Logical and physical addressing as well as group addressing for simultaneous addressing of a defined group of control units.

Administration functions
The MOST standard defines the management mechanisms (network and connection masters) necessary for the operation of a MOST system. These mechanisms are described below.

Network master
The network master is implemented by a marked device in a MOST system and is responsible for the configuration of the system. In current systems, the network master is usually implemented using the head unit (i.e. control panel) of the infotainment system. This device is often also the timing master at the same time. The other devices of the MOST system are referred to as network slaves in this context.

Connection master
The connection master manages the synchronous connections that exist in a MOST system at any particular point in time.

MOST application layer
For the transfer of control commands, status information, and events, the MOST standard defines a corresponding protocol on the application level. This protocol enables triggering of a certain function of an application interface (i.e. of an FBlock = function block) that is provided by any device within the MOST system.

The protocol for MOST control messages includes the following elements of a control message:
– The address of a device in the MOST system (DeviceID)
– An identifier for an FBlock (FBlockID) implemented by this device and its instance in the MOST system (InstID)
– The identifier for the function called up within the FBlock (FunctionID)
– The type of an operation (OpType).

Function block
A function block (FBlock) defines the interface of a certain application or of a system service. The sinks and sources for multimedia data are each assigned to an FBlock that provides the corresponding functions for their administration. An FBlock can therefore have a number of sources and sinks enumerated via a source and sink number.

An FBlock has functions that deliver information regarding the number and type of sources and sinks that it provides (SyncDataInfo, SourceInfo and SinkInfo). Over and above this, each FBlock with a source has an "Allocate" function that it uses to request a synchronous channel and connect the source to that channel. Accordingly, an FBlock with a sink has a "Connect" function to connect the sink to a certain synchronous channel and a "DisConnect" function to break off this connection.

An FBlock is addressed by means of an 8-bit FBlockID, which specifies the type of the FBlock, and an additional 8-bit InstID.

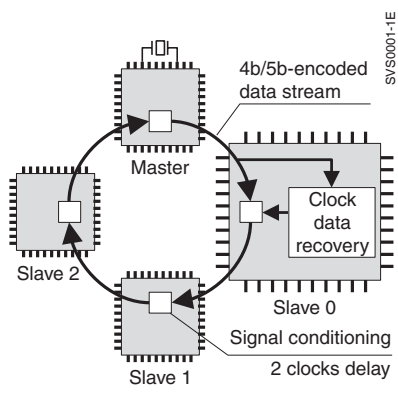
Function classes
To standardize the way in which functions are defined, the MOST standard specifies a series of function classes for properties. These determine which properties the function has and which operations are permissible.

Applications
As well as defining the lower layers necessary for data transfer, the MOST standard defines the interfaces for typical applications from the area of vehicle infotainment systems, e.g. a CD changer, amplifier or radio tuner.

The FBlocks defined by the MOST Cooperation are summarized in a function catalog.

Standardization
The MOST standard is maintained by the MOST Cooperation, which also publishes the corresponding specifications. The specifications are available on the homepage of the MOST Cooperation [7].

The MOST Corporation was founded in 1998 by BMW, Daimler, Becker Radio, and OASIS Silicon Systems with the aim of standardizing MOST technology.



Serial Wire Ring

Internal buses do not leave the ECU. They connect the integrated circuits (ICs) on the board to each other. These buses transmit data from input circuits (e.g. analog-digital converters) to the controller or data to activate output stages from the controller to the output stages. Since these buses are only used inside one ECU, voltage levels, signal type (symmetrical or asymmetrical), impedances, and bit rate can be configured differently, depending on the requirement.

Features
The Serial Wire Ring (SWR) is the modern successor to the Serial Peripheral Interface (SPI). Its advantages are the higher bit rate and only two pins per user as opposed to four pins (CLK, MOSI, MISO, CS) in the SPI. As the price for these advantages the SWR requires a more complex logic in the transmitter and in the receiver, particularly to recover the clock signal from the data stream.

Only two pins per user provide for small housings and less wiring on the board. This is made possible by a ring topology as pictured in Figure 1. This has the additional benefit of the master being able to read back all data and thereby discover transmission errors. This is an important feature for safety-related systems.

Figure 1: Topology of the Serial Wire Ring

Topology
The ring consists exclusively of point-to-point connections, providing for high data rates. Each connection transmits the data from precisely one source to precisely one destination in only one direction (Figure 1):

Master → Slave 0 → Slave 1 → … → Slave $N-1$ → Master.

The ring contains one master and 1 to 16 slaves. Since all are similarly connected to each other in the ring, it is optionally possible for alternately a different module in the ring to assume the role of master.

Each user in the ring forwards the received signal with two clocks delay to the next user. The level of the signal is thereby conditioned. Even small time fluctuations of the signal edges (jitter) are reduced with the aid of clock data recovery (CDR). In this way, different signal levels can be realized within a ring.

4b/5b encoding of data
Clock and data are jointly transmitted via a line in the ring. The receiver extracts the data and the clock from this signal by means of clock data recovery (CDR). To enable the clock to be recovered even in the event of many consecutive “0” or “1”, a special 4b/5b encoding as depicted in Table 1 is used: Every fourth bit is inverted and then sent again. With this encoding there is a change from “0” to “1” or vice versa after five clocks at the latest. The drawback is that five bits have to be sent over the bus to transmit four data bits.

Table 1: 4b/5b code
The lowest-value bit is transmitted first.

0000 → 00001	0001 → 00010
1000 → 10001	1001 → 10010
0100 → 01001	0101 → 01010
1100 → 11001	1101 → 11010
0010 → 00101	0011 → 00110
1010 → 10101	1011 → 10110
0110 → 01101	0111 → 01110
1110 → 11101	1111 → 11110

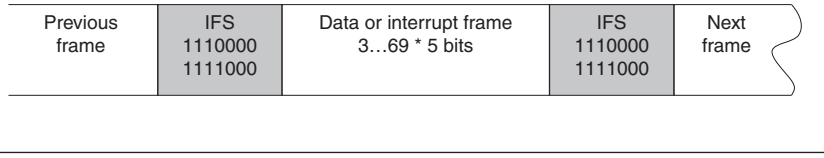
Transmission is performed according to the following scheme: The lowest-value bit is always transmitted first and the highest-value bit is transmitted last.

Clock rate
The clock rate is not tied down to specific values, but can be chosen to suit the required data rate and latency. The lower limit is 1 MHz, the upper limit is determined by the slowest user and the line routing.

Signal transmission from precisely one source to precisely one destination facilitates higher data rates than with a branched line such that the Serial Wire Ring can be operated at 10 to 100 times the clock frequency of the Serial Peripheral Interface. The demand for higher speed mentioned at the start is thus fulfilled.

Data transmission
The interframe symbol and the data frame or the interrupt frame are transmitted alternately by the master on the data line (2).

Addressing
The slaves are addressed via an address field in the data frame. Each slave receives its address automatically via its position in the ring during the initialization of the ring. The first slave receives the address 0, the last of N slaves receives the address $N-1$.



Data frame
The data frame serves to transmit user data between master and slave. With the same data frame the master can also send data to several slaves and receive data from several slaves. At the same time it is possible to transmit data from slave to slave, but only in the circulation direction of the ring.

The master continuously sends frames through the ring. If no data have to be transmitted, it sends “zero frames”.

Interrupt frame
Interrupt frames are regularly sent by the master within a fixed time interval. Each slave which has reserved one or more bits in the interrupt frame can use such a bit to trigger a specific reaction in the master. This reaction usually consists of delivering or collecting data.

Interframe symbol
To enable each user in the ring to detect the start of a frame, the interframe symbol (IFS, Figure 2) is situated between two frames. It is 14 bits long and differs from each possible 14-bit sequence of the 4b/5b-encoded signals in at least two bits. This ensures that a 1-bit error does not lead to the appearance of an interframe symbol in the regular 4b/5b data stream. Each user in the ring compares the last 14 received bits with the interframe symbol. If they match, the user begins to evaluate the frames that now follow. In the event of errors, it aborts the evaluation and waits for the next interframe symbol.

Figure 2: Structure of a data transmission
IFS Interframe symbol.

Data frame

Identifier

Figure 3 shows a data frame in detail. The leading 1 identifies the frame as a data frame. A 01 would indicate a zero frame and a 0010 an interrupt frame.

Data frame counter

The data frame counter (DFC) is a 2-bit counter which the master increments before it sends a new data frame. This is important in the event of a transmission error that the master notices when reading back. It then repeats the data frame with the same DFC. If the error has occurred on the way from the master to the slave, the slave now receives the data frame for the first time and evaluates it. If the error has occurred on the way from the slave to the master, the slave now receives the data frame for the second time, detects this by the unchanged DFC, and now does not evaluate it for a second time.

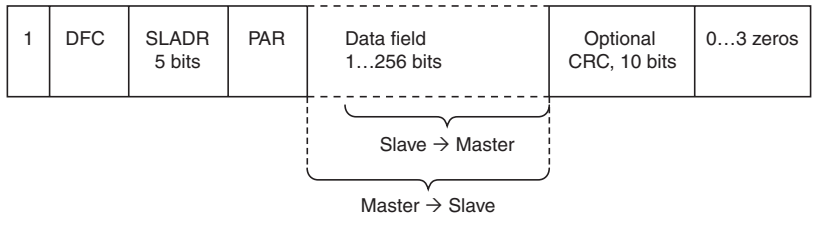
Slave address

The slave address SLADR addresses the slave. The primary addresses 0 to $N-1$ address precisely one slave at the corresponding position in the ring. Higher values up to 31 are used for group addresses. While the ring is being initialized, the master can instruct one or more slaves to execute a particular operation automatically if a certain group address appears, for example to output bits 12 to 16 to five output stages. In this way, the master can carry out complex data transfers later without further instructions and thus very quickly simply by using the associated group address. The participating slaves then "know" what is to be done.

Parity bit

PAR is a parity bit for the first eight bits. It is sufficient in order to detect 100 % of all single-bit errors. Double-bit errors are detected by the master when reading back and lead to a bus reset. Therefore they do not have to be detected by PAR. This procedure is possible because double- and multiple-bit errors are very rare.

Data field



The actual data field comes after PAR. It can contain any number of bits from 1 to 256.

Primary address

In the event of a primary address, i.e. if the master only addresses this slave, the slave processes the entire data field and if necessary places an answer at the end of the data field. In the process it overwrites part of the data field so that the master can no longer read back its message to the slave. If this is not permitted for security reasons or if the slave's answer is already longer than the master's message, the master must configure the data field bigger and for example append zeros. The slave then overwrites only this areas and no old data are lost. However, this gives rise to a larger data field, i.e. a longer transmission time.

Figure 3: Data frame

DFC Data frame counter,
SLADR Slave address,
PAR Parity bit,
CRC Cyclic redundancy check.

Group address
In the event of a group address, each slave can, according to its previously learned instructions, evaluate and change any bits of the data field.

Cyclic redundancy check
The concluding 10-bit CRC (cyclic redundancy check) is supported by slaves for which this is useful. There are also simple slaves which do not support the CRC in order to save costs. The CRC is required to back up critical data on their way from the slave to the master. Because, while the master can detect all the other transmission errors when reading back, this is not possible with the answer data from a slave. The slaves which belong to a group address must all jointly use the CRC, or not.

Filler bits
Because of the 4b/5b encoding the data frame must always contain a multiple of four bits. It may therefore be necessary finally to append up to three more zeros in order to reach the next multiple higher of four.

Sequence control in the master
As transmission rates increase, it is becoming increasing more difficult for a CPU to make available the transmission data in good time via a simple send and receive register and to collect the received data fast enough. Therefore the SWR master automatically accesses the memory. This memory also contains one or more chained lists with instructions as to which transactions the master is to execute (queues).

Once activated, the master works through a queue instruction by instruction down to the last instruction or to an instruction with a set stop bit. A software command, an external trigger (e.g. by a timer) or the already described prompt by a slave by means of interrupt frame can reactivate the queue.

The end of a queue can refer back to the start and thereby form a closed loop. In this way, the same instructions can be executed again and again. If an instruction is disrupted by a transmission error, the master repeats it automatically.

Each instruction contains a priority. This does not play a role as long as only one queue is active. However, as soon as several queues are active and therefore several instructions are due to be executed at the same time, the master selects the instruction with the highest priority.

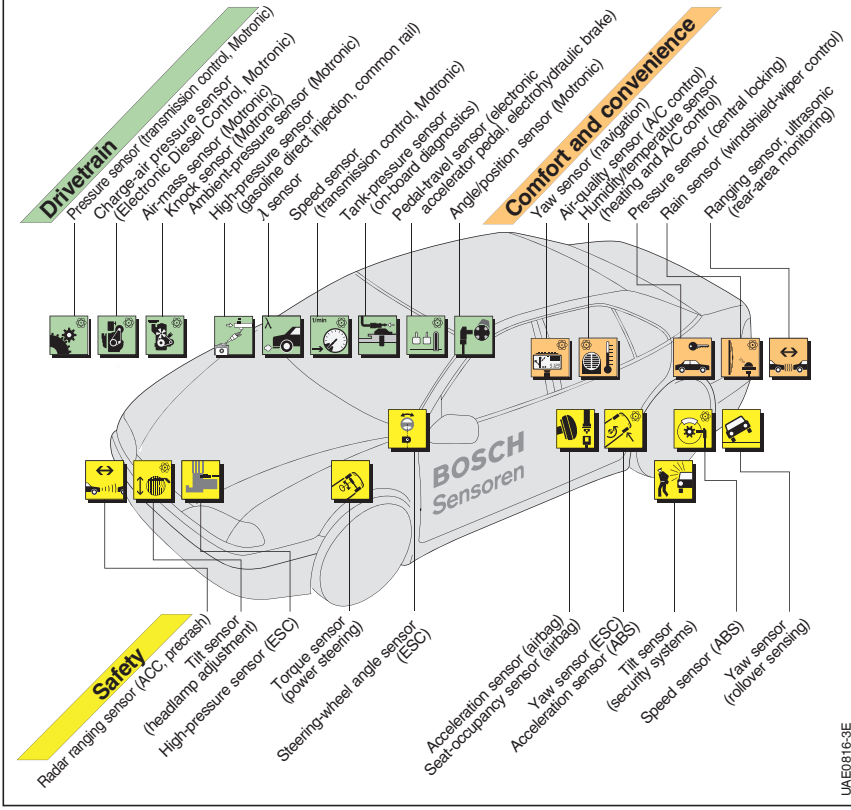
Automotive sensors

Automotive applications

Sensors and actuators form as the periphery the interface between the vehicle with its complex drive, brake, chassis-system, and body functions and the digital electronic control unit (ECU) as the processing unit. The sensors detect physical quantities and convert them into electrical quantities that can be processed by the ECU.



Classification

Classic sensors

Sensors were introduced in motor vehicles with the emergence of electronic control for fuel injection and Ignition. Speed sensors to acquire the engine speed and pressure sensors to measure the intake-manifold pressure were required for this purpose. With the antilock braking system (ABS) it was necessary to acquire the wheel speed. Wheel-speed sensors which operate according to the same measuring principle as the engine-speed sensors were used for this purpose. The further development of these speed sensors led from the inductive sensor to the active sensor with an improvement in measured-value acquisition.

The constantly rising complexity of the electronic systems in motor vehicles led to

Figure 1: Automotive sensors (examples)
The applications of the respective sensors are specified in parentheses.

an increase in sensors. Figure 1 provides an overview of where and for which purposes such sensors are used.

Sensors for driver-assistance systems
A completely new type of sensor was introduced with the ultrasonic sensors for the parking aid. These sensors as well as radar and video sensors sense the vehicle's environment or surroundings and thereby facilitate a wealth of driver-assistance functions (see Driver-assistance systems). These sensors are complex systems and cannot be compared with the classic sensors.

Main requirements
Operating conditions
Automotive sensors are sometimes exposed to extreme conditions in their installation locations. These are mechanical stresses (e.g., vibrations and impacts), climatic influences (e.g. low and extremely high temperatures, moisture), chemical influences (e.g., splash water, salt spray, fuel, engine oil, battery acid), and electromagnetic influences (e.g., high-frequency interference, mains-borne interference pulses, overvoltage). The degree of stress to which a sensor is subjected is determined by the operating conditions at its installation location.

Reliability
According to application and technical requirements, automotive sensors are assigned to one of three reliability classes:
– Steering, brakes, passenger protection,
– Engine, drivetrain, suspension, tires,
– Comfort and convenience, information, diagnosis, theft deterrence.

Size
The constantly increasing number of electronic systems in vehicles on the one hand and the ever more compact shape of vehicles on the other hand force engineers to adopt extremely small designs. In addition, the pressure of increased fuel economy necessitates a consistent reduction of vehicle weight. Various miniaturization concepts are employed to achieve compact sensor dimensions:
– Substrate and hybrid technologies (e.g., for strain-dependent resistors, thermistors, and magnetoresistors),
– Semiconductor technology (e.g., for Hall-effect crankshaft sensors),
– Surface and bulk micromechanics (e.g., for silicon pressure, acceleration, and yaw sensors),
– Microsystem technology (integration of micromechanical or microoptical components with microelectronic circuits in a complex system).

Manufacturing costs
Electronic systems in vehicles contain up to 150 sensors. This abundance of sensors forces engineers to radically reduce costs compared with other areas of use. Extensively automated manufacturing processes working at great efficiency levels are used. In other words, each process step is always performed simultaneously for a larger number of sensors. The manufacture of semiconductor sensors typically involves the simultaneous integration of 100 to 1,000 sensors on one silicon wafer. The automotive industry's huge demand for sensors has set new standards here.

Accuracy requirements
The accuracy requirements for automotive sensors are lower than for sensors for the process industry for example. The permissible deviations are generally greater than 1 % of the upper range value of the measurement range. The inevitable influences of aging must also be taken into consideration here.

However, ever more sophisticated and complex systems call for higher levels of accuracy. This can be achieved to a certain extent by reducing the manufacturing tolerances and by improving the adjustment and compensation technologies. "Integrated sensors" provide for a significant advance here.

Basic principles of classic sensors

Function

Sensors convert a physical or a chemical (usually non-electrical) quantity Φ into an electrical quantity E. This is often also done via further, non-electrical intermediate stages. The sensor data are processed in a digital electronic control unit (ECU) (Figure 2). An adapter circuit is generally used to convert the sensor's signals into the standardized form required by the ECU. In addition, system operation can be influenced by sensor information from other processing elements for example via bus systems and/or by driver-operated switches.

Sensor classification

Sensors can be classified according to very different standpoints. With regard to their use in motor vehicles, they can be categorized as follows.

Assignment and application

– Functional sensors (e.g., pressure sensor, temperature sensor, air-mass sensor), primarily for open- and closed-loop control functions.
– Sensors for safety (passenger protection: airbag and driving-dynamics control) and protection (theft deterrence).
– Sensors for vehicle monitoring (onboard diagnostics, consumption and wear quantities) and for providing information to driver and passengers.

Type of characteristic curve

– Continuous linear characteristic curves (Figure 3a) are used particularly for control functions across a broad measurement range. Linear characteristic curves furthermore have the advantage that they are easy to check and adjust.

Figure 3: Types of characteristic curve

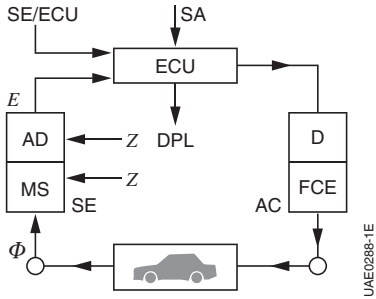

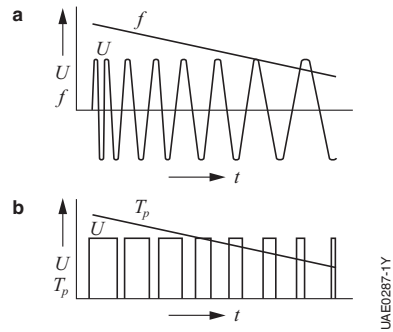

Figure 4: Signal shapes (examples)
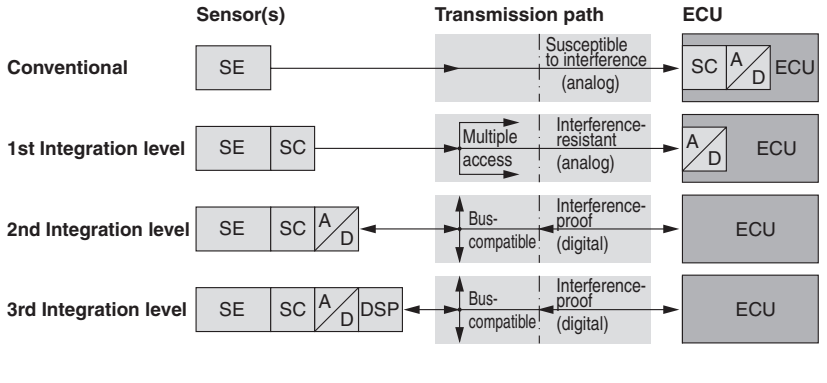
a) Frequency f,
b) Pulse duration T_p,
U Output signal, t Time.

– Continuous nonlinear characteristic curves (Figures 3b) are often used for closed-loop control of a measured variable within a very narrow measurement range (e.g., control of the air/fuel ratio at $\lambda = 1$, control of the compression level).
– Discontinuous dual-stage characteristic curves, with hysteresis in some cases (Figure 3d) are used to monitor limit values where an easy remedy is possible when they are reached. If remedy is more difficult, early warning can be effected at an earlier stage by means of multiple stages (Figure 3c).



Type of output signal
Analog output signal (Figure 4):
– Current or voltage, or corresponding amplitude,
– Frequency or period duration,
– Pulse duration or pulse duty factor.

Discrete output signal:
– dual stage (binary encoded),
– multistage – irregular graduation (analog encoded),
– multistage – equidistant (analog or digital encoded).

Continuous signals are constantly available at the sensor output, discontinuous signals are available only at discrete times. A bit-serially output signal is inevitably discontinuous.

Integrated sensors
Systems range from hybrid and monolithic integrated sensors and electronic signal-processing circuits at the measuring point, through to complex digital circuits, such as analog-digital converters and microcomputers, for complete utilization of the sensor's inherent accuracy "intelligent" sensors, Figure 5). These systems offer the following benefits and options:
– Reduction of load on the ECU,
– Uniform, flexible, bus-compatible interface,
– Multiple application of sensors,
– Multisensor designs,
– Use of small measuring effects and high-frequency measuring effects (by local amplification and demodulation), and
– Correction of sensor deviations at the measuring point, and common calibration and compensation of sensor and circuit, are simplified and improved by storage of the individual correction information in semiconductor memory chips (e.g., PROM).

Micromechanics

Applications

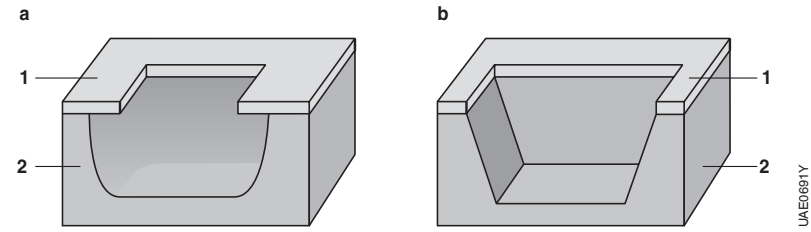
Micromechanics is defined as the application of semiconductor technology in the production of mechanical components from semiconductor materials (usually silicon). This type of application exploits both the semiconducting and the mechanical properties of silicon. The first micro-mechanical silicon pressure sensors were installed in motor vehicles at the beginning of the 1980s. Typical mechanical dimensions can extend into the micrometer range.

The mechanical properties of silicon (e.g. strength, hardness and modulus of elasticity, see Table 1) can be compared to those of steel. However, silicon is significantly lighter and has greater thermal conductivity than steel. Single-crystal silicon wafers are used with almost perfect mechanical properties. Hysteresis and creepage are negligible. Due to the brittleness of the single-crystal material, the stress-strain curve has no plastic range; the material ruptures when the elastic range is exceeded.

Two methods of manufacturing micromechanical structures in silicon have established themselves: volume micromechanics (VMM) and surface micromechanics (SMM). Both methods use the standard procedures of microelectronics (e.g. epitaxial growth, oxidation, diffusion, and photolithography) together with some additional special procedures [1].

Volume micromechanics

The silicon wafer material is processed at the required depth using anisotropic (alkaline) etching with or without an electrochemical etching stop. From the rear, the material is removed from inside the silicon layer, where there is no etching mask resting on top (Figure 5). Using this method, very small membranes can be produced with typical thicknesses of between 5 and 50 µm, as well as openings, beams and webs as are needed for instance in pressure and acceleration sensors.



The problem when etching with alkaline media lies in the fact that the walls run inwards at an angle. In order to be able to effect high-precision etching at depth with vertical walls, it was necessary to develop a new process. Here Bosch made a breakthrough with the development of the DRIE process (Deep Reactive Ion Etching), which has in the meantime come to be known generally in the industry as the “Bosch process”. This involves the creation in a special gas-phase reactor of alternating gases and accompanying conditions for an etching

Table 1: Mechanical properties of silicon

Quantity	Unit	Silicon	Steel (max.)	Stainless steel
Tensile load	10^5 N/cm^2	7.0	4.2	2.1
Knoop hardness	kg/mm^2	850	1,500	660
Modulus of elasticity	10^7 N/cm^2	1.9	2.1	2.0
Density	g/cm^3	2.3	7.9	7.9
Thermal conductivity	W/cm · K	1.57	0.97	0.33
Thermal expansion	10^{-6}/K	2.3	12.0	17.3

1 Etching mask (e.g. oxide or nitride), 2 Silicon.

stage and then a passivation stage. This etching and the subsequent passivation of the walls are set such that very precise vertical walls are created. This process can be used for both volume and surface micromechanics.

Surface micromechanics
In contrast to volume micromechanics, surface micromechanics merely uses the silicon wafer as the substrate. Moving structures are usually formed from polycrystalline silicon layers which, similarly to a manufacturing process for integrated circuits, are deposited on the surface of the silicon by epitaxial growth.

When a surface-micromechanical component is made, a sacrificial layer of silicon oxide is first applied on the wafer and structured with standard semiconductor processes, i.e. partly removed again specifically (Figure 6a). An approx. 10 µm thick polysilicon layer (epipoly layer) is then applied at high temperatures in an epitaxial reactor (Figure 6b) and whose desired structure is anisotropically, i.e. vertically, etched with the aid of a lacquer mask (deep etching or trenching, Figure 6c). The vertical side walls are obtained with the Bosch process by alternating etching and passivation cycles. After an etching cycle, the etched sidewall section is provided during passivation with a polymer as protection so that it is not attacked during the subsequent etching. Vertical side walls with a high representation accuracy are created in this way. In the last process stage (Figure 6d) the sacrificial layer beneath the polysilicon layer is removed with gaseous hydrogen fluoride in order to expose the structures (Figure 7).

Among other things, surface micromechanics is used in the manufacture of capacitive acceleration sensors for airbag systems and in the manufacture of yaw sensors for applications in driving-dynamics control and in rollover sensing.

APSM process
The "Advanced Porous Silicon Membrane" process (APSM process) uses a completely different surface-micromechanical process sequence. It uses the properties of porous silicon to create

Figure 6: Process stages in surface micromechanics

beneath a monocrystalline membrane an exactly defined cavity in which a vacuum is enclosed.

The core of the APSM process is porous silicon. This can be manufactured selectively and on a locally limited basis in p-doped silicon in an electrochemical anodizing process in hydrofluoric acid. In this process some of the silicon is dissolved out of the crystal to leave a porous, sponge-like silicon shell, the "porous silicon".

Porous silicon in turn can be rearranged at high temperatures. The silicon shell dissolves and forms under suitable conditions a thin membrane on the surface. A cavity forms below this membrane (Figure 8). This thin membrane can be enlarged to the target thickness by means of epitaxial growth.

The monocrystalline epitaxial layer is used for example as the diaphragm of a pressure sensor. Evaluating-circuit elements in the epitaxial layer outside the diaphragm provide for a high-precision, small and inexpensive pressure sensor.

Modern pressure sensors, e.g. barometric pressure sensors for engine-management systems, are manufactured using the APSM process.

Wafer bonding

In addition to structuring the silicon, joining two wafers represents another essential task in micromechanical production engineering. Joining technology is required, for example, in order to hermetically seal a reference-vacuum chamber (e.g. for pressure sensors), to protect sensitive structures by applying caps (e.g. in acceleration and yaw sensors, Figure 9), or to join the silicon wafer with intermediate layers which minimize the thermal and mechanical stresses (e.g. glass base on pressure sensors).

In the case of anodic bonding, a Pyrex-glass wafer is joined to a silicon wafer at a voltage of some 100 V and a temperature of approx. 400 °C (Figure 10). A strong electrostatic attraction and an electrochemical reaction (anodic oxidation) result in a permanent hermetic bond between the glass and the silicon.

In the case of seal-glass bonding, two silicon wafers are contacted by way of a glass-solder layer applied in a screen-printing process at approx. 400 °C and under the exertion of pressure. The glass solder melts at this temperature and produces a hermetically sealed bond with the silicon.

Position and angular-position sensors

Measured variables

These sensors record one- or multidimensional displacement and angle positions (translational and rotatory variables) of the most varied types and ranges. Examples of such measured variables are:

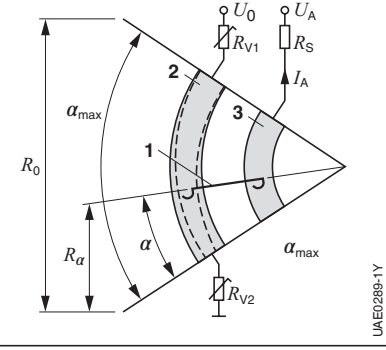
- Accelerator-pedal position for recording the torque request for engine management (driver command),
- Throttle-valve position for controlling the throttle valve,
- Fuel-tank level,
- Steering-wheel angle,
- Position of the transmission selector lever for electronic transmission control
- Seat position,
- Mirror position,
- Control-rack position in the diesel in-line fuel-injection pump,
- Travel of clutch servo unit,
- Brake-pedal position,
- Tilt angle.

In this sector of applications, activities have long since been directed at changing over to proximity or non-contacting sensor principles. Such sensors are wear-free and thus have a longer service life as well as being more reliable. The costs involved though, often force vehicle manufacturers to retain the "wiper-type" sensor principle, and such sensors still perform efficiently enough for many measurement purposes.

In practice, incremental sensor systems are also often referred to as angular-position (or angle-of-rotation) sensors, even when they are used for measuring rotational speed. These sensors are in reality not angular-position (or angle-of-rotation) sensors. Since the increments (steps with which a given quantity increases) which have to be measured with these sensors in order to measure the deflection angle must first be counted with the correct preceding sign (in other words, added), there is the possibility of permanent interference.

Wiper potentiometer

Measurement principle



The wiper potentiometer – usually designed as an angular-position sensor – measures travel by exploiting the proportional relationship between the length of a wire or film resistor (conductor track made of cermet or "conductive plastic") and its electrical resistance (Figure 1). At present, this is the lowest-priced travel and angular-position sensor.

To protect against overloading, supply voltage is usually applied to the measurement track through series resistors R_V. These resistors can also be used for calibration of zero point and curve slope. The shape of the contour across the width of the measurement track (including that of individual sections) influences the shape of the characteristic curve.

The standard wiper connection is furnished by a contact track consisting of the same material mounted on a low-resistance substrate. Wear and measurement distortions can be avoided by reducing the current at the pick-off (I_A < 1 mA) and sealing the unit against dust and liquid. Also essential to minimizing wear is to have an optimum friction pairing of wiper

Figure 1: Wiper potentiometer

and potentiometer track; here wipers can have a spoon or scraper shape and have a single or multiple design, even in the shape of a broom.

The wiper potentiometer together with further resistors form a voltage divider (Figure 2). The picked-off voltage is a measure of the wiper position.

Advantages of the potentiometer are, for example, the low costs, the simple and clear design, the large measuring effect (measuring stroke corresponds to the supply voltage), the wide operating-temperature range up to 250 °C, and the high degree of accuracy (better than 1 % of the upper range value of the measurement range).

Disadvantages of the potentiometer are, for example, mechanical wear caused by abrasion, measuring errors caused by abraded remnants, wiper lift-off in the event of vibrations, and the limited miniaturization capability.

Wiper-potentiometer applications

Throttle-valve angle sensor

Mounted on the throttle valve in a gasoline engines is a throttle-valve sensor (Figure 3), which signals the position of the throttle valve to the engine-management system. The throttle-valve angle sensor has a redundant design for diagnostic purposes (Figure 2). This makes available two independent signals which can be checked for plausibility against each other. Redundant measurement enables faults to be detected.

Accelerator-pedal sensor

The accelerator-pedal (pedal-travel) sensor senses the travel or the angle of the pressed accelerator pedal. The engine-management system interprets this value as a torque request from the driver. The accelerator-pedal sensor is integrated together with the accelerator pedal in the accelerator-pedal module. With these units that are ready for installation there is no need for adjustment on the vehicle.

With the potentiometric sensor design the measurement signal is generated by a potentiometer. The engine ECU converts the measured voltage using the stored sensor curve into the covered pedal travel or into the accelerator pedal's angular position.

Like the throttle-valve sensor the accelerator-pedal sensor has a redundant design. One sensor version operates with a second potentiometer that always delivers half the voltage of the first potentiometer at all operating points. Two independent

signals are thus available for the purpose of fault detection. Sensor versions with low-idle switches were also customary in the past; the state of these sensors had to be plausible with the measurement signal of the potentiometer.

A further switch for detecting a kick-down can be integrated in the accelerator-pedal module of vehicles with automatic transmissions. Alternatively, this signal can be derived from the rate of change of the potentiometer voltage or generated when a threshold value is exceeded.

Fuel-level sensor

The level in the fuel tank is transmitted by the float via the float lever to the potentiometer (Figure 4). Firstly, the prepared measured value is transmitted for display in the instrument cluster; secondly, the fuel level is used to measure fuel consumption (e.g. for displaying the range calculated by the on-board computer).

Magnetically inductive sensors

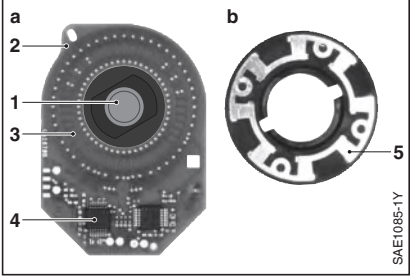
Of all the sensors which perform non-contacting position measurement, magnetic sensors are particularly non-susceptible to interference and robust. This applies in particular to those principles relying on alternating current, in other words magnetically inductive principles. Compared with a micromechanical sensor though, the coil configuration needed here requires far more space. This means therefore that there is no favorable possibility of redundant (parallel measurement) design.

Measurement principle, short-circuiting-ring sensors

Of all the established principles of magnetically inductive sensors it is mainly short-circuiting-ring sensors that have up to now been used by Bosch in motor vehicles. These sensors sense for example the control-rack position in diesel in-line fuel-injection pumps [1]. However, these are no longer used in a macromechanical design form for new developments.

Measurement principle, eddy-current sensors

When an electrically conducting disk (e.g. made of aluminum or copper) approaches a (usually air-core) coil supplied with high-frequency alternating current, eddy currents are created in the disk by the increasing magnetic coupling as a function of the distance (measurement travel s). This influences both the equivalent resistance and the inductance of the coil. The disk thus acts as a damper disk.



Both the damping effect (on account of the equivalent resistance) and the field-displacement effect (on account of the inductance) can be used to convert the measuring effect into an electrical output voltage. The suitable choice is in the first case for example an oscillator of variable amplitude and in the second case an oscillator of variable frequency or a constantly powered, inductive voltage divider.

A high operating frequency is required due to the low coil inductance. This necessitates a direct assignment of electronic circuitry to the sensor.

Application: Position sensor
for transmission control
In automatic transmissions position sensors sense the position of final controlling elements (e.g. selector-lever shaft, selector valve or parking-lock cylinder). Because of the complex requirements from the different transmission topologies and the space and functional requirements different physical measurement principles (Hall, AMR, GMR and eddy-current principles) and types (linear and rotatory sensing) are used.

In the eddy-current sensor the rotor rotates with the selector-lever shaft (Figure 5). A return coil is mounted on the rotor. The fixed sensor board contains redundant transmitter and receiver coils with the associated evaluation electronics. The transmitter coil induces in the return coil an eddy current opposing its cause whose magnetic field induces a voltage in the receiver coil. The geometries of the return coil and the receiver coils are matched to each other in such a way that continuously variable rotor positions can be sensed. The rotatory position sensor thus determines the selector-lever positions P, R, N, D, 4, 3, and 2.

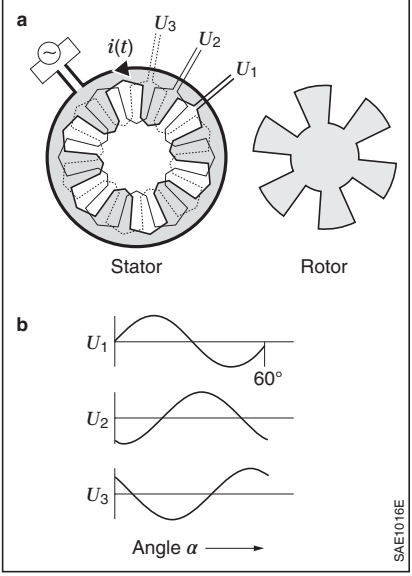


Figure 5: Position sensor using eddy-current principle
a) Sensor board with protective circuit,
b) Rotor.
1 Selector-lever shaft,
2 Sensor board,
3 Redundant transmitter and receiver coils,
4 Redundant evaluation electronics,
5 Rotor with return coil.

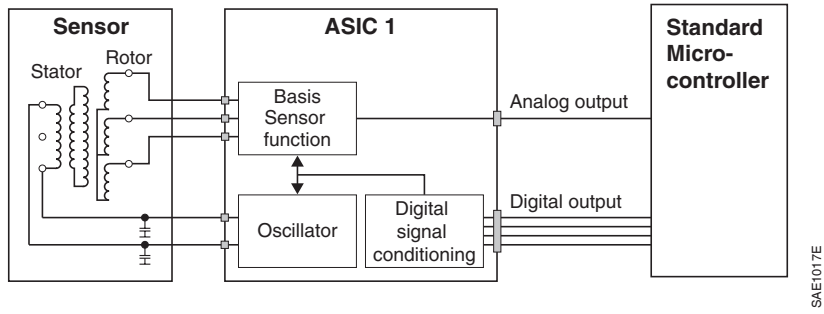
For safety reasons the sensor generates two independent, opposite signals which are checked for plausibility against each other.

Sensors with rotating alternating fields
Two- or multipole alternating-field structures can be arranged either in a circle or linearly with coils energized with alternating current of angular frequency Ω or coil-like configurations (such as meander conductor-track structures) (Figure 6). Compared with a usually fixed set of receiver coils, which have the same pole pitch, these pole structures with fixed pole pitch can be displaced by the movement of the system to be measured – whether it be rotatory or translational in nature. Here, the amplitudes of the receiver signals (U_1, U_2, U_3, etc.) change sinusoidally with the movement. If the receiver coils are offset against each other by a certain part of the pole pitch T (e.g. T/4 or T/3), the sine shape is phase-displaced in each case by a corresponding angle (e.g. by 90° or 120°). After rectification, the angle

Figure 6: Sensor with rotating alternating fields
a) Schematic layout,
b) Output signals.

of rotation to be measured can be calculated with great accuracy from these voltages. This is the mode of operation of the sensors referred to in classical metrology as synchro, resolver, or inductosyn processes, and preferably configured as angular-position encoders.

The angular-position sensor shown in Figure 6 most resembles the inductosyn process. This is a sensor with a six-figure pole structure (n = 6), which in electrical terms converts an angle of rotation of φ = 60° into a phase displacement of signal amplitudes of α = 360 °. All the necessary conductor-track structures are at least in the case of the fixed part (stator) situated on multi-layer board material. The rotor part can also if necessary be designed as a stamping, either self-supported or mounted on plastic carriers (by hot stamping).



Situated on the stator is a circular conductor-track loop which, independently of the angle of rotation, induces at an operating frequency of 20 MHz an eddy current in a self-contained meander loop of roughly equal outside diameter on the rotor. Like the excitation loop, this eddy current creates a secondary magnetic field which overlaps the excitation field such that it attempts to damp it. If there were only a circular conductor track congruent to the stator loop on the rotor instead of the meander, this would simply extinguish the primary field to the greatest possible extent. However, the meander structure creates a resulting multipole field, which can be rotated with the rotor and whose total flux is also virtually zero.

This multipole alternating field is sensed by concentric receiver coils (meanders) of identical shape likewise located on the stator. These coils or meanders are displaced within a pole pitch (of e.g. 60°) by 1/3 in each case, i.e. electrically in their signal amplitude by 120° in each case (Figure 6b). However, the receiver coils stretch over all the n pole pairs (series connection) and utilize the sum total of all the pole fields.

Figure 7 shows the receiver coils star-connected. For the purpose of determining the electrical phase angle α (or the mechanical angle of rotation), the coil signals are routed to an ASIC, which performs the necessary rectification, selection, and ratio formation. The ASIC receives the necessary digital control signals from a nearby microcontroller. A different version of an ASIC is, however, also able to operate the sensor completely independently (stand-alone). The ASICs also permit an end-of-line adjustment of the mechanical and electrical tolerances in production.

For applications with increased safety requirements, it is also possible to design a redundant system with two isolated signal paths and two ASICs. The sensor principle can also be configured very advantageously in an “open” form as a travel sensor. The sensor can therefore be used at many points in a motor vehicle (e.g. recording the throttle-valve angle in the throttle device, lever position on auto-

Figure 7: Protective circuit of sensor with rotating alternating fields

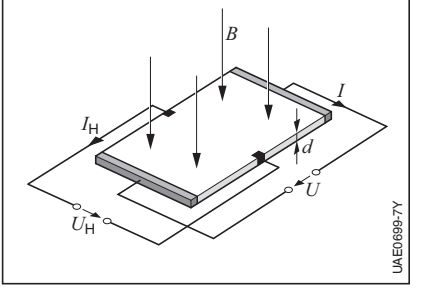
matic transmissions, headlight position for headlight leveling control).

Magnetostatic sensors: Overview
Magnetostatic sensors measure a DC magnetic field. In contrast to the magnetically inductive sensors with coils, they are far more suitable for miniaturization and can be manufactured at reasonable cost using microsystem techniques. Since DC magnetic fields can easily penetrate through housing walls made of plastic but also of non-ferromagnetic metal, magnetostatic sensors have the advantage that the sensitive, generally fixed part can be well encapsulated and protected in respect of the rotatory part – usually a permanent magnet or a soft-magnetic conductive element – and in respect of the environment. Above all, galvanomagnetic effects (Hall and Gaussian effects) and magnetoresistive effects (AMR and GMR) are used.

Hall effect
The Hall effect occurs in thin semiconductor chips. If such a current-carrying chip is permeated vertically by a magnetic induction B, the charge carriers are deflected by the Lorentz force vertically to the field and to the current I by the angle α from their otherwise straight path. It is thus possible to pick off a voltage U_H proportional to the field B and to the current I transversally to the current direction between two opposing marginal points of the chip (Hall voltage, Figure 8):

$$U_H = \frac{R_H I B}{d}$$

where
R_H Hall coefficient,
d Chip thickness.



The coefficient R_H crucial to the measurement sensitivity of the chip is only comparatively small in the case of silicon. However, because the chip thickness d can be made extremely thin using diffusion techniques, the Hall voltage U_H attains a technically acceptable value again.

When silicon is used as the basic material, a signal-conditioning circuit can be integrated on the chip. Sensors using these principles are thus cheap to produce.

In terms of measurement sensitivity, temperature coefficient, and temperature range, however, silicon is by no means the best semiconductor material for Hall sensors. III-V semiconductors such as gallium arsenide or indium antimonide, for example, demonstrate better properties.

Gaussian effect
In addition to the transversally directed Hall effect, semiconductor chips are also subject to a longitudinal resistance effect, otherwise known as the Gaussian effect. Independently of the field direction the series resistance increases according to a roughly parabolic characteristic curve. Elements which utilize this effect are called magnetoresistors (Siemens trade name) and are manufactured from a III-V semiconductor, crystalline indium antimonide (InSb).

Figure 8: Hall effect

U_H Hall voltage,
I_H Hall current.

Hall sensors

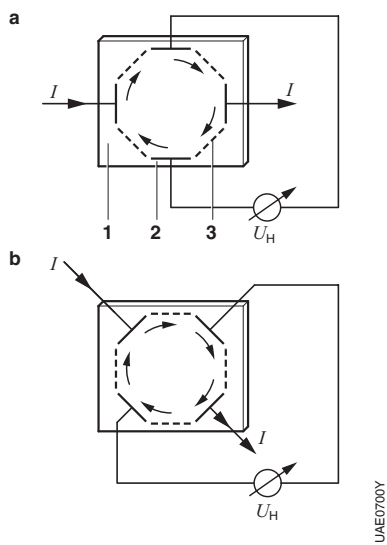
Hall switch

In the most simple case, in the Hall switch the Hall voltage is applied to an electronic threshold circuit integrated in the sensor (Schmitt trigger), which then outputs a digital signal. If the magnetic induction B applied at the sensor is below a given minimum threshold level, the Schmitt trigger's output value corresponds to a logical 0 (release status); if it exceeds a given upper threshold, the output value corresponds to a logical 1 (operate status). Since this behavior is guaranteed across the complete operating-temperature range and for all sensors of a given type, the two threshold values are relatively far apart (approx. 50 mT). In other words, it takes a considerable induction jump ΔB to trigger the Hall switch.

Such Hall sensors manufactured for the most part in bipolar technology are indeed very economical, but are at best only good for switch operation (e.g. Hall vane switches for triggering ignition in earlier ignition systems, digital steering-angle sensor). Hall vane switches are too inaccurate for recording analog variables.

Hall sensors using the spinning-current principle

A disadvantage of a simple Hall sensor is its simultaneous sensitivity to mechanical stresses (piezoelectric effect), which are inevitable due to packaging and result in an unfavorable offset temperature coefficient. This disadvantage has been overcome by the application of the spinning-current principle (Figure 9), combined with the transition to CMOS technology. The piezoelectric effect does arise here too, but is compensated by time averaging of the signal, since it occurs in the event of very fast, electronically controlled switching (rotation) of the electrodes with a different polarity sign.



If the desired aim is to avoid the expense of complex electronics to switch the electrodes, it is also possible to integrate in close proximity several Hall sensors (two, four or eight) with correspondingly different alignment of the current path, and to add up their signals in the form of an averaging.

Only through these measures was it possible for Hall ICs to become well suited to analog sensor applications. These measures though barely resulted in a reduction of the sometimes considerable effects of temperature on the measurement sensitivity.

Such Hall ICs are suitable above all for the measurement of small travel distances, in which they register the fluctuating field strength of a permanent magnet as it approaches (used for example in the force sensor for sensing front-passenger weight). Up to then, similarly good results could only be achieved by the use of individual Hall elements of, for example, III-V semiconductors (e.g. GaAs) with a hybrid downstream amplifier.

Applications of Hall sensors
Position sensors
for transmission control
In this type of position sensor for transmission control for linear position sensing four Hall switches are arranged on a printed-circuit board in such a way that they sense the magnetic encoding of a linearly displaceable multipolar permanent magnet (Figure 10). The magnet carriage is coupled to the linearly actuated selector valve (hydraulic valve in the transmission control plate) or the parking-lock cylinder.

The position sensor senses the positions of the selector valve (P, R, N, D, 4, 3, 2) and the intermediate ranges and outputs these in the form of a 4-bit code to the transmission-control system. For safety reasons the encoding of the position is configured as a single step. In other words, two bit changes are always required until a new position is detected. The sequence of these bit changes corresponds to a Gray code.

Axle sensors
Axle sensors sense the body's inclination angle that changes as a result of vehicle load or during braking and acceleration. The range of the headlamps can be adapted to the conditions with this information (automatic headlamp leveling control).

Vehicle inclination is measured by angle-of-rotation sensors (axle sensors). These are mounted to the body at the front and rear. Compression is measured by a rotary lever which is connected via a pushrod to the vehicle axle. The vehicle inclination is obtained from the difference between the sensor signals on the front and rear axles.

The axle-sensor stator (Figure 11) incorporates a Hall element located in the ring magnet's homogeneous field. The magnetic field induces in the Hall element a Hall voltage that is proportional to the magnetic field strength. During compression the axle-sensor shaft rotates with the ring magnet, and thus the magnetic field is also altered by the Hall element. The Hall element delivers a signal that is dependent on the angle of rotation of the shaft and thus on the compression travel.

Accelerator-pedal sensors
Using a rotatable magnetic ring ("movable magnet"), together with a number of fixed

soft-magnetic conductive elements, a linear output signal can be generated for a larger angular range without conversion being necessary (Figure 12). Here, the movable magnet's bipolar field is directed through a Hall sensor located between semicircular conductive elements. The effective magnetic flux through the Hall-effect sensor is dependent on the angle of rotation φ. The angular range that can be sensed is 180° here.

The Hall angular-position sensor with a measuring range of approximately 90° pictured in Figure 13a is derived from the basic "movable magnet" principle. The magnetic flux from a practically semicircular permanent-magnet disc is returned to the magnet through a pole-shoe, two additional conductive elements each of which contains a Hall sensor in its magnetic path, and the shaft which is also ferromagnetic. Depending upon the angular setting, the flux is led to a greater or lesser degree through the two conductive elements, in the magnetic path of which a Hall sensor is situated. Using this principle, it is possible to achieve a practically linear characteristic curve (Figure 13b).

The simplified version pictured in Figure 14 does without soft magnetic conductive elements. In this version, the magnet moves around the Hall sensor in a circular arc (Figure 14a). Only a relatively small section of the resulting sinusoidal characteristic curve features good linearity. If the Hall sensor is located slightly outside the center of the circular arc, the characteristic curve increasingly deviates from the sinusoidal, and now features a short measuring range of almost 90°, and a longer measuring range of something more than 180° with good linearity. A great disadvantage though is the low level of shielding against external fields, as well as the remaining dependence on the geometric tolerances of the

magnetic circuit, and the intensity fluctuations of the magnetic flux in the permanent magnet as a function of temperature and age.

In the Hall angular-position sensor pictured in Figure 15 it is not the field strength but rather the magnetic-field direction that is evaluated. The magnetic-field lines are sensed by four Hall elements lying in one plane and radially arranged in the x- and y-directions. The sensor is located between two magnets to generate a homogeneous magnetic field. The sensor signal is formed from the measurement signals of the Hall elements (sine and cosine signals) in an evaluation circuit using the arctan function.

Like the potentiometric accelerator-pedal sensor these systems also contain two measuring elements in order to obtain two redundant voltage signals for diagnostic purposes.

Magnetoresistive sensors

In contrast to the Hall sensors, the optimum chip shape for a magnetoresistor tends to be shorter and squatter, and represents a very low resistance. In order to arrive at technically applicable resistance values in the kΩ range, it is therefore necessary to connect a large number of these chips in series. This problem is solved elegantly by adding microscopically fine, highly conductive nickel-antimonide needles to the semiconductor crystal. These are located obliquely to the direction of current flow. A further measure is to apply meander techniques to the semiconductor resistor.

The dependence of the resistance on the magnetic flux density B follows a square-law function up to inductances of approximately 0.3 T, and above this point

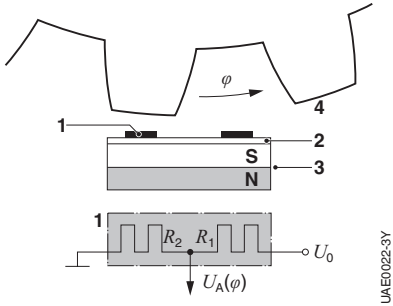
it is increasingly linear. There is no upper limit to the control range, and dynamic response in technical applications can – as is the case with the Hall sensor – be regarded as free from lag.



Since the temperature sensitivity has a pronounced effect on the resistance of magnetoresistors (approximately 50 % reduction for 100 K), they are usually delivered only in the dual-configuration form in voltage-divider circuits (differential magnetoresistors). For the particular application, each of the two resistor sections must then be magnetically triggered (as far as possible with opposite polarities). Notwithstanding the high temperature coefficient of the individual resistors, the voltage-divider circuit guarantees good stability of the working-point (that point at which both resistor sections have the same value).

In order to achieve good measurement sensitivity, it is best to operate the magnetoresistors at a magnetic working point between 0.1 and 0.3 T. Generally, the required magnetic bias is supplied by a small permanent magnet (Figure 16) the effects of which can be increased by using a small magnetic return plate. The magnetoresistor features pronounced temperature sensitivity so that it is used almost exclusively in incremental angle-of-rotation and displacement sensors, or in binary limit-value sensors (with switching characteristic). A magnetoresistive increment sensor is used to measure start-of-injection adjustment in diesel distributor injection pumps.

The magnetoresistor's main advantage is its high signal level which is usually in the volts range. This means that amplification is unnecessary, as well as the local electronic circuitry and the associated protective measures which would otherwise be needed. Furthermore, in their role as passive, resistive components, they are highly insensitive to electromagnetic interference and, as a result of their high bias voltage, practically immune against external magnetic fields.

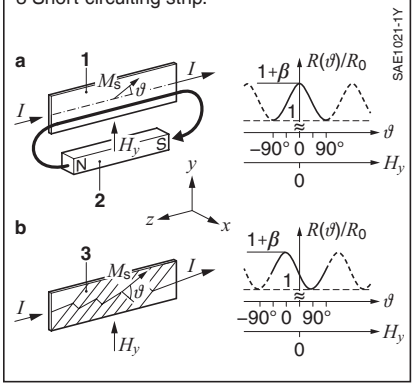
AMR sensors

Anisotropic magnetoresistive effect



NiFe layers only roughly 30 to 50 nm thick display electromagnetically anisotropic properties, i.e. their electrical resistance changes under the influence of a magnetic field. Resistance structures of this type are therefore called AMR sensors (anisotropic magnetoresistive sensors). The metal alloy generally used is also called permalloy.

Types

On an elongated resistance strip, as shown in Figure 17a, a small, spontaneous magnetization M_S occurs in the longi-

tudinal direction of the conductor track even without the application of an external control field (form anisotropy). In order to give this magnetization a clearly defined direction – theoretically, it could be in the other direction – AMR sensors are often, as depicted, provided with weak bias magnets. In this state, the series resistance has its greatest value $R_{\|}$. If the magnetization vector is rotated under the influence of an additional external field H_y through the angle ϑ, the series resistance decreases gradually until it assumes at $\vartheta = 90°$ a minimum value $R_{\perp}$. Here, the resistance is only dependent on the angle ϑ contained by the resulting magnetization M_S and the current I; it has a roughly cosinusoidal characteristic as a function of ϑ:

$$R = R_0(1 + \beta\cos^2\vartheta).$$

Thus the following relationships are obtained for the maximum and minimum values:

$$R_{\|} = R_0(1 + \beta) \text{ and } R_{\perp} = R_0.$$

Figure 18: Pseudo-Hall sensor

b) Modified form with hollowed-out surface,
c) Replacement circuit diagram for b).
B Magnetic flux density,
U_H Hall voltage,
I Supply current,
φ Angle of rotation,
R_H Resistors of AMR elements.

The coefficient β denotes the maximum possible resistance variation, and is approximately 3 %. If the external field is much stronger than the spontaneous magnetization, and this is usually the case when control magnets are used, the effective angle is almost completely a function of the direction of the external field. The field strength is now irrelevant, in other words, the sensor is now operating in the "saturated state".

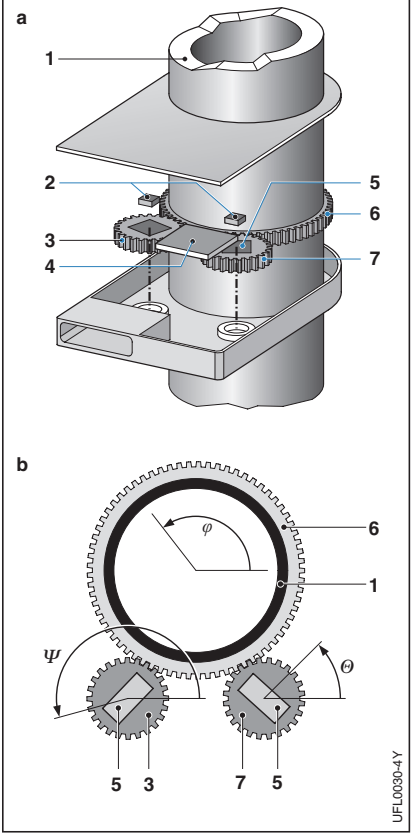
Highly conductive short-circuiting strips (for instance of gold) on the AMR film force the current to flow at an angle of below 45° to the spontaneous magnetization (longitudinal direction) without the application of an external field. In this version – also referred to as the "barber-pole" sensor – the sensor curve shifts by 45° compared to that of the simple resistor (Figure 17b). This means, therefore, that even when the external field strength $H_y = 0$, the curve is at the point of maximum measurement sensitivity (reversal point). The "striping of two resistors in opposite directions" means that they change their resistances in opposite directions under the effects of the same field. In other words, one of the resistances increases while the other drops.

In addition to the simple, two-pole AMR elements, there are also pseudo-Hall sensors, for instance square NiFe thin-film structures, which, like the normal Hall sensors already described, have four terminals: two for the current path and two transverse ones for picking off a Hall voltage (Figure 18a). Unlike a normal Hall sensor, however, a pseudo-Hall sensor is sensitive to magnetic fields in the film plane and not vertically to it. Also, a pseudo-Hall sensor does not demonstrate a proportional characteristic curve; instead, it has a sinusoidal curve with very high faithfulness of shape to the sine, which is in no way dependent on the strength of the control field and the temperature. For a field parallel to the current path, the output voltage disappears in order then to describe a sinusoidal half-period when the field is rotated up to the angle $\varphi = 90°$. The sinusoidal voltage therefore results with amplitude $\hat{u}_H$ as follows:

$$U_H = \hat{u}_H \sin 2\varphi.$$

If the external control field is rotated once through φ = 360°, the output voltage therefore follows two full sinusoidal periods. The amplitude $\hat{u}_H$ is, however, very much dependent on the temperature and the air gap between the sensor and the control magnet; it decreases as the temperature and the air gap increase.

The measurement sensitivity of this so-called pseudo-Hall element can be considerably increased (without excessively falsifying the sinusoidal shape) by "hollowing out" the element from the inside so that only the "frame" remains (Figure 18b). This modification converts the pseudo-Hall sensor to a full bridge consisting of four AMR resistors (Figure 18c). Even when the bridge resistors are meander-shaped, provided a given minimum conductor width is not dropped below, this still has negligible effect on the signal's sinusoidal shape.



Applications

Steering-angle sensor

The function of driving-dynamics systems is to keep the vehicle on the desired course specified by the driver with targeted brake interventions. The steering-wheel angle must be known for this purpose. Potentiometers, optical code sensing and magnetic measurement principles are used for measurement.

A steering-wheel-angle sensor mounted on the steering shaft senses the steering-wheel position. Several rotations of the steering shaft can be measured with a dual configuration of pseudo-Hall angle-of-rotation sensors (each for 180 °). The two associated permanent magnets are rotated via a high-ratio gear train (Figure 19). Because the two smaller output gears, which carry the control magnets, differ by one tooth, their mutual phase angle (difference of angles of rotation: $\Psi - \Theta$) is a clear measure of the absolute angular position of the steering shaft. The system is designed in such a way that this phase difference does not exceed 360° for a total of four rotations of the steering shaft, and thereby the clearness of the measurement is assured. Each individual sensor also offers an indeterminate fine resolution of the angle of rotation. It is possible with such an arrangement to resolve the full steering-angle range, for example, more accurately than 1°.

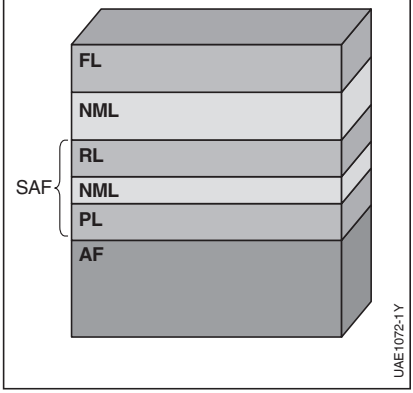
GMR sensors

Giant magnetoresistive effect



GMR-sensor technology (giant magnetoresistive sensor) is used in automotive applications for angular-position and rpm sensing. The main advantages of GMR sensors over AMR sensors are the natural clearness range within 360° for angular-position sensing and the higher magnetic-field sensitivity for rpm sensing.

GMR layer structures consist of antiferromagnetic, ferromagnetic and non-magnetic function layers (Figure 20). The individual layer thicknesses in both systems are in the range of 1 to 5 nm, and therefore only comprise a few atom layers. For angular-position sensing the required reference magnetization is generated by the fact that the direction of magnetization of one of the ferromagnetic layers (PL) is pinned by the interaction with a neighboring antiferromagnetic layer (AF). This is therefore also referred to as a “pinned layer”. On the other hand, the magnetization of the second ferromagnetic layer (FL) magnetically isolated to a large extent via a non-magnetic interlayer (NML) can be freely rotated with the external magnetic field. This is accordingly referred to as a “free layer”.

The resistance changes with a cosinusoidal dependence on the angle between the external field direction and the reference direction. Crucial to the accuracy of the angular-position measurement is the stability of the reference magnetization against the effect of the external field. This stability is greatly increased by using an additional artificial antiferromagnet (SAF).

AF Antiferromagnet,
SAF Artificial antiferromagnet.

Applications of GMR sensors

Steering-wheel-angle sensor

The mechanical structure and the operating principle of this GMR sensor is equivalent to those of the steering-wheel-angle sensor with AMR elements. In view of the greater sensitivity in comparison with the AMR effect the GMR sensor can operate with weaker magnets and larger air gaps. This results in costs benefits with regard to materials and design. The 360° angular-position measurement range of a single GMR element (180° is typical for AMR) enables smaller gears to be used. This in turn means that it takes up less space.

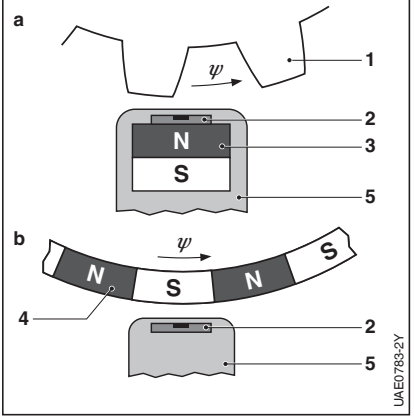
rpm sensors

Measured variables
rpm sensors measure the time required for an angle to be covered during a rotational motion. From this the number of revolutions per unit of time can be determined. In a motor vehicle this usually involves relative measured variables which occur between two components. Examples include:
– Crankshaft speed,
– Camshaft speed,
– Wheel speed (e.g. for the antilock braking system),
– Transmission speed,
– Rotational speed of the diesel distributor-type injection pump.

Measurement principles
rpm sensing usually occurs with an incremental sensor system, consisting of a rotor (e.g. gear or multipole wheel) and the rpm sensor (Figure 1).

Passive rpm sensors
Conventional inductive sensors used in the past were based on the inductive measuring effect. A sensor of this type consists of a permanent magnet and a soft magnetic pole pin surrounded by an induction coil. The pole pin is opposite a ferromagnetic gear. The distance between the gear and the pole pin changes as the gear turns. The time change in the magnetic flux that this causes gives rise to an induced voltage in the coil.



The measuring effect of the inductive sensor is relatively high, eliminating the need for local electronics. It is therefore called a passive sensor. However, the signal amplitude is rotational-speed-dependent. The sensor is therefore unsuitable for the lowest rotational speeds; it permits only a comparatively small air-gap tolerance between pole pin and gear and for the most part is not able to distinguish air-gap fluctuations (chatter) from rotational-speed pulses.

Passive rpm sensors are still used today in commercial vehicles.

Active rpm sensors
Active rpm sensors operate in accordance with the magnetostatic principle. The amplitude of the output signal is not dependent on the rotational speed. rpm sensing is thus possible even at very low rotational speeds (quasistatic rpm sensing).

Hall sensor
A voltage U_H proportional to the magnetic field (Hall voltage) can be picked off transversely to the current direction on a current-carrying wafer which is permeated vertically by a magnetic induction B (see Hall effect). In the sensor arrangement with a ferromagnetic gear (pulse wheel) the magnetic field is generated by a permanent magnet (Figure 1a). Located between the magnet and the pulse wheel is the Hall-sensor element. The magnetic flux which permeates this element depends on whether the sensor is opposite a tooth or a gap. This results in a Hall voltage that is equivalent to the progression of the teeth. This rotational-speed infor-

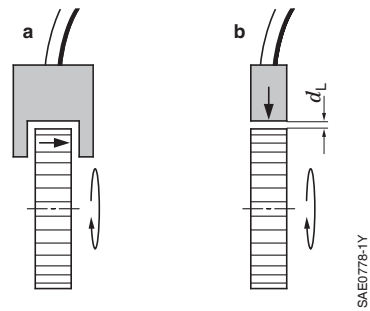
ψ Rotational speed.

mation is conditioned and amplified, and then transmitted as injected current in the form of square-wave signals. Typical values are 7 mA for the low level and 14 mA for the high level. The current is converted into a signal voltage by a measuring shunt in the ECU.



In a differential Hall sensor there are two Hall-sensor elements situated between the magnet and the pulse wheel. Determining the difference between the signals from the two sensor elements reduces magnetic interference signals and improves the signal-to-noise ratio.

Multipole wheels are also used instead of the ferromagnetic pulse wheel. Here, a magnetizable plastic is applied to a non-magnetically metallic substrate and alternately magnetized. These north and south poles assume the function of the teeth on a pulse wheel (Figure 1b).

AMR sensor

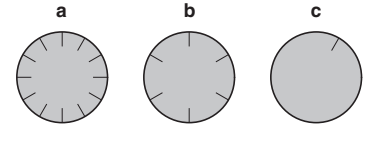
The electrical resistance of magnetoresistive material (AMR, Anisotropic Magneto Resistive) is anisotropic, i.e. it is dependent on the direction of the magnetic field to which it is exposed. This property is exploited in the AMR sensor. The sensor is located between a magnet and the pulse wheel. The magnetic field lines change their direction when the pulse wheel turns. This gives rise to a sinusoidal voltage which is amplified in an evaluation circuit in the sensor and converted into a square-wave signal.

Figure 2: Different sensor shapes
a) Fork shape (vane principle),
b) Rod shape (proximity principle).
d_L Air gap.

GMR sensor

The use of GMR technology (Giant Magneto Resistance) constitutes a further development of active sensors. Their greater sensitivity than AMR sensors means that larger air gaps are possible, which in turn opens up the possibility of use in difficult areas of application. The greater sensitivity also means lower noise at the signal edges.

Sensor shapes



Different sensor shapes are used (Figure 2): the rod shape, the fork shape, and the inner and outer ring shape. Due to its ease of mounting and simplicity, the rod sensor is the most widespread sensor shape. The rod sensor is located near the rotor, the teeth of which approach it and pass by in close proximity. However, it also has the lowest measurement sensitivity. The fork-shaped sensor, which is insensitive to axial and radial play, is permissible in some cases, and is also in service in the field. This sensor must be roughly aligned to the rotor when installed. The sensor type in which the sensor surrounds the rotor shaft in the form of a ring is practically no longer used.

Rotor shapes

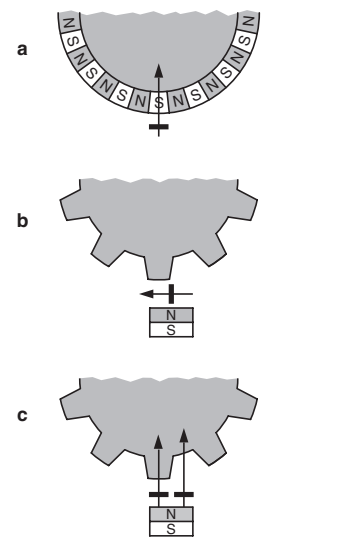
In the incremental detection of relative yaw rate, depending upon the number and size of the scanned peripheral rotor markings, a distinction is made between the following types of sensor (Figure 3):

– Simple sensor, with only a single scanned marking per revolution, so that only the average rotational speed can be registered,

Figure 3: Recording of relative rotational speed
a) Increment sensor,
b) Segment sensor,
c) Simple rpm sensor.

– Segment sensor, with only a small number of scanned peripheral segments (for instance, equivalent to the number of engine cylinders),
– Increment sensor with closely spaced peripheral markings. Up to a certain point, this form of sensor permits instantaneous speed to be measured at points on the circumference, and thus the registration of very fine angular divisions.

The rotor is crucially important to measuring rotational speed; however, it is usually part of the vehicle manufacturer's delivery specification, while the actual sensor comes from the supplier. The rotors used almost exclusively up to now have been magnetically passive types, which therefore consist of soft-magnetic material, usually iron. They are cheaper than hard magnetic pole wheels and are easier to handle, since they are not magnetized, and there is no danger of mutual demagnetization during storage. As a rule, presuming the same increment width and output signal, the pole wheel's intrinsic magnetism (a pole wheel is defined as a magnetically active rotor) permits a considerably larger air gap.



Demands made of rpm sensors

The following demands are made of rpm sensors:
– Static detection (i.e. speed approaching zero, extremely low engine-starting and wheel speeds),
– Large air gaps (non-adjusted mounting on air gap greater than zero),
– Small size,
– Efficient operation independent of air-gap fluctuations,
– Heat-resistant up to 200 °C,
– Identification of the direction of rotation (optional for navigation),
– Reference-mark identification (ignition).

Magnetostatic sensors (e.g. Hall sensors, AMR sensors) are suitable for satisfying the first condition. And, as a rule, they also permit compliance with the second and third stipulations.

Figure 4 shows three basically suitable sensor shapes which generally are insensitive to air-gap fluctuations. Here, a distinction must be made between sensors which sense radially and those which sense tangentially (see also Figure 5). This means that independent of the air gap, magnetostatic sensors are always able to differentiate between the north and south poles of a magnetically active pole wheel. In the case of magnetically passive rotors, the sign of the output signal is then no longer independent of the air gap when they register the tangential-field strength (here though, the fact that the air gap is often enlarged due to the rotor is a disadvantage). Here, though, the fact that the air gap between the rotor and the permanent magnet is often enlarged due to the sensor is a disadvantage. However, types frequently used as well are radially measuring differential-field or gradient sensors, which essentially only register the gradient of the radial field component,

Figure 4: Sensor arrangements which are insensitive to air-gap fluctuations
a) Radial-field sensor with pole wheel,
b) Tangential sensor,
c) Differential sensor with gear.
The sensor measures that part of the magnetic field in a certain direction in space. The arrow marks this direction.

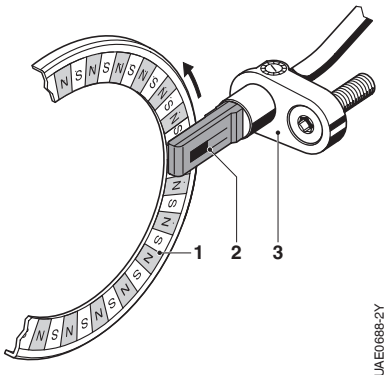
which changes with regard to its sign not with the air gap, but only with the angle of rotation.

In the case of wheel-speed sensors, at the least the sensor tip, because of its proximity to the brake, should be able to withstand higher temperatures.

Sensor arrangements

Gradient sensors

Gradient sensors (e.g. based on differential Hall sensors) incorporate a permanent magnet on which the pole surface facing the gear is homogenized with a thin ferromagnetic wafer. Two sensor elements are located on each element's sensor tip, at a distance of roughly one half a tooth interval. Thus, one of the elements is always opposite a gap between teeth when the other is opposite to a tooth. The sensor measures the difference in field intensity at two adjacent locations on the circumference. The output signal is roughly proportional to the diversion of field strength as a function of the angle at the circumference; polarity is therefore independent of the air gap.



Tangential sensors

Tangential sensors differ from gradient sensors by their reaction to variations in polarity and intensity in the components of a magnetic field located tangentially to the periphery of the rotor. Design options include AMR thin-film technology (barber pole) or single permalloy resistors featuring full- or half-bridge circuits [1]. In contrast to gradient sensors, they need not be matched to the particular tooth pitch of the rotor and can be designed to sense at a given point. Local amplification is necessary, even though their measuring effect is 1 to 2 orders of magnitude larger than that of the silicon-Hall sensors.

In the case of a bearing-integrated crankshaft speed sensor (Simmer shaft-seal module), the AMR thin-film sensor is mounted together with an evaluation IC on a common lead frame. For the purposes of space saving and temperature protection, the evaluation IC is bent at an angle of 90° and also located further away from the sensor tip.

Figure 5: AMR rpm sensor as tangential-field sensor

1 Multipole ring,
2 Measuring cell,
3 Sensor housing.

Applications

Crankshaft-speed sensor

Crankshaft-speed sensors are used to measure the engine speed (crankshaft speed). In addition, the engine-management system requires the position of the crankshaft (position of the pistons) to be able for example to activate ignition coils and fuel injectors at the correct crank angle. The pulse wheel mounted on the crankshaft exhibits a tooth gap for this purpose. With a tooth pitch of 6° and two missing teeth the pulse wheel has 58 teeth. The rpm sensor delivers a square-wave signal (tooth signal) that corresponds to the teeth on the pulse wheel.

The microcontroller in the engine ECU records the value of a running timer at the falling edges of the signal and forms the tooth spacing in terms of time from the difference between two edges. At the first tooth after the gap the measured time is very much greater than the preceding time; at the second tooth after the gap the time is again very much less. This tooth is defined as the reference mark. The pulse wheel is mounted so that this position corresponds to a defined angle opposite the top dead center of cylinder no. 1.

At uniform rotational speed the time between the edges around the tooth gap is three times as long as between two normal edges. Even in the event of greatly fluctuating rotational speed when

the engine is being started, the reference mark can be reliably inferred on account of the measured differences of the tooth spacing.

Camshaft-speed sensor
The camshaft is stepped down by a ratio of 1:2 compared with the crankshaft. It indicates whether a piston moving to top dead center is in the compression cycle or the exhaust cycle. For this reason a camshaft-speed sensor is required in addition to the crankshaft-speed sensor.

Simple pulse wheels lead to different sensor-signal levels only in the area of the reference mark. More complex pulse wheels with segments of different lengths enable the engine position to be detected more quickly when starting and thus provides for rapid starting.

Wheel-speed sensor
Wheel-speed sensors sense the rotational speed of the wheels. This information is needed for example by the driving-dynamics control to calculate the driving speed and the slip. The navigation system requires the wheel-speed signals to calculate the distance traveled when there is no GPS reception (e.g., in tunnels).

The pulse wheel is permanently connected to the wheel hub. Both steel pulse wheels and multipole rings can be used. This sensor has fewer teeth because the pulse wheel is smaller in diameter than that on an engine rpm sensor.

The sensor element with the signal amplifier and signal conditioning is integrated in an IC, hermetically sealed with plastic, and seated in the sensor head.

Digital signal conditioning enables encoded additional information to be transmitted via a pulse-width-modulated output signal. One example is direction-of-rotation detection, which is required for Hill Hold Control that prevents the vehicle from rolling back when starting. The direction of rotation is also used for vehicle navigation to detect backing up (reversing).

Speed sensor for transmission control
Transmission-speed sensors sense shaft speeds in automatic transmissions. Standard geometries are generally not possible due to the compact designs of transmissions. Specific sensor versions are therefore required for each transmission. Evaluation circuits with varying degrees of evaluation-algorithm complexity are used to cover the full spectrum of functional requirements.

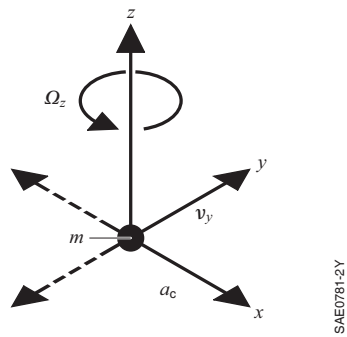
Oscillation gyrometers

Measured variables

Oscillation gyrometers measure the absolute yaw rate along the vehicle vertical axis, the vehicle transverse axis (pitch axis), and the vehicle longitudinal axis (roll rate). The signals generated here are used in numerous systems such as for example driving-dynamics control, rollover protection systems, vehicle navigation, and damping control.

Measurement principle



Oscillation gyrometers are similar in principle to mechanical gyroscopes and for measurement purposes utilize the Coriolis acceleration a_c that occurs during rotary motion in conjunction with an impressed oscillating motion (Figure 1). The acceleration is calculated from the cross product of velocity and yaw rate:

(1) $\vec{a}_c = \vec{a}_x = 2\vec{v}_y \times \vec{\Omega}_z$.

The velocity v is produced by the sinusoidal driving of the inert mass of the sensor along its y-axis at frequency ω. Thus:

(2) $v_y = \hat{v}_y \sin(\omega t)$.

Figure 1: Creation of Coriolis acceleration
When a mass point m moves in the y-direction at velocity v_y and the system simultaneously rotates about the vertical axis z with yaw rate Ω_z, the mass point experiences a Coriolis acceleration a_c in the x-direction.

With a constant yaw rate Ω about the z-axis a Coriolis acceleration is produced along the x-axis. It has the same frequency and phase as the drive velocity v, and the associated amplitude is

(3) $\hat{a}_c = 2\,\hat{v}_y \Omega_z$.

The Coriolis force is one of the so-called pseudo forces and can only be measured in the rotating reference system (like the passenger car here).

The signal evaluation of the sensor demodulates the sinusoidal Coriolis signal of the micromechanical sensor ($a_c \propto \sin(\omega t)$) and in this way determines the yaw rate Ω. In the process, unwanted acceleration from the outside (e.g. bodywork acceleration) is removed.

The utilized measuring effects not only are very small, but also require complex signal conditioning. Signal conditioning directly at the sensor is therefore necessary.

Applications

Micromechanical yaw-rate sensors

A seismic mass in the sensor must be induced to vibrate in order to generate a Coriolis force to measure a yaw rate. In a micromechanical yaw-rate sensor (Figure 2) this is achieved in a permanent-magnet field by utilizing the Lorentz force (electrodynamic drive).

This sensor is based on a formulation of bulk micromechanics: Two thick oscillating elements fashioned from the wafer by means of bulk micromechanics oscillate in push-pull mode at their resonant frequency (< 2 kHz), which is determined by their mass and their coupling-spring stiffness. Each of them is provided with a capacitive, surface-micromechanical acceleration sensor (SMM) which measures Coriolis acceleration.

For drive purposes a sinusoidally modulated current is passed through a simple printed conductor on the relevant oscillating element. This generates within the permanent-magnetic field operating perpendicularly to the chip surface a Lorentz force which starts the oscillating element moving.

If this sensor is rotated at yaw rate Ω about the vertical axis, the drive in the oscillation direction results in a Coriolis acceleration which is measured by the acceleration sensors.

The different physical natures of the drive and sensor systems prevent unwanted crosstalk between the two parts. In order to suppress external acceleration (common-mode signal), the two opposing sensor signals are subtracted from each other. Summation, however, can also be used to measure the external acceleration).

The high-precision micromechanical construction helps to suppress the effects of high oscillatory acceleration which is several factors of 10 higher than the low-level Coriolis acceleration (cross sensitivity far below 40 dB). The drive and measuring systems are mechanically and electrically isolated in rigorous terms here.

Surface-micromechanical yaw-rate sensors

Micromechanical yaw-rate sensors can also be manufactured entirely using SMM technology (surface micromechanics). Here the oscillating element is electrostatically driven by capacitors. In this case the isolation of the drive and detection systems is not longer strictly separated from each other since both systems are capacitive in design.

A centrally mounted rotary oscillator is electrostatically driven to oscillate using comb structures (Figure 3). When the sensor is subjected to a rotation Ω, the Coriolis force induces a simultaneous "out-of-plane" tilting motion. Its amplitude is proportional to the yaw rate and is detected capacitively by electrodes located under the rotary oscillator. To prevent this motion from being excessively damped, it is essential to operate the sensor in a vacuum.

The smaller chip size and the simpler manufacturing process do indeed reduce the cost of such a sensor, but the reduction in size also diminishes the already slight measuring effect and thus the attainable accuracy. It places higher demands on the electronics.

The influence of external accelerations is suppressed in SMM yaw-rate sensors by a special micromechanical design. Here the MEMS element (MEMS, Micro-Electro-Mechanical Systems) exhibits two seismic masses. Their deflection is effected by Coriolis forces in opposite directions, but by external accelerations in the same direction. A differential evaluation of the two oscillators then frees the signal of the unwanted disturbance values.

Further developments of yaw-rate sensors

Ongoing development of systems in the field of active and passive safety means that increased demands are placed on the signal quality and robustness of the yaw-rate sensor. These systems require not only the measurement of the yaw rate, but also the detection of pitching and rolling motion.

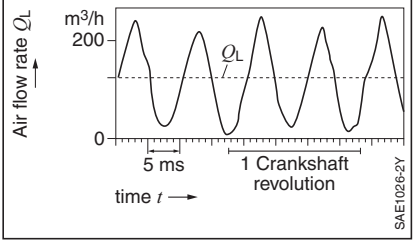
For example, a driving-dynamics control system is based among other things on measurement of the yaw rate Ω_z and on measurement of the lateral acceleration a_y. ACC systems (Adaptive Cruise Control) utilize sensor signals of the yaw rate Ω_z, the lateral acceleration a_y, and the linear acceleration a_x. Rollover protection systems on the other hand use sensor information about the roll axis Ω_x, the vertical acceleration a_z, and also the lateral acceleration a_y.

New sensor generations of micromechanical sensor elements are used here. These sensors measure the yaw rate about either the x-axis or the z-axis; many of the these sensors also incorporate sensing elements for detecting accelerations in the x-, y- or z-direction.

Measurement of the yaw rate is based here on the principle of the surface-micromechanical yaw-rate sensor, while accelerations are detected with capacitive surface-micromechanical acceleration sensors.

Flow meters

Measured variables



The amount of air supplied to the engine must be measured in order to control the combustion process. The mass ratios are the main factors in the chemical process of combustion, thus the actual objective is to measure the mass flow of the intake and charge air. The air-mass flow is the most important load variable in gasoline engines; precise pilot control of the air/fuel ratio presupposes knowledge of the supplied air mass. The exhaust-gas recirculation rate is regulated in gasoline and diesel engines by means of the air-mass flow.

The maximum air-mass flow to be measured lines in the (time) average within the range of 400 to 1,200 kg/h. As a result of the modest idle requirements of modern engines, the ratio between minimum and maximum air flow is 1:90 to 1:100 in gasoline engines and due to the higher idle requirements 1:20 to 1:40 in diesel engines. Because of stringent exhaust-emission and consumption requirements, levels of accuracy of 1 to 2% from the measured value must be achieved. Referred to the measurement range, this can mean an – unusually high for motor vehicles – measurement accuracy of 10^{-4}.

The air is not drawn in continuously by the engine, but rather in time with the opening of the intake valves. For this reason, the air flow pulses strongly – particularly with the throttle valve wide open – at the measuring point (Figure 1). The measuring point is always located in the intake tract between the air filter and the throttle valve. Due to resonances of the intake manifold, pulsation of the intake manifold – above all in 4-cylinder engines in which the induction or charge phases do not overlap – is so strong that even brief reverse flows occur. These must be correctly detected by an accurate flow meter.

Measurement principles and applications

Pitot-tube flow meters

A medium of uniform density ρ at all points flows through a tube with a constant cross-section A at a velocity v which is virtually uniform in the tube cross-section (inlet flow). The following applies:

(1) Volume flow rate $Q_V = v\,A$,
(2) Mass flow rate $Q_M = \rho\,v\,A$.

If an orifice plate is then installed for flow measurement in the flow duct, forming a restriction, this will result in a pressure differential (dynamic pressure) Δp in accordance with Bernoulli's Law. The following applies:

(3) $\Delta p = \text{const} \cdot \rho\,v^2$,

where the constant is dependent on the tube and the orifice-plate cross-sections. This pressure difference can be measured directly with a differential-pressure sensor or as a force acting on a sensor plate. Pivoting, variable-position sensor flaps (Figure 2) leave a variable section of the flow cross-section unobstructed, with the size of the free diameter being dependent on the flow rate. The sensor flap is pressed as the flow increases against a mostly constant counterforce. A potentiometer monitors the characteristic flap positions for the respective flow rates.

Measurement errors can occur in cases where the sensor-plate mechanical inertia prevents it from keeping pace with a rapidly pulsating air current (full-load condition at high engine speeds).

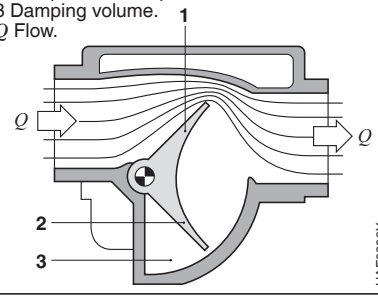
If the density ρ changes due to temperature fluctuations or the altitude, the measurement signal changes with $\sqrt{\rho}$. An air-temperature sensor and a barometric pressure sensor must be used to compensate for this.

The higher sensitivity of the output signal required for a large measurement range with small air masses is obtained from the mechanical and electrical design of the air-flow sensor used in for example the earlier L-Jetronic gasoline injection system.

This method of flow measurement has not been used in new developments for some time now.

Hot-wire air-mass meters

Hot-wire air-mass meters operate without mechanically moving parts. The hot wire is made from for example platinum whose electrical resistance R increases with temperature. The wire heats up when a current I_H is passed through it. It is cooled when it is in an air flow. The cooling process reduces the resistance of the wire and increases the electric current to produce an equilibrium between the input power P_{el} and the power P_V output by the flow:



$$(4)\ P_{el} = I_H^2\, R = P_V = c_1\, \lambda\, \Delta T.$$

The dimensions of the hot wire and its air flow assume the constant c_1. The heat conduction λ is approximately proportional to the root of the mass flow ($\sqrt{Q_M}$). Furthermore, if thermal convection is taken into consideration with the medium at rest (no air flow) with the coefficient c_2, the following equation is obtained for the heating current I_H:

$$(5)\ I_H = c_1 \cdot \sqrt{\left(\sqrt{Q_M} + c_2\right)} \cdot \sqrt{\frac{\Delta T}{R}}\ .$$

Figure 2: Pitot-tube flow meter (air-flow sensor)

1 Sensor flap,
2 Compensation flap,

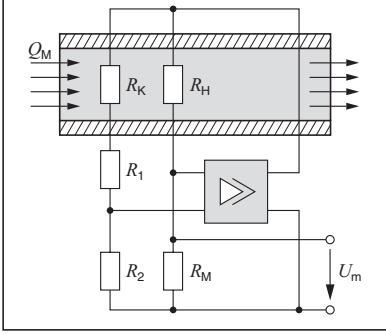
Q Flow.



The closed-loop control circuit in the sensor housing (Figure 3, the controller is shown as a box) maintains the heater element (platinum hot wire) at a constant overtemperature in relation to the air temperature. The air temperature is taken into consideration with the compensation resistor R_K, whose resistance value is dependent on the air temperature. The current required for heating provides an extremely precise – albeit nonlinear – index of air-mass flow rate. The associated ECU generally converts the signal into linear form and performs other signal-evaluation tasks, with the air-mass meter signal being sensed in millisecond intervals. Due to its closed-loop design, this type of flow meter can also monitor fast flow-rate variations in the millisecond range since, because of the constant overtemperature of the heater element, its enthalpy (heat content) does not have to be changed by means of time-consuming heat transfers.

However, the flow direction is not recognized with this method, and for this reason these sensors sometimes exhibit substantial deviations when strong pulsations occur in the intake manifold.

To ensure stable and reliable performance throughout an extended service life, the system must burn off all accumulated deposits from the hot wire's surface

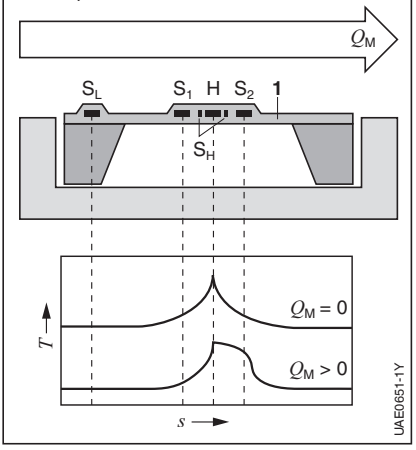
at approx. 1,000 °C after each phase of active operation (when the ignition is switched off).

The hot-wire air-mass meter was used in earlier engine-management systems (Motronic) and has since been replaced by the hot-film air-mass meter (HFM).

Hot-film air-mass meters using thick-film technology

The first hot-film air-mass meter still manufactured using thick-film technology (HFM2 from Bosch) operates according to the same principle as the hot-wire air-mass meter, but combines all the measuring elements and the control electronics on a single substrate. The flat-design heating resistor is located on the back of the base wafer, with the corresponding temperature sensor on the front. The greater thermal inertia of the ceramic wafer results in somewhat greater response lag than that associated with the hot-wire air-mass meter. The compensation resistor and the heater element are thermally decoupled by means of a laser cut in the ceramic substrate. More favorable air-flow characteristics make it possible to dispense with the hot-wire meter's burn-off decontamination process.



Micromechanical hot-film air-mass meters

Extremely compact micromechanical hot-film air-mass meters (sensor types from Bosch from HFM5 upwards, Figure 4) also operate according to thermal principles. Here the heating and measuring resistors are in the form of thin platinum layers sputtered (vapor-deposited) onto the silicon chip acting as substrate. Thermal decoupling from the mounting is obtained by installing this chip in the area of the heating resistor H on a micromechanically thinned section of the substrate (similar to a pressure-sensor diaphragm). The adjacent heater-temperature sensor S_H and the air-temperature sensor S_L (on the thick edge of the silicon chip) maintain the heating resistor H at a constant overtemperature. This method differs from earlier techniques in dispensing with the heating current as an output signal. Instead, the signal is derived from the temperature difference in the diaphragm detected by the two temperature sensors S_1 and S_2. Temperature sensors are located in the flow path upstream and downstream from the heating resistor H.

Without air inflow (Q_M = 0) the temperature profile is the same on both sides of the heating zone; for the temperature at the measuring points $T_1 = T_2$ applies (Figure 4). If, on the other hand, air flows through the sensor measuring cell ($Q_M > 0$), the area upstream of the heater element is cooled by the cold air and a lower temperature is measured at S_1. Downstream of the heater element the air flowing past is heated by the heater element; a higher temperature is therefore measured at S_2. The temperature difference is, irrespective of the absolute temperature of the air flowing past, a measure of the mass of the air flow. Although (as with the earlier process) the response pattern remains nonlinear, the fact that the initial value also indicates the flow direction represents an improvement over the former method using the heating current.

In the HFM5 the evaluation electronics integrated in the sensor convert the temperature difference measured at S_1 and S_2 with the aid of an analog circuit into an analog voltage signal between 0 V and 5 V (Figure 6). In the HFM6 and HFM7 the signal is processed with the aid of digital electronics to achieve greater accuracy and a frequency signal is generated. The HFM7 is a further-developed version of the HFM6 with improved electronics and the possibility of outputting an analog signal as an alternative to the frequency signal. This voltage or the frequency is converted in the engine ECU via the sensor curve stored in the program into an air-mass flow. The HFM8 can also output the conditioned measurement signal via the SENT digital bus interface. The accuracy of measured-value acquisition could also be increased with the HFM8.

The hot-film air-mass meter projects with its housing into a measuring tube (Figure 5). A flow rectifier mounted on the measuring tube (e.g., a wire grill) ensures a uniform flow in the measuring tube. The measuring tube is installed after the air filter in the intake tract.

Because of the small size of the measuring element, this flow meter is a partial flow meter, which detects only a specific and very small part of the total flow. The constancy and reproducibility of this division factor have a direct impact on the accuracy of the sensor. A calibration establishes the interrelationship between the air mass Q_M flowing through the measuring tube and the measurement signal generated from the partial air flow.

The inlet and outlet to the micromechanical measuring element are designed and optimized in such a way that heavier particles, such as dust particles and liquid droplets, do not approach the measuring element directly, but are rather diverted ahead of it. Further modifications to the measuring passage resulted in improved protection against contamination directly upstream of the sensor element.

Acceleration and vibration sensors

Measured variables
The acceleration values a to be measured in motor vehicles are frequently expressed as a multiple of gravitational acceleration g ($1\ g \approx 9.81\ \mathrm{m/s^2}$). Acceleration and vibration sensors are used in the following applications:
– Triggering restraint systems such as e.g. airbag and seat-belt pretensioner (35…100 g).
– Side-impact and upfront sensing (100…500 g).
– Rollover detection (3…7 g).
– Sensing acceleration by the vehicle for the antilock braking system (ABS) and driving-dynamics control (0.8…1.8 g).
– Evaluating bodywork acceleration for chassis control systems: body acceleration (1…2 g), axle and damper (10…20 g).
– Detecting changes in vehicle inclination for anti-theft alarm systems (approx. 1 g).
– Knock control in gasoline engines (measurement range up to 40 g).

Measurement principles
Acceleration sensors measure the force exerted by an acceleration a on an inert mass m:

(1) $F = m\,a$.

There are both position- and (mechanically) stress-measuring systems.

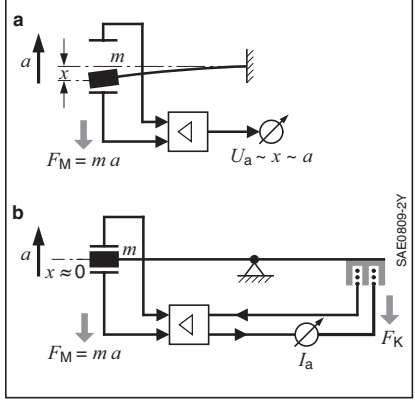
Position-measuring systems
Position-measuring systems are used particularly in the range of very small accelerations. All acceleration sensors are spring-bound right down to the gravitational pendulum. In other words, the inert mass is elastically connected to the body whose acceleration a is to be measured (Figure 1a).

Excursion-measuring sensor
In the static case the acceleration force is in equilibrium with the restoring force applied to the spring which has been deflected by x:

(2) $F = m\,a = c\,x$
where c = spring constant.

The resulting excursion is converted by means of a suitable measurement method (e.g. piezoelectric, capacitive, piezoresistive or thermal) into an electrical signal.

The system's measurement sensitivity S is therefore:



(3) $S = \frac{x}{a} = \frac{m}{c}$.

In other words, a large mass together with low spring stiffness (or constant) result in high measurement sensitivity.

In the dynamic case a damping force and an inertial force must be taken into account as well as the spring force. The damping force is proportional to the velocity $\dot{x}$ and is described with the damping coefficient p. The inertial force is proportional to the acceleration $\ddot{x}$. The oscillatory (resonant) system is described by the following equation:

(4) $F = m\,a = c\,x + p\,\dot{x} + m\,\ddot{x}$.

Figure 1: Displacement-measuring acceleration sensors

b) Position-controlled acceleration sensor.
a Measurement acceleration,
x System excursion,
F_M Measuring force (inertial force on mass m),
F_K Compensation force,
I_A Output current,
U_A Output voltage.

If negligible friction ($p \approx 0$) is presumed, the system resonates at the natural frequency ω_0:

(5) $\omega_0 = \sqrt{\frac{c}{m}}$.

Thus, according to equation (3), the measurement sensitivity S is directly linked to the resonant frequency ω_0 in the following manner:

(6) $S\,\omega_0^2 = 1$.

In other words, it can be expected that sensitivity is reduced to a factor of ¼ when the resonant frequency is increased by a factor of 2. It is only below their resonant frequency that such spring-mass systems display adequate proportionality between measured variable and excursion.

Position-controlled sensor

Position-measuring systems also permit the use of the compensation method in which the system excursion caused by acceleration is compensated for by an equivalent restoring force (Figure 1b). In practical terms the system then ideally always operates very close to its zero point (high linearity, minimum cross sensitivity, high temperature stability). These position-controlled systems also have, on account of their control, higher stiffness and cutoff frequency than excursion systems of the same kind. Any lack of mechanical damping can be electronically generated here.

System behavior

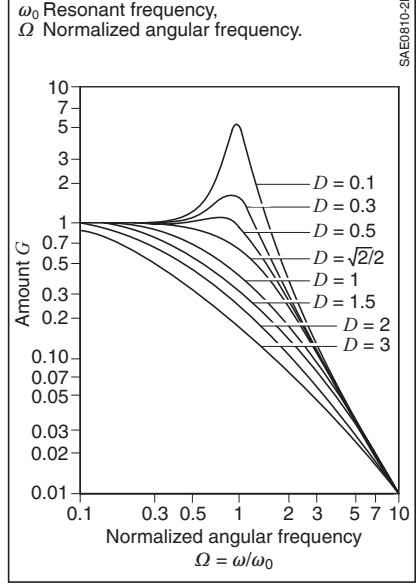
In non-position-controlled systems the damping and resonance of the systems play key roles in system behavior. The application of Lehr's damping ratio D has proved effective in describing this behavior:

(7) $D = \frac{p}{m} \cdot \frac{1}{2\omega_0}$.

Equation (4) can then be formulated as

(8) $\frac{F}{m} = \ddot{x} + 2\,\omega_0 D\,\dot{x} + \omega_0^2 x$.

Using the dimensionless variable D permits a simple comparison to be made of different oscillatory systems: transient response and resonant response are defined to a large extent by this damping ratio.



With very low damping ($D \rightarrow 0$) the system exhibits a resonance sharpness at ω_0. This is often unwelcome in that on the one hand it can lead to the system being destroyed and on the other hand it results in a nonuniform transfer function ($G >> 1$).

As damping factors increase, the system's resonance sharpness continues to decrease. While no more resonance sharpness is obtained under periodic excitation for damping factors $D = \sqrt{2}/2$ (Figure 2), any oscillating transient condition in the case of a step excitation disappears for factors $D > 1$.

In order to achieve as uniform a system response as possible in the region $G \approx 1$ over a wide frequency range, it is important when designing the system to define its damping precisely. Ideally this is influenced for example only slightly by

Figure 2: Amplitude-resonance curve

G Transfer function,
D Damping,
ω Angular frequency,
ω_0 Resonant frequency,
Ω Normalized angular frequency.

fluctuations in temperature. In practice sensors are therefore often designed in the range D = 0.5…1.0.

Mechanical stress-measuring systems
The piezoelectric effect can also be utilized to measure an acceleration. In this case the exertion of force by the external acceleration causes a mechanical stress in the piezoelectric material. These piezoelectric materials generate a charge Q under the influence of a force F on its surfaces, which are fitted with electrodes (Figure 3). This charge is proportional to the mechanical stress generated by the force.

For use as a sensor the generated charges are discharged via the external resistor of a measuring circuit or via an internal resistor of the sensor. The sensor therefore can measure dynamically, but not statically. The typical cutoff frequency is above 1 Hz.

The piezoelectric effect is utilized for example in piezoceramic bimorphous spring elements and in piezoelectric knock sensors.

Thermal acceleration sensors
These sensors generate a confined heated gas zone (Figure 4). The gas in this zone has a lower density than the surrounding cooler gas. During an acceleration the low-density gas zone moves within the surrounding cooler gas. The resulting asymmetry can be sensed by temperature sensors which are interconnected in a bridge circuit. The bridge voltage constitutes the acceleration signal.

This principle is used in numerous applications such as for example rollover sensing, the driving-dynamics control, and even in smart phones.

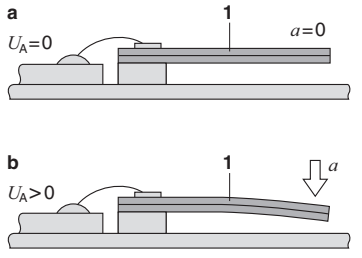
Applications



Piezoelectric acceleration sensors

Piezoelectric bimorphous spring elements or two-layer piezoceramics (Figure 5) are used for restraint-system sensors for triggering seat-belt tighteners, airbags, and rollover bars. Their intrinsic mass causes them to deflect under acceleration to provide a dynamic (not DC response pattern) signal with excellent processing characteristics (typical cutoff frequency: 10 Hz). The sensor element is located in a sealed housing shared with the initial signal-amplification stage. It is sometimes encased in gel for physical protection. It consists of two oppositely polarized piezoelectric layers which are bonded to each other (bimorphous). An acceleration acting on it causes a mechanical tensile stress ($\varepsilon > 0$) in one layer and a compressive stress ($\varepsilon < 0$) in the other layer. The metallic layers on the upper and lower sides of the spring element serve as electrodes via which the resulting voltage is tapped.

This structure is packed together with the evaluation electronics in a hermetically sealed housing. The electronic circuit consists of an impedance transformer and an adjustable amplifier with specified filter characteristic.

The sensor's actuating principle can also be inverted: The sensor can be checked with an additional actuator electrode (on-board diagnosis).

Micromechanical bulk silicon acceleration sensors

The first generation of micromechanical sensors relied on anisotropic and selective etching techniques to fabricate the required spring-mass system from the full silicon wafer (bulk silicon micromechanics) and produce the spring profile (Figure 6).

Capacitive taps have proven especially effective for the high-precision measurement of this seismic-mass deflection. This design entails the use of supplementary silicon or glass wafers with counter-electrodes above and below the spring-held seismic mass. This leads to a 3-layer structure, whereby the wafers and their counter-electrodes also provide overload protection. This layout corresponds to a series connection of two capacitors ($C_{1\text{-}M}$ and $C_{2\text{-}M}$). Alternating voltages are supplied at the connections C_1 and C_2, the superposition of these voltages is tapped at C_M, i.e. at the seismic mass. In the rest state the capacitances $C_{1\text{-}M}$ and $C_{2\text{-}M}$ are ideally equal. When an acceleration a acts in the measurement direction, the silicon center wafer is deflected as the seismic

Figure 6: Bulk silicon acceleration sensor

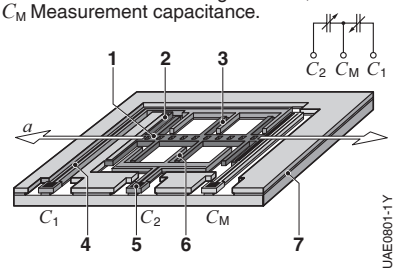
4 Silicon center wafer M (seismic mass),
5 Glass substrate.
a Acceleration,
C Measurement capacitances.

mass. The change in distance between the upper and lower wafers gives rise to a change in capacitance in the capacitors $C_{1\text{-M}}$ and $C_{2\text{-M}}$, and thus a difference ΔC that is proportional to the applied acceleration. This in turn changes the electrical signal at C_M, which is amplified and filtered in the evaluation electronics.

Filling the sensor's hermetically sealed oscillatory system with a precisely metered charge of air leads to a very space-saving, inexpensive form of damping which also exhibits low temperature sensitivity.



This type of sensor is mainly used for low-level accelerations (< $2g$) and relies upon a two-chip concept (sensor chip + CMOS processing chip).

Surface-micromechanical acceleration sensors

Surface-micromechanical sensors (SMM) have more compact dimensions than bulk silicon sensors. In SMM technology an additive process is employed to construct the spring-mass system on the surface of the silicon wafer (Figure 7). In the sensor core the seismic mass with its comb-shaped electrodes is connected by spring elements to anchor points of the silicon oxide. The chip features fixed, also comb-shaped electrodes on both sides of these moving electrodes. The fixed and moving electrode fingers create individual capacitances which are connected in parallel. This produces an effective total capacitance of 300 fF up to 1 pF. Two rows of electrode fingers connected in parallel produce two useful capacitances (C_1-C_M and C_2-C_M), which change in opposite directions when the seismic mass is deflected. The spring-mass system is subjected during an acceleration to a deflection which behaves linearly to the acceleration via the spring restoring force. An electrical output signal that is linearly dependent on the acceleration can be obtained by evaluation of this differential capacitor.

Figure 7: Surface-micromechanical acceleration sensor with capacitive tap

a Acceleration in sensing direction,
C_M Measurement capacitance.

Because of the low capacitance of typically 1 pF the evaluation electronics are therefore integrated together with the sensor on the same chip, or very closely connected to it on the same substrate or leadframe. The raw signal is amplified, filtered, and conditioned for the output interface. Analog voltages, pulse-width-modulated signals, SPI protocols (Serial Peripheral Interface) or PSI5 protocols (current interfaces, see PSI5) are usual for this purpose.

The mechanical and electrical signal paths of the sensor can be checked with a self-test function. The sensor structure is deflected by means of an electrostatic force (simulation of an acceleration) and the resulting sensor signal is compared with a setpoint value.

Depending on the applications, the sensor elements are designed for different measurement ranges between 1 g and 500 g. Initially these sensors were used for high acceleration rates (50…100 g, for passenger-protection systems), but are now also used for lower acceleration rates (e.g. for the driving-dynamics control).

Piezoelectric knock sensor

The knock sensor is in principle a vibration sensor. It senses structure-borne sound vibrations that occur as "knocking" in a gasoline engine during uncontrolled combustions (Figure 7). The structure-borne sound vibrations must be able to be introduced from the measuring location on the engine block undamped and without resonance into the knock sensor. A suitable measuring point and a fixed screw connection are required for this purpose.

The knock sensor is screwed to the engine block (Figure 8). A seismic mass exerts as a result of its inertia pressure forces in time with the exciting vibrations on an annular piezoceramic element. These forces induce a charge transfer within the ceramic element. This generates between the upper and lower sides of the ceramic element a voltage that is tapped via contact disks. The knock signal generated in the sensor is forwarded to the engine ECU, where it is conditioned and evaluated.

When knocking noises are detected the engine ECU retards the ignition timing and thus counteracts any further knocking (see Knock control). The vibration frequency is typically 5 to 25 kHz.

Pressure sensors

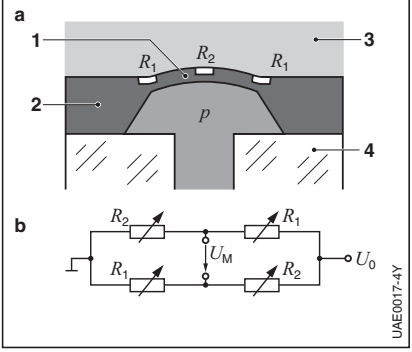
Measured variables
The measured variable pressure is defined as a nondirectional force acting in all directions which occurs in gases and liquids. It still propagates very well in gelatinous substances and soft sealing compounds. The most important measured pressures in a motor vehicle are:
– Intake-manifold pressure and charge-air pressure (1 to 6 bar),
– Ambient pressure (approx. 1 bar), e.g. for boost-pressure control,
– Vacuum in the brake booster (approx. 1 bar relative to atmosphere),
– Differential pressure at the diesel particulate filter for detecting the filter-load state and leaks (up to 1 bar differential pressure),
– Brake pressure (10 bar) in electropneumatic brakes,
– Air-spring pressure (16 bar) for vehicles with air suspension,
– Tire pressure (5 bar absolute) for monitoring tire pressure,
– Hydraulic reservoir pressure (approx. 200 bar) for the antilock braking system and power steering,
– Shock-absorber pressure (200 bar) for chassis-control systems,
– Refrigerant pressure (35 bar) in air-conditioning systems,
– Modulation pressure (35 bar) in automatic transmissions,
– Fluid pressure for clutch actuation in double-clutch transmissions (20 bar),
– Engine-oil pressure for demand-controlled oil pumps (10 bar),
– Brake pressure in brake master and wheel-brake cylinders (200 bar) and for automatic yaw-moment compensation in electronically controlled brakes,
– Positive and vacuum pressure in fuel tank (0.5 bar) for on-board diagnosis,
– Combustion-chamber pressure (100 bar, dynamic) for misfiring and knock detection,
– Pump-side pressure in diesel distributor-type injection pumps (up to 1,000 bar, dynamic) for electronic governing,
– Fuel pressure in the low-pressure circuit for demand-controlled fuel pumps (diesel and gasoline; 10 bar),
– Rail pressure in LPG and CNG systems (4 to 16 bar),
– Rail pressure for diesel common rail (up to 2,700 bar),
– Rail pressure for gasoline direct injection (up to 280 bar),
– Oil pressure for taking into account the engine load in the service display.

Measurement principles
Dynamically and statically acting pickups or sensors are used to measure pressures. Dynamically acting pressure sensors include for example microphones, which are insensitive to static pressures and are only used to measure pressure pulsations in gaseous or liquid media. Since up to now, practically only static pressure sensors have been used in automobiles, these will be dealt with in more detail here. Static pressure measurement is effected directly by the deformation of a diaphragm.

Diaphragm-type sensors
Design
The most common method used for pressure measurement (also in automotive applications) uses a thin diaphragm as the intermediate stage. The pressure to be measured is first of all applied to one side of this diaphragm so that this bends to a greater or lesser degree as a function of the pressure (Figure 1a). Within a very wide range, its diameter and thickness can be adapted to the particular pressure range. Low-pressure measuring ranges lead to comparatively large diaphragms which can deform in the range from 0.01 to 1 mm. Higher pressures demand thicker, low-diameter diaphragms which only deform very slightly by a few micrometers.

To be precise, a diaphragm's deformation depends upon the difference in the pressure applied to its top and bottom sides. Accordingly, there are three different basic types of pressure sensor:
– Absolute-pressure sensors,
– Differential-pressure sensors,
– Relative-pressure sensors.

Relative-pressure sensors measure the differential pressure relative to the ambient pressure.



Voltage-measuring methods dominate in all pressure ranges and here in practical terms only strain-gage technology is used.

Strain-gage technology

The strains on the diaphragm when a diaphragm-type sensor is subjected to deformation are sensed by strain gages (strain-gage resistors) which are applied to the diaphragm (e.g. diffused or vapor-deposited) (Figure 1a). Under the influence of mechanical stresses their electrical resistance changes on account of the piezoresistive effect. The K factor (gage factor) specifies the relative change of the strain-gage resistor referred to the relative change of its length. For the resistors diffused into the monocrystalline silicon in micromechanical pressure sensors this factor is especially high, typically $K \approx 100$.

Figure 1: Semiconductor absolute-pressure sensor

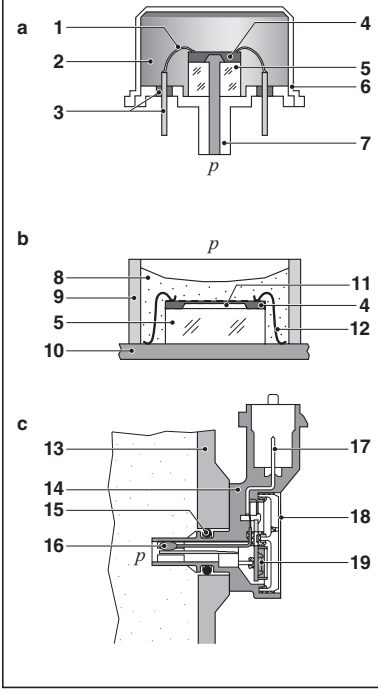
p Measured pressure,
U_0 Supply voltage,
U_M Measurement voltage,
R_1 Strain-gage resistor (compressed),
R_2 Strain-gage resistor (stretched).

The resistors are interconnected to form a Wheatstone bridge (Figure 1b). The diaphragm is deformed to varying degrees depending on the effective pressure; in the process two resistors are stretched and two resistors are compressed. This alters their electrical resistance and thus also the measurement voltage (bridge voltage). The measured voltage is a measure of the pressure. This circuit produces a higher measurement voltage than is the case when a single resistor is evaluated. The Wheatstone bridge thus provides for a highly sensitive sensor.

Applications

Micromechanical pressure sensors

Micromechanical pressure sensors are used for pressure ranges of less than 6 bar (in low-pressure sensors) and for pressure ranges of less than 70 bar (in medium-pressure sensors).



The measuring cell of the micromechanical pressure sensor consists of a silicon chip in which a thin diaphragm is micromechanically etched (Figure 1). Four resistors arranged in a Wheatstone-bridge circuit are diffused on the diaphragm (see above). The bridge voltage is a measure of the pressure on the diaphragm.

The bridge signal must still be linearized and amplified. Temperature effects must also be compensated. This is performed either in a circuit integrated on the measuring chip or in a separate ASIC (application-specific integrated circuit). The output signal can be transferred either in the form of an analog voltage (0 to 5 V) or in digital form, e.g. via the SENT interface.

The advantage of digital transfer protocols over analog signals is that interface tolerances (contact and cable resistances) play no role and that as a rule additional information (fault codes, temperature signals, etc.) can still be transferred.

In the case of sensors for very aggressive or liquid measured media (e.g. for fuel-pressure and charge-air pressure sensor) “reverse assembly” is often used in which the measured pressure is conducted to an electronically passive cavity recessed into the side of the sensor

chip (Figure 2a). For maximum protection, the – much more sensitive – side of the chip with the measuring resistors, evaluation electronics and contacts is enclosed in a reference-vacuum chamber located between the housing's base and the soldered metal cap.

However, a cheaper arrangement is to seat the silicon chip with etched diaphragm and four strain-gage resistors as a measuring cell on a glass base. The reference-vacuum chamber is located in a cavity between the diaphragm and the glass base (Figure 2b). Alternatively, measuring chips made of porous silicon with an enclosed reference-vacuum chamber can be used for absolute-pressure sensors. The silicon chip is subjected to pressure from the side on which the measuring resistors and the evaluation electronics are located. This sensitive side of the chip is protected by a suitable gel against the pressure medium. The compact design of integrated single-chip sensors means that they are suitable for mounting directly on the intake manifold (Figure 2c).

Low-pressure sensors
This design is used in virtually all low-pressure sensors (maximum pressure less than 6 bar) such as for example charge-air pressure sensors and barometric sensors. For differential-pressure sensors (e.g. for diesel particulate filters or brake boosters) both sides of the diaphragm are subjected to the pressure medium.

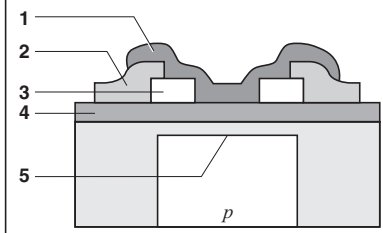
These sensors can also be used in tire-pressure monitoring systems. Measurement will be continuous and non-contacting.

Medium-pressure sensors
The range of medium-pressure sensors is essentially described by a maximum pressure-measuring range of approx. 6 to 70 bar. These sensors are used to measure engine-oil pressure, fuel pressure ahead of the high-pressure pump, hydraulic pressure in automatic transmissions (torque-converter, double-clutch, and CVT transmissions), to measure pressure in LPG and CNG systems, and to measure pressure in air-conditioning systems.

The wide variety of applications means that there is a broad range of mechanical and electrical interfaces. The sensors are screwed into lines or into the crankcase and transmission case. A metallic taper seal has proven effective, but O-rings and sealing rings are also used. The design of the medium-pressure sensor very much follows that of the high-pressure sensor, with the metal diaphragm being replaced by a silicon-micromechanics-technology sensor element. In this case the sensor elements used in low-pressure sensors have been adapted by optimized etching methods for higher pressures and increased bursting-pressure strength. Here too the measurement signal of a Wheatstone-bridge circuit is evaluated. The sensor signal is conditioned and issued as an analog or a digital output signal. This is done either integrated in a silicon chip (1-chip technology) or by measuring element and evaluation ASIC (2-chip technology).

Combined sensors for pressure and temperature are used in some applications (e.g. in the engine oil-level sensor). For this purpose an NTC is integrated in the threaded fitting and the thermistor of the NTC is evaluated in the ECU by suitable circuits. The SENT protocol offers the opportunity to issue the pressure and temperature signals in a joint output signal. This dispenses with the need for a separate line for the temperature signal.

High-pressure sensors with metal diaphragm



Diaphragms made of high-quality spring steel are used at very high pressures as have to be measured for example in the rail of the common-rail system or gasoline direct injection for closed-loop control (Figures 3 and 4). Further applications include braking systems such as the anti-lock braking system and driving-dynamics control, and also industrial hydraulics.

Four thin-film strain gages are applied to the diaphragm; the measurement principle is the same as for micromechanical pressure sensors. The steel diaphragm insulates the measured medium, differs from silicon in retaining a yield range for enhanced burst resistance, and is easy to install in metallic housings.

Insulated sputtered (vapor-deposited) metallic thin-film strain gages ($K \approx 2$) and even polysilicon strain gages ($K \approx 40$) offer permanently high sensor accuracy. Amplification, calibration, and compensation elements can be combined in a single ASIC, which is then integrated together with the required EMC protection on a small carrier in the sensor housing.

Temperature sensors

Measured variables

Temperature is defined as a nondirectional quantity which characterizes the energy state of a given medium, and which can be a function of time and location.

(1) $T = T(x, y, z, t)$,
x, y, z Space coordinates,
t Time,
T measured according to the Celsius or Kelvin scale.

In the case of gaseous and liquid measured media, it is generally possible to measure temperature at all points without any problems; in the case of solid bodies, measurement is usually confined to the surface. The temperature sensors mostly commonly used need to have direct, close contact with the measured medium (contact thermometer) to enable them to assume the medium temperature as precisely as possible. Outside temperature, intake-air temperature, and exhaust-gas temperature are examples of temperature measurement of gaseous media. Coolant temperature and engine-oil temperature are examples of temperature measurement of liquid media. Further areas of application of temperature measurement in vehicles are shown in Table 1. They can differ greatly in terms of required measuring accuracy and permissible measuring time.

For special cases non-contact temperature sensors are also used which determine the temperature of a body or a medium on the basis of the (infrared) heat radiation emitted by it (radiation thermometer, pyrometer, thermal imaging camera). These temperature sensors are used in night-vision systems (see Far-infrared systems) and for pedestrian recognition with infrared cameras.

At many locations temperature is also measured as a secondary variable in order that it can be compensated in cases where temperature variations trigger faults or act as an undesirable influencing variable – for example in sensors for other physical variables whose measured value is to depend as little as possible on the temperature.

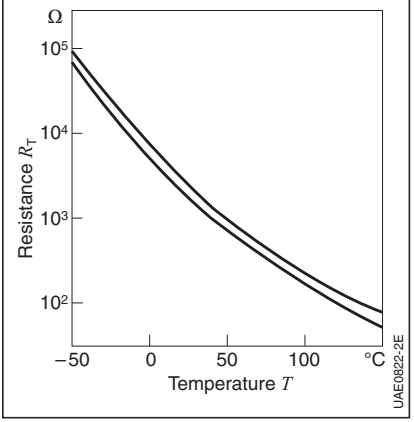

Table 1: Temperature ranges in motor vehicles

Measuring point	Range in °C
Intake and charge air	–40…170
Outside atmosphere	–40…60
Passenger compartment	–20…85
Ventilation & heating air	–20…60
Evaporator (air conditioner)	–10…50
Coolant	–40…130
Engine oil	–40…170
Battery	–40…100
Fuel	–40…120
Tire air	–40…120
Exhaust emissions	100…1,000
Brake calipers	–40…2,000

Measurement principle

Temperature measurements in motor vehicles are conducted almost entirely by exploiting the sensitivity to temperature variation found in electrical resistance materials with a positive temperature coefficient (PTC, NTC thermistor) or with a negative temperature coefficient (NTC, PTC thermistor) as contact thermometers. Depending on the temperature, the sensor exhibits a certain resistance

Figure 1: Temperature curve with limits of variation of an NTC thermistor

value (Figure 1). Conversion of the resistance variation into an analog voltage is performed predominantly by adding a temperature-neutral or inversely sensitive resistance to a voltage divider (Figure 2a) or by supplying an injected current (Figure 2b). For the voltage-divider circuit the following is obtained

$$U_A(T) = U_0 \frac{R(T)}{R(T)+R_V}.$$

With the injected current I_0 the measurement voltage is obtained at

$$U_A(T) = I_0\, R(T).$$

The voltage measured at the measuring resistor is thus temperature-dependent. This analog voltage is digitized in the ECU by an analog-digital converter and then assigned via a characteristic curve to a temperature value.

Alternatively, signal processing can also be performed by an evaluation circuit integrated in the sensor; the temperature value is then transferred via a digital interface (see PSI5).

Sensor types

Sintered-ceramic resistors (NTC)

Semiconducting sintered-ceramic resistors made of heavy-metal oxides and oxidized mixed crystals (sintered in pearl or plate form) display an exponentially falling temperature curve (Figure 1). It can be described to good approximation by the following exponential equation:

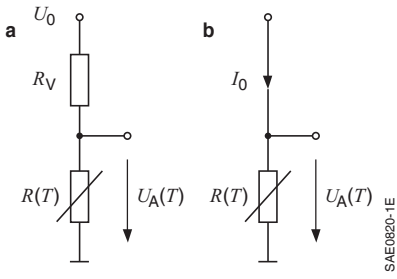
$$R(T) = R_0\, e^{B\left(\frac{1}{T}-\frac{1}{T_0}\right)},$$

where
$R_0 = R(T_0)$,
B = 2,000…5,000 K,
T Temperature in K.

The resistance value can vary up to five powers of ten, for example typically from some 100 kiloohms to some 10 ohms. High thermal sensitivity means that applications are restricted to a "window" of approximately 200 K; however, this range can be defined within a latitude of −40 °C to approximately 850 °C by selecting an appropriate NTC. Close tolerances of ±0.5 K at a selectable reference point are possible for example by means of read-out, but this is also reflected in the cost.

Thin-film metallic resistors (PTC)

Thin-film metallic resistors, integrated on a single substrate wafer (e.g. by vapor-depositing or sputtering) with two supplementary, temperature-neutral trimming resistors (Figure 3a), are characterized by extreme precision, as they can be manufactured and then "trimmed" with lasers to maintain exact response-curve tolerances over long periods of time (Figure 3b). Here the values of the trimming resistor connected in series to the measuring resistor and of the trimming resistor connected in parallel are changed.



The use of layer technology makes it possible to adapt the substrate (ceramic, glass, plastic foil) and the upper layers (plastic molding or paint, sealed foil, glass and ceramic coatings) to the respective application, and thus provide protection against the monitored medium.

Although metallic layers are less sensitive to thermal variations than the ceramic-oxide semiconductor sensors, both linearity and reproducibility are better. The following formulation is used to provide the computational description:

$$R(T) = R_0\,(1+\alpha\,\Delta T + \beta\,\Delta T^2+\ldots)$$

Figure 2: Resistance-measurement methods

$U_A(T)$ Measurement voltage.

where
$\Delta T = T - T_0$,
T_0 = 20 °C (reference temperature),
α Linear temperature coefficient,
β Quadratic temperature coefficient.

The coefficient β is small for metals, but not entirely negligible. Therefore in sensors of this type the measurement sensitivity is characterized with a mean temperature coefficient, "TC 100". It corresponds to the mean characteristic-curve gradient between 0 °C and 100 °C (Figure 4) and is obtained from the following relationship:

$$TC\,100 = \frac{R(100\,°C) - R(0\,°C)}{R(0\,°C)\cdot 100\ K} = \alpha_{100}\,.$$

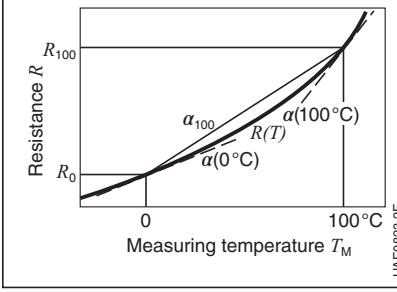
Table 2 shows the mean temperature coefficients for some metals.

Metal-film resistors are generally manufactured and marketed with a basic value (resistance value at 20 °C) of 100 Ω or 1,000 Ω (e.g. under the designation Pt 100 or Pt 1000) in different tolerance classes. Platinum resistors (Pt) do have the lowest temperature coefficient, but are very accurate and resistant to aging.



In addition to compensating elements, further active and passive circuit elements for the thin-film sensor can basically be integrated on the carrier chip. This facilitates initial, advantageous signal conditioning and conversion at the measuring point.

Thick-film resistors (PTC and NTC)
Thick-film resistors consist of a carrier chip (e.g. thin ceramic wafer) on which the resistor material is applied as paste (e.g.

Table 2: Mean temperature coefficient of some metals

Sensor material	TC 100	Measurement range
Nickel (Ni)	$6.18\cdot10^{-3}$/K	–60...250 °C
Copper (Cu), value dependent on composition	$3.8\cdot10^{-3}$/K up to $4.3\cdot10^{-3}$/K	–50...200 °C
Platinum (Pt) (DIN EN 60751, [1])	$3.85\cdot10^{-3}$/K	–200...850 °C

Figure 4: Definition of mean temperature coefficient TC 100 = α_{100}

metal oxide) using thick-film technology and sintered at 800 °C to the substrate.

Thick-film resistors with their higher resistivity (low surface-area requirement) and positive and negative temperature coefficients are generally employed as temperature sensors for compensation purposes. They have nonlinear response characteristics (without, however, the extreme variations of the massive NTC resistor) and can for example be laser-trimmed. The measurement effect can be enhanced by using NTC and PTC materials to form voltage-divider circuits.

Monocrystalline silicon semiconductor resistors (PTC)

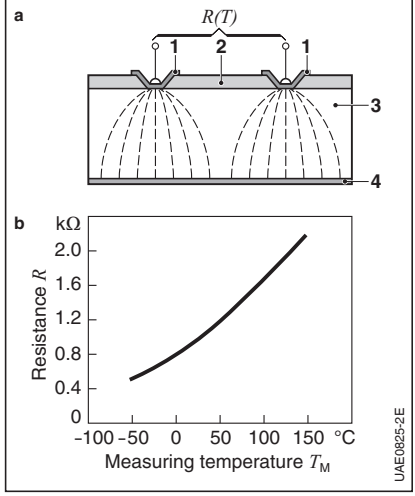
When monocrystalline semiconductor materials, such as silicon, are used to manufacture the temperature sensor, it is possible to integrate additional active and passive circuitry on the sensor chip. This facilitates initial signal conditioning at the measuring point. Due to the closer tolerancing which is possible, the measuring element is manufactured according to the "spreading-resistance" principle. The current flows through the measuring resistor and through a surface-point contact before arriving at the silicon bulk material. It then proceeds, widely distributed, to a counter-electrode covering the base of the sensor chip (Figure 5).

As well as the highly reproducible material constants, the high current density after the contact point (high precision achieved through photolithographic manufacture) almost exclusively determines the sensor's resistance value. To eliminate polarity sensitivity the sensors are mostly series-connected in a pair in opposite alignment (double-hole version, Figure 5). The bottom electrode can then be designed as a metallic temperature contact (with no electrical function).

Measurement sensitivity is practically double that of a platinum resistor (TC 100 = $7.73 \cdot 10^{-3}$/K). However, the temperature-response curve is less linear than that of a metallic sensor. The measuring range is limited to approximately 150 °C by the material's intrinsic conductivity.

Applications in motor vehicles

These temperature sensors are used in many motor-vehicle applications. Here are some examples:



– Coolant-temperature sensor,
– Fuel-temperature sensor,
– Engine-oil temperature sensor,
– Intake-air temperature sensor,
– Charge-air temperature sensor,
– Outside-temperature sensor,
– Interior-temperature sensor,
– Exhaust-gas temperature sensor, etc.

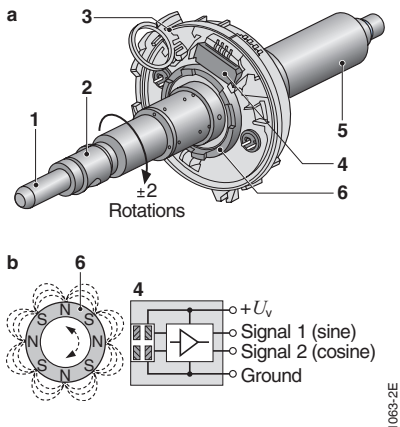
Torque sensor

Measured variables and application
Torque measurement is utilized in a variety of applications in motor vehicles. Torque sensors are used for example to sense the steering torque initiated by the driver.

Electromechanical power-steering systems are increasingly being used in vehicles. The essential benefits are simple installation and start-up in the vehicle, energy saving, and the suitability of these systems in the vehicle's ECU network for assistance systems to increase comfort and safety.



Measurement principle
When it comes to torque measurement, there are two different methods: angle and stress measurement. In contrast to stress-measurement methods (with strain gages), angle-measurement methods require a certain length of the torsion bar over which the torsion angle can be picked off.

To sense the driver command, it is necessary in an electromechanical power-steering system to measure the torque initiated by the driver. The sensors currently used in series production incorporate in the steering shaft a torsion bar which in the course of a steering torque applied by the driver undergoes a defined torsion linear to the initiated torque (Figure 1). The torsion is in turn measured by appropriate means and converted into electrical signals. The required measurement range of a torque sensor for use in an electromechanical power-steering system is usually around ±8 to ±10 Nm. The maximum torsion angle is mechanically limited by carrier elements to protect the torsion bar against overload and destruction.

To be able to measure the torsion and thus the applied torque, a magnetoresistive sensor is mounted on one side of the torsion bar which samples the field of a magnetic multipole wheel mounted on the other side. The number of poles on this wheel is chosen so that the sensor outputs a clear signal within its maximum measurement range to provide at all times a clear indication of the applied torque. The magnetoresistive sensor used supplies over the measurement range two signals which describe a sine signal and a cosine signal when shown against the torsion-bar torsion angle. The torsion angle and thus the torque are calculated in an ECU with the aid of an arc-tangent function.

Because the two signals are always permanently assigned over the defined measurement range, in the event of a deviation from these signals sensor faults can be detected and the necessary substitute measures initiated.

Force sensor

Measured variables and application

One application of force measurement in motor vehicles is the sensing of the front passenger's weight. Classifying the front passenger by measuring their weight enables the airbag to be deactivated when a small child is sitting in the seat.

Measurement principle

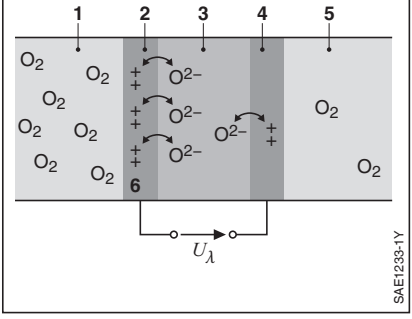
The operating principle of the iBolt sensor is based on measuring the deflection of a bending beam in response to the front passenger's weight. The extent of this deflection is detected by measuring the magnetic field strength with a Hall sensor (Figure 2a).

The sensor is designed in such a way that preferably the vertical component of the front passenger's weights causes a deflection of the bending beam. The magnet and the Hall IC are arranged in the sensor in such a way that the static magnetic field that penetrates the Hall IC produces an electrical signal linear to the deflection of the bending beam. The special design of the sensor prevents a horizontal deflection of the Hall IC in respect of the magnet in order to minimize the influence of transverse forces and torques. In addition, the maximum stress in the bending beam is limited by a mechanical overload stop (Figure 2b). This protects the sensor particularly in overload situations in the event of a crash.

The force generated by the front passenger's weight is directed from the upper seat structure via the sleeve into the bending beam (Figure 2a). The force is then directed from the bending beam into the lower seat structure. The bending beam is designed as a double bending beam as this has an S-shaped deformation line. Here the two vertical connecting points of the double bending beam remain vertical for the entire deflection range. This ensures a linear and parallel movement of the Hall IC in respect of the magnet, producing a linear output signal.

Gas and concentration sensors

λ sensors



Measurement principle

λ sensors measure the oxygen content in the exhaust gas. They are used to regulate the air/fuel ratio in motor vehicles. The name is derived from the excess-air factor λ. This factor indicates the ratio of the current air volume to the theoretical air volume which is required for a full combustion of the fuel. It cannot be determined directly in the exhaust gas, but only indirectly via the oxygen volume present in the exhaust gas or required to fully convert combustible components. λ sensors consist of platinum electrodes which are mounted on a ceramic solid electrolyte that conducts oxygen ions (e.g. ZrO_2).

The signal from all the λ sensors is based on electrochemical processes with the involvement of oxygen (see Electrochemistry). The platinum electrodes used catalyze the reaction of remnants of oxidizable components in the exhaust gas (CO, H_2 and hydrocarbons $C_xH_yO_z$) with exhaust-gas oxygen. λ sensors consequently measure not the real oxygen content in the exhaust gas, but instead that content which corresponds to the chemical equilibrium of the exhaust gas.

Figure 1: Nernst cell

U_λ Sensor voltage (Nernst voltage).

Applications

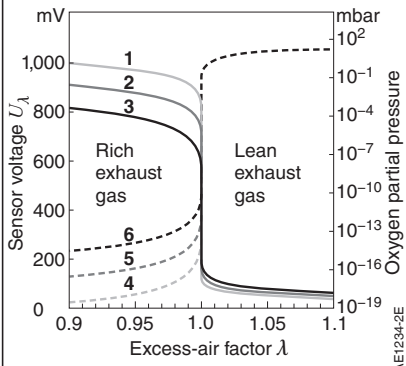
λ sensors are used in gasoline engines during the regulation of a stoichiometric mixture (λ = 1) to deliver the lowest-pollutant exhaust gas possible. Optimum impact by the three-way catalytic converter is guaranteed in this range.

Two-point λ sensors (step-change or switching-type sensors) indicate whether the mixture is rich (λ < 1, excess fuel) or lean (λ > 1, excess air). With these sensors the oxygen partial pressure of stoichiometric air/fuel mixtures can be measured very accurately due to the steep part of the sensor characteristic curve in this environment. Outside this environment, however, the characteristic curve is very flat (Figure 2).

Only the large measurement range of wide-band λ sensors (from λ = 0.6 to clean air) allow their use in systems with direct injection in stratified-charge operation and in diesel engines. λ control that can be achieved with wide-band λ sensors results in significant system and emission advantages over two-point control with a step-change sensor and further applications such as, for example, more accurate monitoring of the catalytic converter and controlled component protection. The high signal dynamic response of wide-band λ sensors with response times of less than 100 ms improves λ control.

Operating concept

All the exhaust-gas sensors described in the following consist of two modules: Nernst cell and pump cells.



Nernst cell

The incorporation and removal of oxygen ions in the lattice of the solid electrolyte is dependent on the oxygen partial pressure on the surface of the electrode (Figure 1). Thus at low partial pressure more oxygen ions leave than enter. The vacant spaces in the lattice are reoccupied by advancing oxygen ions. An electric field is generated on account of the resulting charge separation at different oxygen partial pressures at the two electrodes. The electric field forces push advancing oxygen ions back and an equilibrium develops at the so-called Nernst voltage.

Pump cell
When a voltage is applied that is less or greater than the developing Nernst voltage, this state of equilibrium can be changed and oxygen ions actively transported through the ceramic. This creates between the electrodes a current, borne by oxygen ions. Crucial to the direction and intensity is the difference between the applied voltage (pump voltage U_P) and the developing Nernst voltage. This process is called electrochemical pumping.

Two-point λ sensors
Design
Two-point λ sensors indicate whether the mixture is rich (λ < 1, excess fuel) or lean (λ > 1, excess air). With these sensors the oxygen partial pressure of virtually stoichiometric air/fuel mixtures can be measured very accurately due to the steep part of the characteristic curve in this environment and the lowest-pollutant exhaust gas possible achieved by regulating the fuel quantity.

Figure 2: Characteristic curve of a two-point λ sensor at different sensor-element temperatures
U_λ Sensor voltage,
$p_A(O_2)$ Oxygen partial pressure in the exhaust gas,
λ Excess-air factor.
1 U_λ at 500 °C,
2 U_λ at 700 °C,
3 U_λ at 900 °C,
4 $p_A(O_2)$ at 500 °C,
5 $p_A(O_2)$ at 700 °C,
6 $p_A(O_2)$ at 900 °C.

Operating concept
The operating concept is based on the principle of a Nernst cell (Figure 1). The useful signal is the Nernst voltage U_λ that develops between an electrode exposed to the exhaust gas and an electrode exposed to the reference gas. The characteristic curve is very steep at λ = 1 (Figure 2). In lean mixtures the Nernst voltage increases linearly with the temperature. In rich mixtures, on the other hand, the influence of temperature on the oxygen partial pressure dominates in the state of equilibrium. The higher the temperature, the higher this oxygen partial pressure.

The establishment of equilibrium at the exhaust-gas electrode is also the cause of very small deviations of the λ jump from the exact value. The exhaust-gas electrode is covered with a porous protective ceramic layer to protect against contamination and to encourage the establishment of equilibrium by limiting the number of arriving gas particles. Hydrogen and oxygen diffuse through the porous protective layer and are converted on the electrode. More oxygen must be available on the protective layer to ensure that the faster-diffusing hydrogen is fully converted on the electrode; in all there must be a slightly lean mixture in the exhaust gas. The characteristic curve is therefore shifted in the lean direction. This "λ shift" is electronically compensated during control.

To deliver the signal a reference gas is required that is separated (gas-tight) from the exhaust gas by the ZrO_2 ceramic. Figure 3 depicts the structure of a planar sensor element with reference-air passage. Ambient air is used as reference gas in this type. Figure 4 shows the element in the sensor housing. The exhaust-gas and reference-gas sides are separated from each other (gas-tight) by means of a packing seal. The reference-gas side in the housing is permanently supplied with reference air via the supply leads.

Systems with a "pumped" reference are increasingly being used as an alternative to reference air. Pumping refers here to the active transportation of oxygen in the ZrO_2 ceramic by injecting a current, in which the current is set so low that it does not interfere with the actual measurement. The reference electrode itself is connected via a tighter output in the element to the reference-gas chamber. This results in a build-up of excess oxygen pressure at the reference electrode. This system offers additional protection against unwanted gas components penetrating into the reference-gas chamber.

Robustness

The ceramic sensor element is protected by a protective tube ahead of the direct exhaust-gas flow (Figure 4). This contains openings through which only a small amount of the exhaust gas is directed to the sensor element. It prevents heavy thermal stresses from the exhaust-gas flow and at the same time provides mechanical protection for the ceramic element.

The housing must meet stringent temperature requirements, meaning that high-quality materials must be used. Temperatures in excess of 1,000 °C can be recorded in the exhaust gas, as well as 700 °C at the hexagon head and up to 280 °C at the cable outlet. For this reason, only ceramic and metallic materials are used in the hot area of the sensor.

Most two-point λ sensors are also fitted with a heater element (Figure 3). This quickly heats (FLO, fast light-off) the sensor element to operating temperature and provides for fast control readiness.

In practice the λ sensor after engine starting is switched on only after a delay. Water that is produced as a combustion product and condenses again in the cold exhaust-gas system is transported by the exhaust gas and can reach the sensor element. If a droplet of this water touches a hot sensor element, it vaporizes immediately and abstracts a large amount of heat locally from the sensor element. The heavy mechanical stresses that occur as a result of thermal shock can cause the ceramic sensor element to break. For this reason, the sensor is often switched on only after the exhaust-gas system has been sufficiently heated. In more recent developments the ceramic elements are enclosed in a further porous, ceramic layer which significantly increases robustness against thermal shock. When a water droplet touches the elements, it spreads in the porous layer. Local cooling is spread over a wider area and mechanical stresses are reduced.

Protective circuit

Figure 3 shows the protective circuit of a two-point λ sensor. Because the sensor when cold cannot generate a signal due to the absence of conductivity of the ZrO_2 ceramic, it is connected via a resistor to a voltage divider. In the cold state the sensor signal is therefore 450 mV, the value of a stoichiometrically combusted gas ($\lambda = 1$). As the temperature increases the sensor is able to develop the Nernst voltage. After approximately 10 s the sensor is at sufficiently high temperature to indicate externally specified lean/rich changes. It is then possible to switch to closed-loop control in the vehicle.

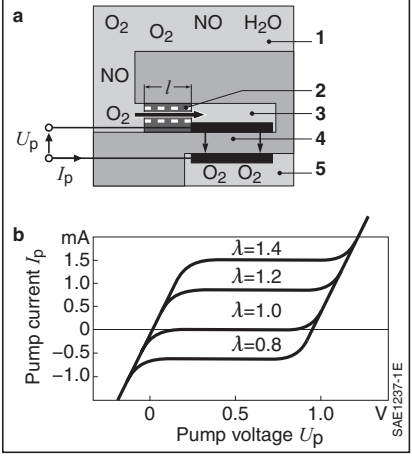
Types

Two-point λ sensors come in different types. The sensor elements can be shaped in the form of a finger with a separate heater element or as a planar element with an integrated heater element which is manufactured using film technology (Figure 3).

Wide-band λ sensor

Design and function

With the two-point λ sensor the oxygen partial pressure of stoichiometric air/fuel mixtures can be measured very accurately in the steep part of the characteristic curve. However, where there is excess air ($\lambda > 1$) or excess fuel ($\lambda < 1$), the characteristic curve is very flat (Figure 2).



The large measurement range of wide-band λ sensors ($0.6 < \lambda < \infty$) enables them to be used in systems with direct injection and stratified-charge operation and in diesel engines. A continuous control concept that can be achieved with a wide-band λ sensor delivers significant system advantages, such as for example controlled component protection. The high signal dynamic response of wide-band λ sensors ($t_{63} < 100$ ms) improves exhaust emissions to the point of low-emission vehicles, which necessarily calls for measures such as individual-cylinder closed-loop control.

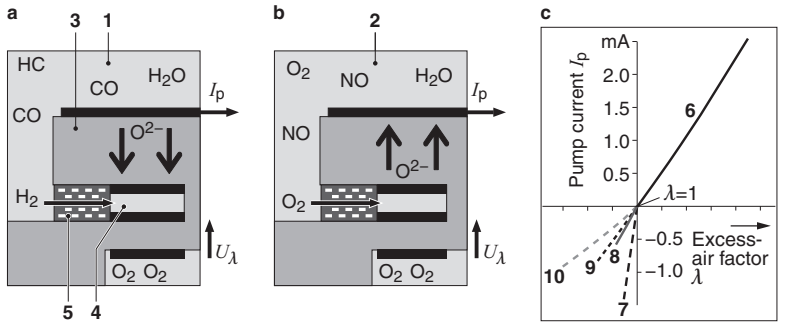
Design and operating principle

The Nernst principle is reversed to wide the measurement range. When a voltage greater than the Nernst voltage is applied to the measuring cell, oxygen is transported as oxygen ions through the pump-cell ceramic to the internal pump and discharged there as free, molecular oxygen into the reference-air chamber. The resulting pump voltage is obtained from the difference between pump voltage (U_P) and the developing Nernst voltage.

The inflow of oxygen molecules is limited in order to establish a linear connection with the externally applied oxygen concentration. To this end the admission of exhaust-gas is limited by a porous, ceramic structure with specifically set pore radii, the so-called diffusion barrier.

Figure 5: Once-cell λ sensor in lean exhaust gas
a) Cross-section,
b) Characteristic curves.
l Length of diffusion barrier.
1 Lean exhaust gas,
2 Diffusion barrier,
3 Cavity,
4 Pump cell,
5 Reference air.
The arrows in the pump cell indicate the pumping direction.

The pump current I_P that flows at sufficient pump voltage is, on account of the law of diffusion, directly proportional to the partial pressure in the exhaust gas:



$$\frac{I_P}{4F} = I_M = \frac{A\,D(T)}{R\,T\,l}\left(p_A(O_2) - p_H(O_2)\right).$$

Here $p(O_2)$ is the oxygen partial pressure in the exhaust gas ($p_A(O_2)$) or in the cavity ($p_H(O_2)$), T the temperature, $D(T)$ the temperature-dependent diffusion constant of the diffusion barrier, A its cross-sectional area, and l its length (Figure 5). F is the Faraday constant (F = 96485.3365 C/mol), R the general gas constant (R = 8.3144621 J/mol·K).

If rich exhaust gas is present, the created Nernst voltage of approx. 1,000 mV counteracts the applied pump voltage such that the resulting negative voltage pumps oxygen in the opposite direction into the cavity and thus the linear shape of the characteristic curve is extended into the rich range. The oxygen is obtained for this purpose from the reduction of water and CO_2 on the outer electrode.

The drawback of this simple form of wide-band λ sensor is that the fixed pump voltage must be sufficient in rich exhaust gas to pump oxygen into the cavity and in

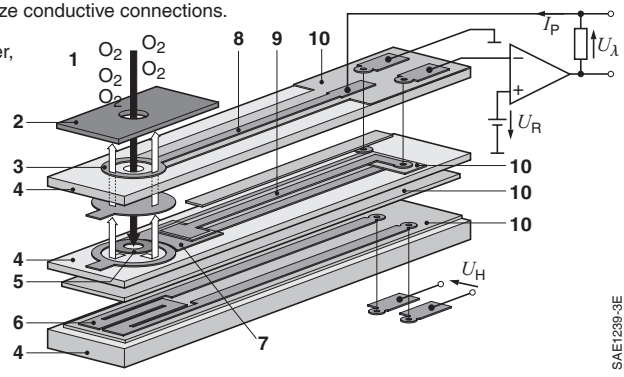
Figure 6: Two-cell λ sensor in rich and lean exhaust gas
a) and b) Cross-section,
c) Sensor characteristic curves.
Depending on the polarity of pump current I_p predominantly reducing exhaust-gas constituents (section a) or oxygen (section b) diffuse through the diffusion barrier.
For $\lambda < 1$ the characteristic curve (section c) is dependent on the exhaust-gas composition, here the characteristic curves of individual exhaust-gas constituents are plotted.
1 Rich exhaust gas, 2 Lean exhaust gas, 3 Pump cell, 4 Nernst cell, 5 Diffusion barrier,
6 Curve for O_2, 7 Curve for H_2, 8 Curve for CH_4,
9 Curve for CO, 10 Curve for C_3H_6.

lean exhaust gas to pump oxygen out of it. The internal resistance of the pump cell should therefore be very low. In addition, the measurement range in the rich range is limited by the molecule inflow in the reference passage. An oxygen deficiency in the reference caused by a reference-air contamination or over-range cannot be clearly distinguished. In the case of exhaust-gas exchanges the dynamic response of the one-cell sensor is limited by recharging of the electrode capacities when the pump voltage is changed.

To eliminate these drawbacks, the Nernst cell familiar from the step-change sensor is combined with the oxygen pump cell described above. In the case of rich exhaust gas (Figure 6a), in response to reversing the voltage at the outer pump electrode, oxygen is generated from H_2O and CO_2, transported inwards through the ceramic, and discharged again in the cavity. There the oxygen reacts with the diffusing, reducing exhaust-gas components. The created inert reaction products H_2O and CO_2 diffused through the diffusion barrier in an outward direction.

The oxygen partial pressure in the cavity is measured by the Nernst cell also connected to the cavity and the pump voltage is corrected by a controller (Figure 7) to a specified reference voltage (e.g. 450 mV). There is then an oxygen partial pressure of 10^{-2} Pa in the cavity.

Because the diffusion limit current increases with the sensor temperature, the temperature must be kept as constant as possible. The highly temperature-dependent resistance of the Nernst cell is measured for this purpose. The operating electronics regulate it by means of the heater element operated with a pulse-width-modulated voltage.



Where the exhaust gas is rich the different diffusion coefficients, which are functions of the masses of the gas molecules, become noticeable through different sensitivities (Figure 6). The signal is therefore used in the ECU for a characteristic curve applied for the relevant gas composition.

The sensor's diffusion limit current and thus the sensitivity are very much dependent on the geometry of the diffusion barrier. It is necessary to adjust the pump current in order to achieve the high accuracy requirement in the manufacturing tolerance. In some sensor types this is done by a hybrid resistor in the sensor plug which acts together with the measuring resistor as current divider. Alternatively, the diffusion limit current can be adjusted already in the sensor-element production process by means of specific openings so that there is no need to make an adjustment at the plug. For subsequent calibration of the sensor in the vehicle the oxygen concentration of the air can be measured in overrun conditions and thus the characteristic curve corrected in the ECU.

NO_x sensor

Application

NO_x sensors are used in the denitrification systems of diesel and gasoline engines. In systems with diesel engines they are installed upstream and downstream of SCR catalytic converters (selective catalytic reduction) and downstream of NO_x storage catalytic converters (NSC, NO_x storage catalysts). In systems with gasoline engines they are used downstream of the NO_x storage catalytic converter.

In these positions the NO_x sensors determine the nitrogen-oxide and oxygen concentrations in the exhaust gas and downstream of SCR catalytic converters also the ammonia concentration as a cumulative signal. In this way the engine-management system receives the current residual concentration of nitrogen oxides, provides for exact metering, and detects any faults in the exhaust system.

Nitrogen oxides are stored as nitrates in NO_x storage catalytic converters. In short rich phases the catalytic converter is regenerated, whereby the nitrates are reduced with the aid of carbon monoxide and hydrogen to nitrogen.

Design and operating principle

The NO_x sensor in Figure 8 is a planar three-cell limit-current sensor. A Nernst concentration cell and two modified oxygen pump cells (oxygen pump cell and NO_x cell), as are already familiar from wide-band λ sensors, form the overall sensor system.

The sensor element consists of several oxygen-conducting, ceramic solid-electrolyte layers insulated against each other, on which six electrodes are mounted. The sensor is fitted with an integrated heater element which heats the ceramic to an operating temperature of 600 °C to 800 °C.

The outer pump electrode exposed to the exhaust gas and the inner pump electrode in the first cavity, which is separated from the exhaust gas by a diffusion barrier, form the oxygen pump cell.

Figure 9: Characteristic curve of the nitrogen-oxide signal

8 Second cavity, 9 Common return conductor, 10 Oxygen regulator with voltage transformer,
11 NO current amplifier and voltage transformer, 12 Heater element, 13 Reference electrode,
14 Reference-gas chamber, 15 NO_x counter-electrode, 16 NO_x pump electrode.

The first cavity contains the Nernst electrode, while the reference-gas chamber contains the reference electrode. Together they form the Nernst cell. These are the functional components which are identical to those of wide-band λ sensors.

In addition, there is a third cell – the NO_x pump electrode and its counter-electrode. The former is situated in a second cavity, which is separated from the first by a further diffusion barrier, the latter is located in the reference-gas chamber. All the electrodes in the first and second cavities have a common return conductor.

The inner pump electrode is, unlike the inner pump electrode in wide-band λ sensors, greatly limited in its catalytic activity by the alloying of platinum with gold. The applied pump voltage U_{P1} is only enough to split (dissociate) oxygen molecules. NO is only minimally dissociated at the adjusted pump voltage and passes the first cavity with low losses. NO_2 as a strong oxidizing agent is converted on the inner pump electrode directly into NO. Ammonia reacts to this in the presence of oxygen and at temperatures of 650 °C into NO and water.

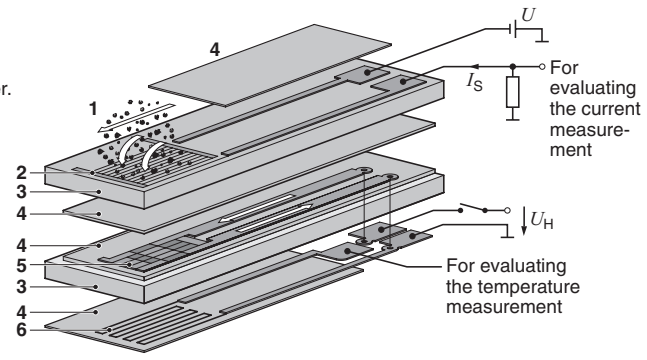
Because of the higher voltage at the NO pump electrode and its catalytically improved activity due to the admixture of rhodium, NO is completely dissociated at this electrode and the oxygen is pumped away through the solid electrolyte.

Electronics

In contrast to the other ceramic exhaust-gas sensors, the NO_x sensor is equipped with evaluation electronics (SCU, sensor control unit). It delivers via CAN bus the oxygen signal, the NO_x signal, and in each case the status of these signals.

Incorporated in the evaluation electronics are a microcontroller, an ASIC (Application-Specific Integrated Circuit) for operating the oxygen pump cell, and a high-precision instrument amplifier for the very small NO signal currents.

Characteristic curves



The oxygen signal is 3.7 mA for air. The oxygen characteristic curve is identical to that familiar from wide-band λ sensors (Figure 6c). The NO_x characteristic curve is shown in Figure 9.

Particulate sensor

The emission regulations in the USA and in Europe necessitate the use of diesel particulate filters (DPF) in diesel vehicles. Particulate sensors in addition to the differential pressure sensor are required to comply with future on-board diagnosis legislation (OBD), which places more stringent demands on the monitoring of the functional capability of these particulate filters. The particulate sensors measure the soot emissions downstream of the particulate filter.

Figure 10: Exploded view of the particulate sensor

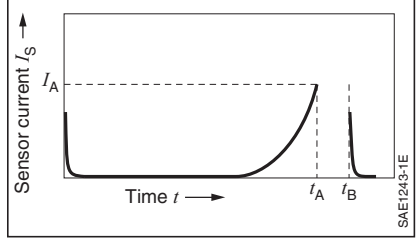
3 Ceramic,
4 Insulation,
5 Heater element,
6 Platinum meander.
U Direct voltage, e.g. 60 V,
I_S Sensor current,
U_H Heating voltage.

Design
The sensor element consists of an interdigital structure with two comb-shaped platinum electrodes on a ceramic substrate with an integrated heater element, as is familiar from the λ sensor (Figure 10). A platinum meander serves to measure the temperature of the sensor element.

Operating principle
The particulate sensor is a resistive sensor. A direct voltage of for example 60 V is applied at the interdigital structure with initially very high electrical resistance. As a result of the field forces soot particles from the exhaust gas collect on the interdigital electrodes and form increasingly conductive soot paths between the two comb-shaped structures. This produces a monotonously increasing current between the electrodes (Figure 11). A predefined current threshold value is reached after a certain collection time. This triggers regeneration, in which the initial state is re-established when the sensor element is heated and the soot is burned off at temperatures above 600 °C.

The time between the start of measurement and the start of regeneration is defined as the trigger time. An integrated temperature-measurement meander is used to control the temperature to ensure that a controlled regeneration of the sensor element takes place.

The particulate-sensor element is, like that of the λ sensor, installed in a sensor housing. Because particulate deposits on the sensor element are desired here, particular emphasis is placed on the design of the protective tube.



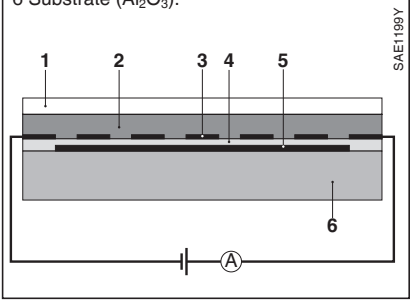
Electronics
The particulate sensor, like the NO_x sensor, is equipped with evaluation electronics. The latter supply the sensor current and the signal status via a CAN bus. A microcontroller controls the timing of measurement and regeneration and the compensation of data in response to the measured sensor-element temperature. The electronics also include a voltage stabilizer, a CAN driver, and the output stage for the heater element.

Hydrogen sensors
The use of fuel cells in motor vehicles necessitates the incorporation of hydrogen sensors. This sensor system has two functions – safety monitoring with leak detection (measurement range 0 to 4 % hydrogen content in air) and process control with adjustment of operating conditions (measurement range 0 to 100 %).

The most common measurement principles are described in descending frequency of use. For the most part different methods are combined to reduce cross-sensitivity to other gases or to increase sensitivity and widen the measurement range [3].

Electrochemical measurement principle
In the case of amperometric measurement a constant voltage is applied to an electrolyte that conducts only protons (e.g. sulfonated tetrafluoroethylene polymer). The electrolyte is covered by a diffusion barrier which is very selective in admitting only hydrogen. These sensors thus have long-term stability. At the electrode hydrogen splits into protons, which flow as pump current through the electrolyte. The electrons flow through the electrodes, driven by the applied voltage, via the outer electric circuit to the other side of the electrolyte. Here they recombine with oxygen on the electrode to form water. The current intensity is according to Faraday's law proportional to the number of protons, which in turn is determined by the diffusion by the diffusion barrier (see λ sensor).

Figure 11: Current curve between the electrodes of a particulate sensor
I_A Trigger threshold,
t_A Trigger point for regeneration,
t_B Start of next measurement cycle.



Potentiometric measurement methods utilize the potential difference between two electrodes. One electrode with a platinum or palladium catalyst is situated in the hydrogen environment, the other electrode is situated for example in air. According to the Nernst equation a potential difference develops (see Fuel cell). The potentiometric sensors are cross-sensitive to carbon monoxide that covers the catalyst. The age quickly and have a high drift. The measurement range is between 100 ppm and 100 %.

Resistance-based measurement principle
Palladium and semiconductor metal oxides (e.g. SnO_2) exhibit a change in resistance after the adsorption of hydrogen. The semiconductor metal-oxide sensor (Figure 12) consists of a gas-filtering diaphragm which should only admit hydrogen. The sensitive layer absorbs the hydrogen and induces the change in resistance, which is measured by a Wheatstone bridge.

A MOSFET (see Field-effect transistor) can also be used with a palladium gate as a variant. These alters the current between source and drain proportionally to the hydrogen absorbed at the gate. In a Schottky-diode arrangement (see Schottky diode) the breakdown voltage decreases when hydrogen is adsorbed.

Figure 12: Resistance-based measurement principle of a hydrogen sensor
1 Gas-filtering diaphragm,
2 Sensitive layer,
3 Semiconductor metal-oxide film,
4 Insulating layer,
5 Heater,
6 Substrate (Al_2O_3).

The measurement range for the resistance-based measurement principles is between 10 ppm and 2 %.

Catalytic measurement principle
Heat is generated when adsorbed gases oxidize on the surface of a catalyst. In a pellistor a wire consisting of catalyst material (e.g. platinum or palladium) exposed to the hydrogen is heated and as a result undergoes a change in resistance dependent on the hydrogen concentration, while the temperature and resistance of a reference wire remain unchanged. The resistors are integral parts of a Wheatstone-bridge circuit, with which the change in resistance is measured and from this the hydrogen concentration is inferred.

In the thermoelectric method the voltage build-up due to the temperature difference (Seebeck effect) is utilized.

The catalytic methods are cross-sensitive to other oxidizable gases and require a minimum quantity of oxygen (5 to 10 %) as the oxidation partner; the measurement range therefore is between 1 % and 90 to 95 % hydrogen concentration.

Optoelectronic sensors

Internal photoelectric effect

The internal photoelectric effect forms the basis of optoelectronic sensor elements. Light can be seen as a stream of individual light quanta (photons). The energy E_{Ph} of a photon is only dependent on its frequency f or its wavelength λ:

(1) $E_{Ph} = h f = \frac{h c}{\lambda}$

where
h Planck's action quantum,
c Speed of light.

When photons strike atoms, they can each release an electron from the outer electron shell if the energy is sufficient. The energy required for release corresponds to the difference between the energy level E_V of the valence band of the atom and the level E_L of the conduction band, i.e. the band gap E_g.

(2) $E_g = E_L - E_V$.

To release an electron, the photon energy E_{Ph} must therefore be greater than the band gap E_g. In a pure semiconductor, charge-carrier pairs (electrons and holes) are created by the absorption of photons. The band gap to be overcome of, for example, silicon is E_g = 1.12 eV at room temperature. Without special measures the charge-carrier pairs created recombine already after a short time. However, the radiation created in the process is not in the visible range in the case of silicon.

In highly doped semiconductors, the above-mentioned intrinsic photoelectric effect is supplemented by the extrinsic photoelectric effect. Because the energy gap to be overcome is significantly lower in such extrinsic sensors, they are also suitable for radiating a larger wavelength (infrared range).

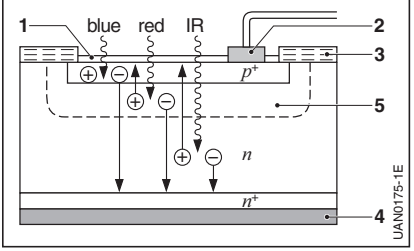
No further release occurs for energies $E_{Ph} < E_g$. According to equation (1), this corresponds in the case of silicon to a limit wavelength of λ_g = 1.1 µm (near infrared). Light with larger wavelengths or lower frequency is not longer absorbed; silicon becomes transparent here.

Light-sensitive sensor elements

Photoresistors

Incident light causes charge-carrier pairs to be created in a sensor configured as a resistor (LDR, light-dependent resistor); these charge-carrier pairs increase the conductance G. They recombine after a short time (milliseconds range); but nevertheless the charge-carrier concentration increases in stationary equilibrium with the illuminance E according to the following law:

(3) $G = \text{const} \cdot E^{\gamma}$ where γ = 0.7 to 1.



The light-sensitive materials usually used are cadmium sulfide CdS (E_g = 1.8 eV; λ_g = 0.7 µm) and cadmium selenide CdSe (E_g = 1.5 eV; λ_g = 0.8 µm) on ceramic substrates.

Semiconductor pn junctions

There is essentially no difference between a photocell, a photodiode, and a phototransistor. They all use the photocurrent or no-load voltage in illuminated *pn* semiconductor contacts as the measuring effect. The elements differ, however, in the way they operate.

Charge carriers which are created by the internal photoeffect in the depletion layer of a *pn* semiconductor contact (Figure 1) are immediately accelerated by the electric field in the space-charge region with low charge-carrier concen-

Figure 1: Separation of created electron-hole pairs in a planar semiconductor component with *pn* junction
1 Optical coating,
2 Contact,
3 SiO_2,
4 Metal contact,
5 Space-charge region.

tration, as a result of which the charge carriers are immediately split after they have been created (drift current). Their recombination is practically prevented and photosensitivity is significantly increased.

Photocells

Photocells are operated without external bias and can be operated both at no load (photovoltaic effect) and in a short-circuit. They have accordingly a low background noise and thus a high detection capability.

The characteristic curves applicable to these operating modes (Figure 2) can be easily derived as special cases from a diode polarized in the forward direction with the voltage U with the thermally conditioned off-state saturation current I_S and the photocurrent I_{ph} also flowing in reverse direction:

(4) $I = I_S\, e^{\frac{eU}{kT}} - I_S - I_{ph}$

where
e Elementary charge,
k Boltzmann's constant,
T Absolute temperature.

Special cases:

(5) $U = 0$ (short-circuit)
$\rightarrow I = I_K = -I_{ph}$;

(6) $I = 0$ (no load):

$$\rightarrow U = U_L = \frac{kT}{e} \cdot \ln\left(\frac{I_{ph}}{I_S} + 1\right).$$

Photocells are usually configured with a very large irradiation-sensitive surface, and provide accordingly relatively high photovoltaic current also (e.g. I_{ph} = 250 µA at E = 1,000 lx). Their time constant is proportionally high and is typically approximately 20 ms.

Photodiodes and phototransistors

Photodiodes are operated with constant bias U_S in the reverse direction, where the photocurrent flowing as reverse current is linearly dependent on the illuminance E (Figure 3). The space-charge region is increased in size by the applied

Figure 3: Characteristic curves for a photodiode for constant illuminance *E*

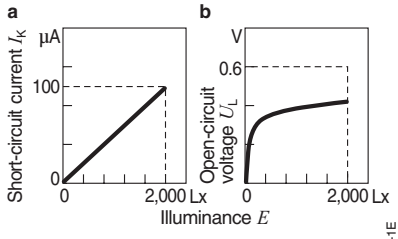
a) Short-circuit current I_K,
b) Open-circuit voltage U_L.



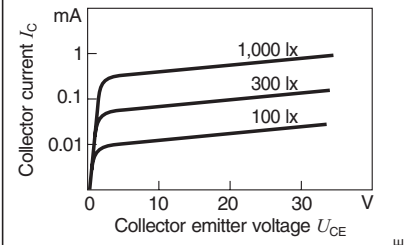


Figure 4: Characteristic curves for a phototransistor for constant illuminance *E*

reverse voltage. This reduces the junction capacitance in such a way that the cutoff frequency of such a photodiode is typically a few MHz.

In the case of the phototransistor shown in Figure 4 (*npn* type), the collector-base diode polarized in the reverse direction acts as a photodiode. In this way, the collector, like every transistor, supplies a photocurrent higher by the current-amplification factor B (≈ 100 to 500) (corresponding to base current). However, the higher sensitivity comes at the expense of a slightly worse frequency dynamic and a slightly worse thermal characteristic.

Application

Dirt sensor

The sensor measures the level of contamination on the headlamp lens to furnish the data required for automatic lens cleaning systems.

The sensor's photoelectric reflected-light barrier consists of a light source (LED) and a light receiver (phototransistor). The source is positioned on the inside of the lens, within the cleansed area (Figure 5), but not directly in the headlamp beam path. When the lens is clean, or covered with rain droplets, the infrared measurement beam emitted by the unit passes through the lens without being obstructed. Only a minuscule part is reflected back to the light receiver. However, if it encounters dirt particles on the outer surface of the lens, it is reflected back to the receiver at an intensity that is proportional to the degree of contamination and automatically activates the headlamp washer unit once a defined level is reached.

Rain sensor

The rain sensor recognizes rain droplets on the windshield, so that the windshield wipers can be triggered automatically. The driver, however, can still use the manual controls.

The sensor consists of an optical transmission and reception path (similar to the dirt sensor). However, the light is directed toward the windshield at an angle. A dry outer surface reflects all the light (total reflection) back to the receiver which is also mounted at an angle (Figure 6). When water droplets are present on the outer surface, a substantial amount of the light is refracted outward, thus weakening the return signal. The windshield wiper also responds to dirt once the activation threshold is exceeded.

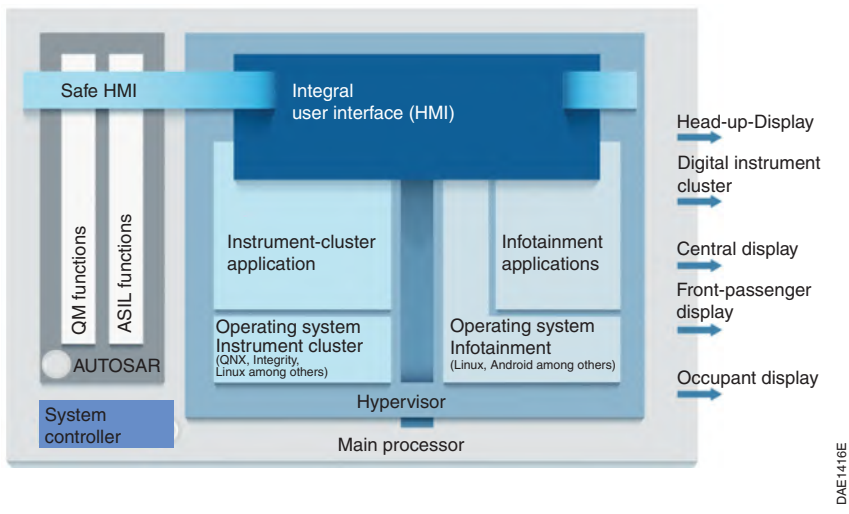
Infotainment and cockpit solutions

History

In-car entertainment had already been available in the 1920s with the first car radio in the legendary Ford Model T. In 1933 the Berlin-based Radiotelefon und Apparatefabrik Ideal AG, a subsidiary of Bosch, brought out a car radio for the medium- and long-wave ranges – VHF reception first became available only in 1949 – with five electron tubes. This appliance was developed together with Bosch. Station tuning was at that time performed with Bowden cables from the steering column; only later were all the components integrated in the instrument panel. The volume comprised around ten liters.

Enhanced comfort arrived in the 1950s with automatic station search and push-buttons for storing several stations. Appliances became more compact with the introduction of transistor technology.

In 1968 the first car radios with integrated cassette players came out. This made individual in-car entertainment possible.



In 1974 the Autofahrer-Rundfunk-Informationssystem (ARI), a radio traffic-information system for drivers, was launched in Germany. This enabled traffic information to be automatically detected on the car radio.

In the mid-1980s the first car radios with an integrated CD player were introduced, delivering bettering sound quality than the cassette player.

In 1988 the Radio Data System (RDS) was launched. This enabled a car radio to automatically process traffic reports and receive station names and further additional information. Later, with the Traffic Message Channel (TMC), the RDS traffic reports could also be shown independently of the received radio program in the car radio's display.

In the 1990s navigation devices found their way into cars, giving rise to combinations of car radio, CD player, and navigation systems.

Figure 1: Information Domain Computer

Infotainment systems

Technology of the present day

Entertainment and information have played a significant role in motor vehicles for a long time. The demands imposed on the units have increased continuously.

Quickly updating the favorites playlist before starting a journey and checking the current traffic situation en route in real time – infotainment systems have long been more than just a radio. Integrated in these systems are entertainment components, intelligent vehicle navigation, telematics, and driver-assistance systems. Connectivity with the Internet and the vehicle bus system facilitates communication between driver, vehicle, and outside world. Intuitive operation minimizes driver distraction, making driving safer. The HMI (Human Machine Interface) as the interface between human and machine is optimized here for distraction-free driving.

Such systems in the meantime have become standard features in motor vehicles. The car radio and the navigation system are integrated in the central display in the center console and controlled via the touchscreen. Speedometer, rev counter, coolant temperature, and further information such as for example navigation-system route-direction symbols are displayed in the instrument cluster.

With a fully digital instrument cluster the electromechanical indicating instruments for engine speed, torque and coolant temperature are rendered superfluous. The indicating instruments are reproduced electronically.

In the additional front-passenger display the front passenger can for example watch a video or surf the Internet without the driver being distracted.

Solutions for the future

The demands imposed on the vehicle cockpits of the future are high. As with the smartphone or other digital companions, car drivers expect the greatest possible connectivity, personalization and intuitive operation from their vehicles. Vehicle manufacturers must offer suitable solutions for different markets and vehicle segments and in the process expect the greatest possible flexibility with low costs.

Information Domain Computer

System overview

The "Information Domain Computer" from Bosch (Figure 1) is based on a modular platform concept and will fulfill all these requirements. It provides a consistent, networked user experience, satisfies the high safety requirements, and offers car makers a high degree of flexibility in the configuration of their solution.

At present, multiple ECUs control and regulate the different displays and other electronic cockpit functions in production vehicles. In future more and more functions will be merged in one single processor. The Information Domain Computer is based on a "System on a Chip" (SoC) with the main processor controlling all the functions on just one chip. All the displays in the vehicle can be activated by this Domain Computer. This reduces the complexity and the demand for additional ECUs in the cockpit. The computing functions of the previously separate domains of infotainment and Instrumentation as well as other functions are bundled on one processor. This saves costs, installation space, and weight and consumes less energy.

An ECU for the entire user interface – the merging of the previously separate systems in the cockpit facilitates the synchronization of the infotainment system, the instrument cluster and other displays so that all the given information can be orchestrated, managed and displayed at any time in the entire vehicle. This is a prerequisite for a seamless, uniform design language and the possibility of always flexibly displaying information where the driver needs it. The complete system is updatable "over-the-air", i.e., the Information Domain Computer can be updated in real time.

The infotainment system integrates numerous functions such as the media player, radio reception, intelligent navigation, smartphone integration, voice recognition, and third-party software.

The hypervisor enables the different operating systems for example for infotainment and driver-information displays to be operated in separate virtual machines.

Safety-relevant functions from the domains of infotainment and instrument

cluster run on the AUTOSAR operating system. Examples are the rearview camera and an oil-level warning display, which must be immediately reliably available when the vehicle is started.

The system controller has a shorter boot time than the main processor itself and thus guarantees the immediate availability of all the safety-relevant functions.

Digital instrument cluster
As well as the classic instrument-cluster displays, further functions such as climate control, driver-assistance functions, and driver-monitoring camera with their own operating systems can be optionally integrated. Thanks to the intelligent algorithms only such information that the driver needs depending on the situation is displayed in the digital instrument cluster. This reduces the risk of the driver being overwhelmed by the increasing amount of information from driver-assistance functions. Displayed content can be flexibly adapted, reducing the degree of driver distraction and at the same time helping to improve road safety.

Because a lot of driver information is safety-relevant, modern digital instrument clusters must offer adaptive concepts (e.g., the “Safe HMI” for satisfying ASIL requirements). Complex functionalities and technologies, such as for example the driver-monitoring camera, can also be integrated in the instrument cluster.

Smartphone connection to the infotainment system

Application
Safely, comfortably and without distraction – mySPIN is a platform-independent solution from Bosch that is designed to let the user connect their smartphone easily to their car or motorcycle. In this way, selected apps and networked services are displayed in a driver- and rider-friendly format in the vehicle's cluster.

Once the smartphone is connected to the vehicle via WLAN, Bluetooth or USB, many interesting apps and important smartphone functions (e.g., telephony) are available to the driver or rider in the vehicle display. The user has access to their smartphone at all times during their journey. mySPIN offers comfortable use of apps both in passenger cars and on motorcycles or two-wheelers of any kind.

Whether iOS or Android, once connected to the vehicle, the driver or rider can use compatible smartphone apps directly via the touchscreen – on a motorcycle quite easily via the handlebar control unit. So as not to distract the driver or rider from the surrounding traffic and to provide driver- and rider-friendly and safe operation, all apps have been specially adapted to mobile use and exclusively make available all the important basic functions and information.

mySPIN already today offers the user an impressive selection of popular apps from a wide variety of categories, including navigation, point of interest and events, parking search, news, and music streaming. The pool of mySPIN-compatible apps that provide international as well as local content for regions like Europe, America, India, and China is growing continuously.

mySPIN offers the automobile manufacturers a great many interesting options too, including a seamless integration of the application in the vehicle's user interface and the facility to process vehicle data such as for example the current fuel level.

On top of this come specially developed applications with which the driver or rider can trace and share their routes with their community or download routes shared with the community. The make navigation functions and the latest traffic information available. The pool of apps is being continuously extended – nationally and internationally. Developers not only customize already existing apps for mySPIN, but also widen the app pool with new innovative ideas.

Manufacturers have, thanks to the cloud connectivity of mySPIN, the opportunity to address the driver or rider directly and keep them up to date with important, personalized information. Manufacturers themselves decide on the availability of the apps and their scope and can extend the portfolio to include new functions and apps.

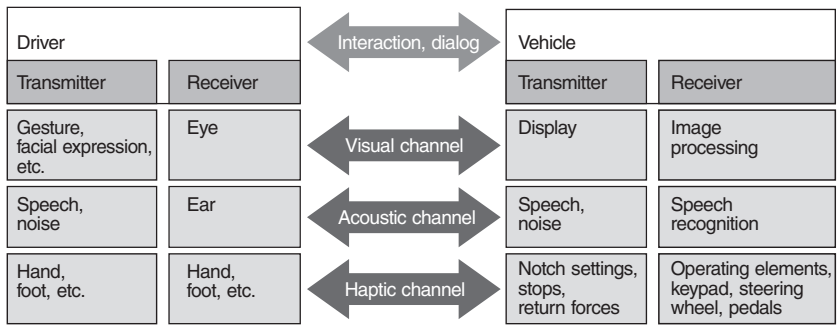
Benefits for the user

– Comfortable use of apps while driving or riding without the driver or rider being distracted.
– Easy operation via touchscreen in the vehicle or via the handlebar control unit on the motorcycle.
– A large selection of apps from different categories.
– Compatible with iOS and Android operating systems.
– Driver- and rider-friendly display for optimal operation.
– Extensive customization options for vehicle manufacturers.
– Flexibility with regard to choice and scope of apps and additional functions in the vehicles.
– Access to vehicle data for data analyses – possibility of integration of cloud services.
– Real-time information on dangers and state of roads.
– Offline use of the navigation apps.
– Wide range of smartphone apps.
– Selected and optimized apps specially for the two-wheeler and powersports segment.
– Intuitive and safe use of smartphones and apps in the motorcycle and powersports segment: for more safety, comfort, and fun on the road.

Display and control

Interaction channels

Drivers have to process a constantly increasing stream of information originating from their own and other vehicles, from the road, and from telecommunication equipment. All this information must be conveyed to drivers on suitable display and indicating equipment that complies with ergonomic requirements.



Visual channel – seeing
A human being discerns their environment predominantly through their sense of sight (Figure 1). Other road users, their position, their suspected behavior, the lane, and objects in the road area are detected with the human being's sight apparatus and their subsequent highly powerful image processing and interpretation, selected and evaluated by further structures in the brain with regard to their development and relevance.

Road-traffic infrastructure makes demands on above all the visual channel: Road signs communicate rules, markings delimit lanes from each other, direction-indicator lamps indicate a change of driving direction, stop lamps warn against vehicles that are slowing down. The visual channel is therefore extremely important to the driving environment. This applies to conscious vision, whereby the driver turns their eyes specifically to objects and focuses on them, but also to peripheral vision, which is crucial to positioning the vehicle within the lane. For this reason, additional glances at displays in the vehicle during interaction with driver-information and driver-assistance systems or their monitoring must be carefully assessed as to possible effects on road safety.

Acoustic channel – speaking and hearing
For communication with other road users, particularly the display and signaling of danger, the acoustic channel is used by human beings and by driver-assistance systems. In the driver's own vehicle this channel is also used to input commands via speech input systems and to output warnings and information from the driver-assistance system to the driver with acoustic signals and speech output.

The input of voice commands does not require the driver to turn their eyes, but does take up the driver's attention. Hearing does not require the driver to turn their eyes, but can convey spatial and complex information (e.g., description of the situation at intersections) poorly. Even drivers who do not have an adequate sense of hearing must be able to communicate with the driver-assistance system.

Figure 1: Information channels between driver and vehicle

Haptic and kinesthetic channels – operation and feeling

The haptic channel provides feedback to the driver in the case of all motor operations when switches are operated and during steering and braking. Warning the driver by tightening their seat belt briefly and by vibrating the seat in the event of an imminent departure from the present lane has already been introduced in series production. A further possibility for arousing the driver's attention is the vibration of the steering wheel. Increased resistance on the accelerator pedal can support a speed recommendation and heightens the driver's attention. A torque that the driver can feel can be exerted on the steering wheel to suggest an evasive maneuver.

Even the kinesthetic channel, which helps the driver to perceive instances of acceleration while driving, is already in use in production vehicles for the purpose of arousing the driver's attention, for instance by way of a short braking jolt.

The haptic channel is however continuously required for steering and cruise control, and additional manual operations (e.g., operation of the cellular phone's keypad) may impair lateral guidance by distracting the driver.

Instrumentation

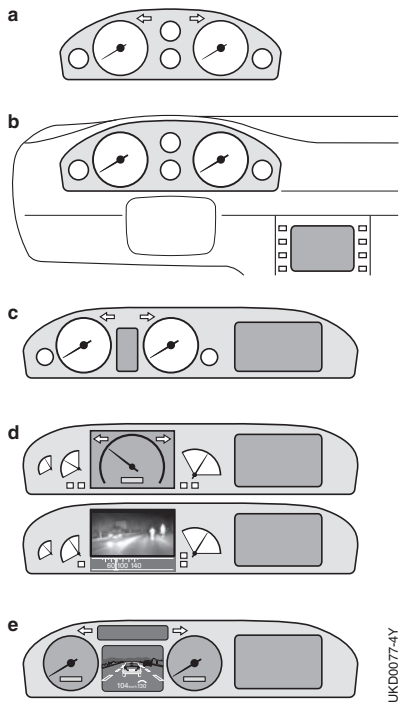
Information and communication areas

In any vehicle, there are four information and communication areas which must satisfy different requirements in terms of their display features: the instrument cluster, the windshield, the center console, and the rear cabin.

The supply of available information and the necessary, advisable or desirable information for the respective occupant determine which communication areas are used in the case. Dynamic information (e.g., driving speed) and monitoring information (e.g., fuel level), to which the driver should respond, is displayed in the instrument cluster in a favorable reading position close to the driver's primary field of vision.

A head-up display (HUD), which reflects the information on the windshield, is ideally suited to engaging the driver's attention (e.g., in the case of warnings from a driver-assistance system or for route directions). The head-up display is also suitable for displaying the speed in a digital form. A supplementary feature is the output of acoustic signals or speech.

Status information or more extensive operation dialogs (e.g., for vehicle navigation) are preferably shown in the central display in the center console. The operating units are usually assigned to this central display for more compact vehicles. For more spacious vehicles with a high-mounted central display (see Figures 2c and 2d), the preferred place to arrange the control units is in the primary reach area in the form of a rotary/push control element on the transmission hump.

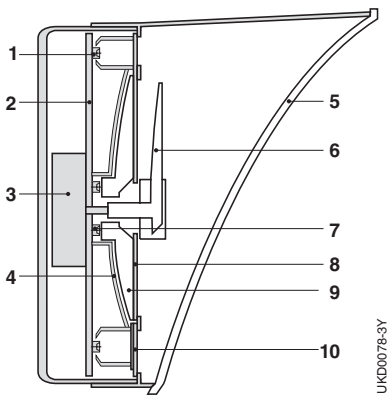


Information of an entertainment nature is featured in the vehicle rear compartment, away from the primary field of vision. This is also the ideal location for a mobile office. The backrest of the front-passenger seat is a suitable installation location for the monitor and operator unit of a laptop computer.

"Dual View" or "Split View" displays for the center console have additionally been available since 2009; these displays can show different information to driver and passenger so that the passenger can, for example, watch videos without distracting the driver while the driver sees the navigation-system information.

Instrument clusters
Earlier single instruments for the optical output of information (e.g., driving speed, engine rpm, fuel level, and engine temperature) were initially superseded by more cost-effective, well-lit and antireflective instrument clusters (combination of several information units in one housing).

Figure 2: Driver information area with instrument cluster and monitor in the center-console area (development steps)
a) Needle instruments,
b) Needle instruments with TN LCD and separate AMLCD in center console,
c) Needle instruments with integrated (D)STN LCD or AMLCD and AMLCD-technology monitor in center-console area,
d) Freely programmable instrument cluster with two AMLCD components with different display options,
e) Two freely programmed liquid-crystal displays.



For designations, see Display types.

The passage of time, with the continual increase in information, saw the creation of the modern instrument cluster in the existing space available, with several needle instruments and numerous indicator lamps (Figure 2a). This first generation of instrument cluster was dominated by the eddy-current measuring instrument for the speedometer, the moving-coil measuring instrument for the rev counter, and the hot-wire instrument for the fuel level.

Measuring instruments
Even today most instruments still operate with mechanical needles and dial faces (Figures 2a to 2c). Initially moving permanent-magnet ratiometer elements replaced the voluminous, mechanically driven eddy-current measurement instruments. Today stepping motors with low overall depth and high torque are predominant. Due to a compact magnetic circuit and (mostly) two-stage gearing with power consumption of only approx. 100 mW, these motors permit swift and highly accurate needle positioning (Figure 3).

Figure 3: Instrument cluster (design)

3 Stepping motor,
4 Reflector,
5 View cover,
6 Needle,
7 Backlighting with backlit-technology LED,
8 Dial face,
9 Optical waveguide,
10 LCD (odometer).

Digital displays
The digital instruments fitted up to the 1990s (e.g., for indicating driving speed) displayed information using vacuum-fluorescence display (VFD) technology and, later, liquid-crystal (LCD) technology, but they have now largely disappeared in Europe. This unfortunately means that the advantage of a demonstrably fast and accurate speed reading has been lost. Today's Formula 1 cars all have digital speedometers.

Digital displays in instrument clusters can be found today in Japan (e.g., Toyota Prius) and in luxury-class cars in the USA.

Lighting
To illuminate instrument clusters, backlighting technology has, on account of its attractive appearance, gained acceptance to a large extent over the frontlighting technology used previously. Bulbs have been replaced by long-lasting light-emitting diodes (LEDs). LEDs are suitable both as warning lamps and as backlighting for scales, displays and needles (using plastic optical waveguides if necessary).

Where for a long time only monochrome LEDs in the colors yellow, orange and red were available, now blue and highly efficient white LEDs are available.

Color LCDs, on account of their very low transmission (typically approx. 6 %), had initially required cold cathode fluorescent lamps (CCFLs) for the backlighting in order to achieve a good contrast in daylight. These have in the meantime been replaced by highly efficient white LEDs.

Graphics modules in the instrument area
Fitting vehicles with a driver's airbag and power-assisted steering as standard has resulted in a reduction in the view through the top half of the steering wheel. At the same time the amount of information that has to be displayed in the installation space available has increased. Prior to the availability of graphics displays whose display surfaces can show any information – flexibly and ordered by priority – engineers tried to solve this installation dilemma initially using additional displays which were positioned on the dashboard – e.g., trip computers and the first monitors for displaying navigation information, which were sometimes also mounted on a gooseneck. The availability of graphics monitors resulted in the hybrid instrument with classic needle instruments and a graphics module (Figure 2c).

The graphics module in the instrument cluster mainly enables an indication of driver-related functions such as, for example, service intervals, check functions covering the vehicle's operating state, as well as vehicle diagnostics as needed by a workshop. They can naturally also show route-direction information from the navigation system, where, due to the small surface area of these modules, digitized map excerpts must be missed out so that only route-direction symbols such as turnoff instructions or intersection symbols appear in the display. This limitation has also been retained in newer vehicles. The initially monochrome modules were quickly followed in higher-specification vehicles by color displays which can be read more quickly and accurately because of their color resolution.

Since 2005 active-matrix displays (see below) have also been in use to represent analog instruments (Figure 2d). One example is the instrumentation in the Mercedes S-Class, in which the speed indication is emulated using an LCD monitor. During changeover to the night-vision function (see Night-vision system) the camera's conditioned video image appears, while the engine rpm indication is shown in bar form under the video image.

With the launch of the Mercedes S-Class in model year 2013 the instrument cluster was replaced for the first time by a full-screen liquid-crystal monitor. Such a freely programmable instrument offers many benefits. Either the information can be arranged according to customer preference (e.g., at the end of the line) in the display or drivers who are familiar with digital media can program their instrument clusters themselves. This option is offered in the Chevrolet Corvette C7.

In view of the drop in prices of these displays it can be assumed that the digital display in the instrument cluster will become widely accepted because in this way the variety of versions of entire vehicle model series can be reduced to a single, flexibly programmable unit, resulting in huge logistical savings.

The introduction of the graphics monitor as the instrument cluster was also accompanied by a growth in the format of the center-console display.

Central display and operating unit in the center-console area

The arrival of driver-information systems, initially mainly navigation and telephone, saw the establishment of a further monitor with accompanying operating elements in the center console (Figure 2). It was initially positioned here because it was possible here to create sufficient installation space with the installation bay for the car radio and the ashtray. The operating elements were arranged along the edges of the display (Figure 2b). The vehicle manufacturers have since switched to the ergonomically more favorable solution of installing the monitor in the center-console area at the height of the instrument cluster (Figure 2c). In this connection, most German automobile manufacturers have replaced the button input on the monitor edge with a combined rotary/push input button in the driver's primary area of reach on the center console. Operation directly via the display is possible with touch screens.

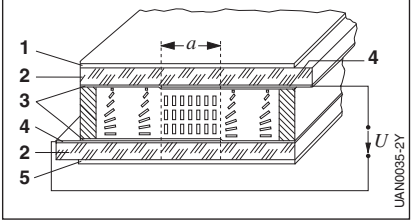
A wealth of information is shown on this central monitor, e.g., navigation, communication (telephone, SMS, Internet), audio (radio, digital sound recording media), video and TV when the vehicle is stationary, climate control, and settings (date, time). Information from the new driver-assistance systems (e.g., parking and maneuvering aids) can also be usefully displayed here.

The important issue for all visual displays is that they can be easily read within the driver's primary field of vision or its immediate vicinity so as to ensure that the driver does not have to look away from the road for long periods. Positioning this terminal, which is of universal use to driver and passenger, in the upper center-console area is effective and necessary from both ergonomic and technical standpoints. The demands placed by TV reproduction and the navigation system on the video and map display determine the demands placed on the resolution and the color reproduction of the monitor.

For this central display monitor, there has initially been a change from a small 6" monitor with a 4:3 aspect ratio to a wider format with a 16:9 aspect ratio, which allows additional route-direction symbols to be displayed as well as the map. Newer vehicles with the central monitor located in the upper center-console area sometimes have, due to the greater space available, much larger monitor formats. The Tesla Model S even uses a vertically arranged monitor with a diagonal of 17" as a combined display and operating unit in the center console.

Display types

Liquid-crystal display
The most display most commonly used today in vehicles is the liquid-crystal display (LCD). Being a passive display which emits no light itself but modulates incident light, it requires additional lighting.



Twisted Nematic LCD
TN LCD (Twisted Nematic Liquid-Crystal Display) is the most commonly used form of display. The name derives from the arrangement internally of rectangular molecules twisted through 90° at zero voltage. This causes the polarization plane of the light passing through the cell to rotate through 90° (Figure 4). If this cell is arranged between crossed polarizers, it is transparent in the de-energized (zero-voltage) state. When a voltage is applied, the molecules are rotated in the field direction (Figure 4, middle segment). The cell becomes non-transparent, i.e., it is a light valve.

The operating range is –40 to 125 °C. The switching times are slightly longer at low temperatures due to the viscous properties of the liquid-crystal material.

Depending on the choice of polarization direction of the externally applied polarizer film, the TN LCD can be operated in positive contrast (dark characters on a light background) or negative contrast (light characters on a dark background). The TN LCD is usually operated in negative contrast in the vehicle since this comes close to the familiar appearance of printed dials. Negative-contrast cells always required backlighting.

Separately controlled segment areas can be used to portray numbers, letters, and symbols. TN technology is suitable not only for smaller display modules but also for larger display areas and modular LCD instrument clusters such as the instrument cluster in the Audi Quattro model year 1984.

a Segment area.

Active-matrix LCD
Dot matrix displays with graphics capabilities are needed to display infinitely variable information. The task of the visually sophisticated and rapidly changing display of complex information in the area of the instrument cluster and the center console with high-resolution liquid-crystal monitors with video capabilities can only be performed effectively by an active-matrix liquid LCD (AMLCD). The pixels are addressed with thin-film field-effect film transistors (TFT LCD, Thin-Film Transistor LCD). Display monitors with diagonals of 3.5 to 10 inches in the center-console area and an extended temperature range (-25 to 110 °C) are available for motor vehicles and are the most widely used monitor technology in vehicles today. Formats of 10 inches and more are used for the freely programmable instrument cluster.

AMLCDs (Figure 5) consist of the "active" glass substrate with the semiconductor structures and the opposing plate with the color-filter structures. The active substrate accommodates the pixel electrodes made from indium tin oxide, the metallic row and column conductors, and semiconductor structures. At each intersecting point of the row and column conductors, there is a thin-film field-effect transistor, which is etched in several masking steps from a previously applied sequence of layers. A capacitor is generated at each pixel as well.

The opposite glass plate accommodates the color filters and a "black matrix" structure for covering the metallic row and column conductors, which improves display contrast. These structures are applied to the glass in a sequence of photolithographic processes. A continuous counter-electrode is applied on top of them for all the pixels. The color filters are

applied either in the form of continuous strips (good reproduction of graphics information) or as mosaic filters (especially suitable for video pictures).

Organic light-emitting diodes

The luminescence excitation for organic, electroluminescent display units (OLED, organic light-emitting diode) occurs, as in light-emitting diodes (LEDs), through injected charge carriers, but here in a layer of organic materials. Three processes have to take place within the system of coatings for electroluminescence to occur: Injection, transportation of both types of charge carriers (electrons, holes) through the layer as well as their recombination.

The organic layers are embedded between two electrodes. Figure 6 shows the basic structure of an OLED picture element. Glass (or plastic foil) coated with indium tin oxide (ITO) is typically used as the anode; this lets the generated light through (downwards in the graphic). The cathode is made of metal. The organic material is located between them. Charge carriers are injected into the material using the electric contact points by applying a voltage. These are moved toward each other by the polymer layer. When charge carriers of different charges meet (electrons and holes), this causes the radiative recombination as described above (see also OLED, electronics).

Figure 7 shows the structure of an OLED matrix display. The organic layer is located between the row and column electrodes arranged perpendicularly to each other. Multi-color reproduction is achieved by OLED materials in a dot matrix that emit different colors.

OLED displays have already been established in the consumer area (e.g., mobile phones) for years. Due to the high requirements for resistance to climatic conditions, OLEDs have only been used for small, monochrome, alphanumeric and simple graphic displays to date, e.g., for

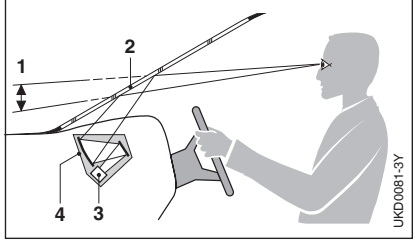
displaying air-conditioner functions. The option to construct OLEDs with curved surfaces using plastic substrates could attract interest in the future from the standpoint of providing good anti-reflection conditions in a vehicle.



Head-up display

Conventional instrument clusters are situated at a viewing distance of 0.8 to 1.2 m. In order to read information in the area of the instrument cluster, the driver must adjust his or her eyes from long distance (observing the road scene) to the short viewing distance for the instrument. This accustomization process usually requires, depending on the driver's age, 0.3 to 0.5 s.

Head-up displays (HUDs) were first used in military-aviation applications. For motor-vehicle applications they were available in a simple design, usually as a digital speedometer, in parallel with the analog speedometer in Japan and in the USA as an optional extra. An improved form was initially used in the USA and later also in European vehicles.

The image of a head-up display is projected with the aid of the windshield into the driver's primary field of vision. The optical system generates a virtual image at such a viewing distance that the human eye can remain adjusted to long distance. Head-up displays do not require the driver to divert their eyes from the road – thus allowing the driver to register at all times safety-critical driving situations without being distracted. The driver does not need to look at the instrument cluster when important information is shown in the head-up display.

Figure 8: Head-up display (principle)
1 Virtual image,
2 Reflection in the windshield,
3 Display module: liquid-crystal display (LCD) with backlighting,
4 Optical system.

Design

A typical head-up display (Figure 8) features an activated display module for generating the image, a lighting facility, an optical imaging unit, and a combiner, which reflects the image to the driver's eyes. In a motor vehicle it is usually the windshield which acts as the combiner. To avoid double images – caused by reflections on the inner and outer boundary surfaces – the windshield is slightly wedge-shaped in design. From the driver's perspective the two images created at the boundary surfaces then coincide.

A real image is created in the display module. This module can be a display or a back-projection onto a diffusing surface, e.g., with a scanning laser beam. This real image is only roughly 20×40 mm in size, but the luminance required for good readability in daylight is more than 50,000 cd/m^2, i.e., 100 times more than a conventional direct-view display. This image is reflected through the windshield into the driver's eyes. For the driver this virtual image of the driving situation in front of the vehicle is superimposed.

Optical elements (lenses, concentrating reflectors) are generally inserted into the beam path to increase the virtual distance of the image.

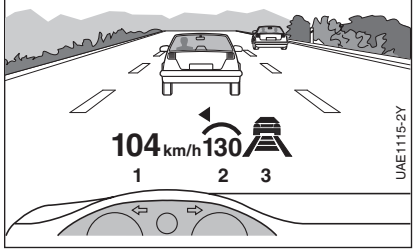
Particularly high-contrast segment TN LCDs can be used as the display for monochrome head-up displays with modest levels of information content. More sophisticated, multicolor displays use polysilicon-technology AMLCDs.

Display of information of head-up displays

The virtual image should not cover and obscure the road scene ahead; it is therefore displayed in an area with low information content, in other words "floating above the hood" (Figure 9). In order to prevent the driver from being overwhelmed with stimuli in his or her primary field of vision, the head-up display should not be overloaded with information, and is therefore never a practical substitute for the conventional instrument cluster. It is, however, particularly well suited for

displaying navigation notices (arrows) and safety-related information such as warnings or information from the ACC system (Adaptive Cruise Control, see Adaptive cruise control system).

Because of the beneficial display of information, it can be assumed that the number of head-up displays worldwide will increase dramatically.



Augmented-reality head-up display

"Augmented-reality" head-up displays offer an even greater benefit than showing information in the head-up display without local reference to the environment. They are called "augmented-reality displays" in the English-speaking world. They require a greater level of technical sophistication in realizing the projection unit by using a laser or a DLP module to generate the image. DLP stands for "Digital Light Projection", the generation of images by micromechanical elements, as are also used in projectors.

Augmented-reality head-up displays are characterized by a larger projection field. This enables the system to display the warning of an obstacle in the driver's field of vision and at the virtual distance in which it is located in nature. To enable the information to be read without parallax, however, a position correction depending on the position of the driver's head is required. With this system, route-direction information can be displayed for example at an intersection precisely where the junction suggested by the navigation system is situated; at an expressway/highway exit the arrow for recommending the exit can be positioned on the deceleration lane [1].

Figure 9: Information shown in the head-up display

1 Present speed,
2 Desired speed,
3 ACC status (Adaptive Cruise Control).

Touchscreen

The infotainment-system display is a touch-sensitive screen (touchscreen). Most of the functions of for example the radio, the navigation system or the smartphone paired by Bluetooth with the infotainment system can be operated by tapping the display with a finger.

Voice control

Voice input can be used to enter addresses in the navigation system or enter contacts that the user wishes to call on the smartphone paired with the infotainment system. Modern in-car voice-control systems have taken a tremendous technological step forward in recent years thanks to the integration of artificial intelligence, “natural language understanding” (NLU), and “cognitive computing”. Communication between driver and system is becoming more natural and speech-recognition capabilities have improved, even when it comes to understanding regional accents.

Conventional speech-recognition systems, like the ones in smartphones, always require a fast data connection to process voice commands. Speech is recorded and then transmitted to an external computer system for analysis. This method is only of limited use for in-car applications. After all, a fast data connection is not always available out on the road. Speech recognition must for this reason function without dependence on an external data connection. The on-board infotainment system handles all the computing operations. The voice thus remains a reliable means of control, even in tunnels or in well-developed areas with adequate cellular coverage.

Voice control for the infotainment system provides the following product benefits:
– The system is available everywhere because the software functions offline,
– recognition of regional accents thanks to innovative software,
– cultural and regional differences are taken into consideration,
– safe and comfortable driving owing to fewer distractions.

Radio and TV reception in motor vehicles

Wireless signal transmission

Wireless transmission technology permits the simultaneous broadcasting of information to large populations. It is also of major significance to mobile radio reception as used in motor vehicles. At present, the importance of digital transmission methods is growing. The wireless section of the transmission chain also uses analog signal transmission, so the two technologies are basically identical.

Radio and TV broadcasting

Wireless radio and TV broadcasting is primarily used for terrestrial transmissions. In the case of analog radio broadcasting, the audio signal is modulated on the high-frequency signal. In the receiver, the received high-frequency signal is then converted to the baseband frequency and demodulated. The final signal obtained in this way is identical to the useful signal.

In telecommunications, the propagation of an electromagnetic wave is used to transmit information whereby the amplitude, the phase or the frequency of this oscillation is altered depending on the information to be transmitted. The customary frequencies range from a few kilohertz up to 100 GHz. Some of the commonly used frequency ranges are set out in Table 1. The use of frequency bands is subject to legal control (Telecommunications Act for Germany, 2004). Each country's frequency allocation plan is based on international agreements that are set out in Article S5 of the Radio Regulations of the ITU (International Telecommunication Union, [1]).

Information transmission using highfrequency waves

The variation in a high-frequency signal used to transmit a useful signal from a transmitter to a receiver is called modulation. The modulated high-frequency signal is emitted within a precisely determined, narrowly defined frequency band by an antenna. The receiver selects precisely that frequency band from the large number of frequencies received by the antenna. In this way, wave propagation between transmitter and receiver is a link within the signal transmission chain.

For example, when it comes to the transmission of an audio signal, the useful signal in contrast to the high-frequency carrier signal is made up of various frequencies ranging up to a maximum of 20 kHz. The high-frequency carrier is modulated with this low-frequency signal. A transmitter antenna beams out the carrier wave.

Table 1: Overview of some frequency bands in radio and TV broadcasting

Wavebands	Wavelengths λ in m	Frequencies f in MHz	Examples
Long wave (LW)	≈ 2,000 – ≈ 1,000	0.148 – 0.283	Analog radio broadcasting
Medium wave (MW)	≈ 1,000 – ≈ 100	0.526 – 1.606	Digital Radio Mondiale (DRM)
Short wave (SW)	≈ 100 – ≈ 10	3.950 – 26.10	
Very high frequency (VHF)	≈ 10 – ≈ 1	30 – 300	
Band 1		47 – 68	TV
Band 2		87.5 – 108	Digital Audio Broadcasting (DAB)
Band 3		174 – 223	
Ultra high frequency (UHF)	≈ 1 – ≈ 0.1	300 – 3,000	
Band 4		470 – 582	TV
Band 5		610 – 790	Digital Video Broadcasting (DVB-T2), Digital Video Broadcasting (DVB-H)
L-band		1,453 – 1,491	Digital Audio Broadcasting (DAB)
Super high frequency (SHF)	≈ 0.1 – ≈ 0.01	3,000 – 30,000	
		10,700 – 12,750	Digital Video Broadcasting (DVB-S)

The maximum distance at which the signal can still be received and the reception quality depend on the frequency, among other things. Short-wave and long-wave have very long ranges, in some cases intercontinental, whereas the reception range of VHF transmissions is hardly any further than the line of sight.

The receiver station demodulates the signal. The resulting low-frequency electrical oscillation is then converted by a loudspeaker into acoustic oscillations.

Amplitude modulation
Amplitude modulation (AM) is the change in amplitude A_H of the high-frequency oscillation at frequency f_H in synchronization with the low-frequency oscillation (A_N, f_N) (Figure 1).

Amplitude modulation is used in the short-wave, medium-wave and long-wave bands, for example.

Frequency modulation
Frequency modulation (FM) is the change in frequency f_H of the high-frequency oscillation in synchronization with the low-frequency oscillation (Figure 2).

Frequency modulation is used for FM radio and the sound channel of analog TV transmissions, for example. The transmissions of frequency-modulated signals are impaired by amplitude-modulation interference (e.g. caused by the ignition systems of spark-ignition engines) to a lesser degree than the transmissions of amplitude-modulation transmitters.

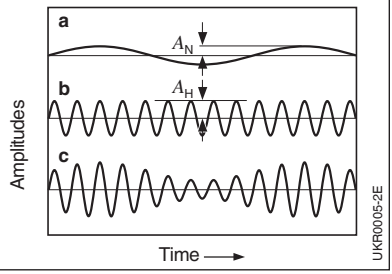
Digital modulation processes
In the case of digital modulation processes, the amplitude or the frequency of the carrier is discretely altered. One or more bits can thus be allocated to each of these carrier states so as to enable digital information to be transmitted.

Reception problems
VHF signals have virtually a linear propagation. As a result, a car radio may lose the signal from a VHF transmitter that is only 30 km away if there is high ground between the car and the transmitter. On the other hand, reception may be unimpaired at a location further away if there is a clear "line of sight" between the car and the transmitter. Such "radio shadows" are thus often covered by a fill-in transmitter.

Signals may be reflected off the sides of valleys or high-rise buildings. The reflected signals then arrive at the receiving antenna with a time delay and are superimposed on the signals received directly from the transmitter. This produces what is known as "multi-channel reception". It causes multipath interference and results in the deterioration of sound quality in radio reception.

Propagation of electromagnetic waves is impaired by conductors within the transmitter's radiation field (e.g. steel masts or power lines) and even nearby forests, houses, or locations in deep valleys. The characteristics of wave propagation are important when it comes to suppressing interference in motor vehi-

Figure 1: Amplitude modulation (AM)
a) Low-frequency oscillation at amplitude A_N and frequency f_N,
b) Unmodulated high-frequency oscillation,
c) Modulated high-frequency oscillation.



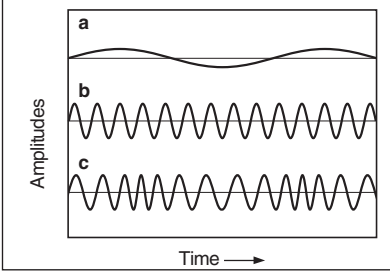


Figure 2: Frequency modulation (FM)
a) Low-frequency oscillation at amplitude A_N and frequency f_N,
b) Unmodulated high-frequency oscillation,
c) Modulated high-frequency oscillation.

cles effectively. Interference-free reception is impossible if the signals received from the transmitter are too weak. Thus, reception of a previously perfectly interference-free signal will break down suddenly when a car enters a tunnel, for example. This can be explained by the shielding effect of the reinforced-concrete tunnel walls which reduce the useful field strength of the transmitter signal to which the radio is tuned. At the same time, the interference-field strength remains the same. Under certain conditions, it may not be possible at all to continue to receive the radio-station signal. Similar phenomena can also be experienced when traveling in mountains, for example.

Radio interference

Radio interference is caused by undesirable high-frequency waves which are directed together with the desired signal to the receiver. It occurs wherever electrical currents are suddenly interrupted or switched on. High-frequency interference waves are thus produced, for example, by the ignition of a spark-ignition engine, the actuation of a switch, or the switching operations on the commutator of an electric motor. Such rapid changes of current generate high-frequency waves which interfere with radio reception by receivers located close by. The effect of the interference depends on the steepness of the signal pulse and its amplitude, among other things.

Radio interference caused by such steeply rising current pulses can be reduced or completely eliminated by EMC measures (electromagnetic compatibility).

Interference can travel to the receiver in different ways: directly through wires connecting the interference source and the receiver, or by wireless transmission of electromagnetic radiation, or by capacitive or inductive coupling. Strictly speaking, the last three options cannot be separated from one another.

Signal-to-noise ratio

Reception quality depends on the strength of the electromagnetic field generated by the transmitter. This should be substantially greater than the strength of the interference field, i.e. the ratio between the strength of the transmitter signal and the strength of the interference field – the signal-to-noise ratio – should be as large as possible.

A receiver close to the interference source receives not only the useful signal from the desired transmitter, but also the undesired interference signal, if it is transmitted at the same frequency. Nevertheless, good-quality reception is still possible provided that the field strength of the desired transmitter signal at the point of reception is very high in comparison with the strength of the electromagnetic field generated by the interference source. The useful field strength of the signal from the transmitter depends on transmitter power, transmitter frequency, the distance between the transmitter and the receiver, and the propagation characteristics of the electromagnetic waves. In the case of medium-wave and long-wave signals, the field strength of the transmitter signal can be weakened by difficult topology to such an extent that the signals of even powerful transmitters have low useful field strengths at some reception locations. VHF signals may be subject to heavy fluctuations in useful field strength under certain conditions. Receivers in motor vehicles may also suffer from relatively low useful voltages at the receiver input due to the short effective height of the antenna. Accordingly, the opportunities for improving the signal-to-noise ratio in the receiver are very limited.

By optimizing antenna positioning, the available useful voltage at the receiver input can be increased, thereby improving the signal-to-noise ratio, which is the decisive factor in reception quality. Frequently, however, a compromise is made between design considerations and technical demands. Another means of improving signal-to-noise ratio is by reducing the strength of the radiated interference signals.

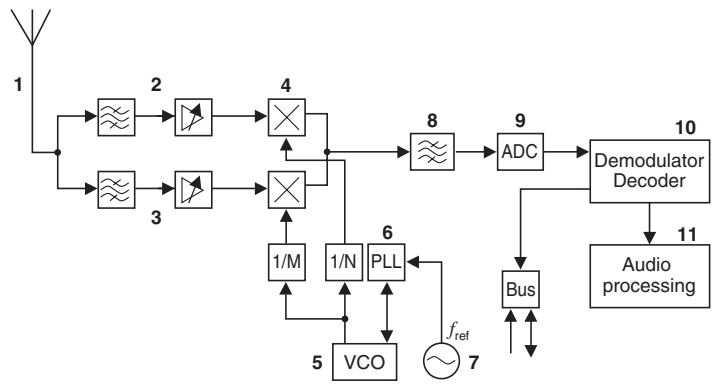
Receiver design also has an impact on reception quality. In addition to metallic shielding, which prevents the direct entry of radiated interference, and filters on the power source input, some receivers have circuits fitted with automatic interference suppression (see section entitled “Reception improvement”).

Radio tuners

Radio tuners in motor vehicles are frequently called car radios or automotive sound systems. However, this term refers not only to a radio tuner but also to devices with a large number of integrated information and entertainment functions. These include, for instance, the analysis of supplementary information (e.g. traffic news), players for reproducing from storage media (e.g. CDs and SD cards), as well as integrated radio communication interfaces, cellular phones and other devices.

In the past few years, conventional analog transmission technology has developed new systems. For this reason, modern car tuners are capable of receiving a wide variety of radio broadcast systems worldwide. As well as conventional radio broadcasting, these systems include among others DAB (Digital Audio Broadcasting), DRM (Digital Radio Mondiale) and SDARS (Satellite Digital Audio Radio Services).

The conventional radio tuner is designed to receive analog FM and AM modulation and has an analog signal path from the antenna to the audio signal. Modern car tuners with the highest received power, on the other hand, process signals digitally. The IF signal (intermediate frequency) supplied by the tuner is digitized by an analog-digital converter, and then processed. In standards covering digital modulation essentially only demodulation in the digital part of the signal path changes.



Conventional tuners

Signal processing

The antenna, which is predominantly designed as a rod or window antenna, picks up the electromagnetic signal emitted by the transmitter. This consists of different channels with a fixed frequency spacing. The high-frequency alternating voltage generated at the base of the antenna is routed to the receiver and processed there.

The conventional tuner for analog radio reception basically contains two signal paths: one for processing amplitude-modulated signals and one for processing frequency-modulated signals. These are

Figure 3: Block diagram of a radio tuner

f_{ref} Reference frequency.

usually divided into the blocks described in the following (Figure 3).

AM input stage
A bandpass filter limits the amplitude-modulated signal in the LW, MW and SW bands, and the resulting signal is amplified in the following stage with low noise.

FM input stage
The frequency-modulated VHF signal is received by a separate input stage. The input filter is either tuned to the frequency to be received or configured to the entire received band. The received-signal level is then adjusted to the desired input level for the following mixer stage with low noise by an automatically controlled amplifier.

Voltage-controlled oscillator
The oscillator (VCO, voltage-controlled oscillator), whose frequency is controlled by a phase-locked loop (PLL), generates a high-frequency oscillation which is subdivided. The input signal is converted with the aid of this signal into a constant intermediate frequency (IF) in the mixer stage. A quartz-stabilized signal serves as reference frequency.

Mixer stage
The mixer stage converts the input signal into a constant intermediate frequency. Different mixer stages are frequently used for receiving FM and AM signals. On the other hand, the principle of frequency conversion is the same.

IF filter and amplifier
The IF signal recovered in this way is then fed to an IF filter and a controlled amplifier.

Analog-digital converter (ADC)
The analog-digital converter (ADC) converts the analog IF signal into a digital signal.

Demodulator
The demodulator generates the digital audio signal from the digital IF signal.

Decoder
Additional information, such as RDS data (Radio Data System), is decoded by the decoder and passed on to a processor for processing.

Audio processing
After demodulation, the audio signal may be adapted, for example, to the vehicle conditions and the listener's preferences. This can be achieved by using the appropriate controls to adjust tone and volume or to vary the level between front and rear or between left and right.

Digital receivers
A digital receiver (ADR, advanced digital receiver) is a highly integrated receiver module whose input signal is the analog or digital IF signal. The analog signal is converted into a digital signal, the digital signal is processed on the digital level. This technology allows a type of signal processing that would not be possible using analog technology. It generates, for example, IF filters which provide for exceptionally good harmonic-distortion levels, and whose bandwidth is variable and can be adapted to the reception conditions. In addition, there is a larger number of other means of processing the received signal in such a way as to substantially reduce interference in the audio signal (see SHARX, DDA and DDS).

Digital equalizer
The digital equalizer (DEQ) consists of a multiband parametric equalizer which provides separate adjustment features for the mid-frequency, and the amplification/attenuation of individual filters. The suppression of unwanted resonances thus obtained optimizes sound quality inside the vehicle. The frequency response of the speakers can also be linearized.

Preset equalizer filters can also be implemented in some devices. These can be activated according to music genre or vehicle type (e.g. jazz or pop, van or sedan).

Digital Sound Adjustment
"Digital Sound Adjustment" (DSA) is a system which automatically analyzes and corrects frequency response in in-car systems. A microphone and a digital signal processor (DSP) are used to pick up and analyze a test signal generated by the speakers. The optimum sound curve for the vehicle is then set on the equalizer.

Dynamic Noise Covering
While the vehicle is in motion, the "Dynamic Noise Covering" (DNC) function uses a microphone to constantly detect and analyze the vehicle-noise spectrum that is blocking out the audio signal and impairing the perceived sound quality. The function uses selective amplification or selective dynamic compression (reduction of dynamic response between minimum and maximum values) of the interference frequencies to maintain optimum reproduction of sound quality, regardless of driving noise.

Reception quality
Analog radio broadcasting is primarily used for terrestrial transmissions. The transmission path is not always ideal, with the result that reception quality may be impaired, depending on the transmitter/receiver constellation and environmental conditions. In the case of VHF reception, reception locations may be critical because of the transmission-path problems described below.

Fading
Fading is caused by fluctuations in signal reception level due to obstacles in the signal path, such as tunnels, high-rise buildings, or mountains.

Multipath reception
Multipath reception is caused by the reflection of signals off buildings, trees or water. This can easily lead to a substantial dip in reception field strength, and even total signal loss. The differences in the strength of the received signal field strength occur within a few centimeters of each other. Such fluctuation has a particularly detrimental effect on mobile receivers, such as car tuners.

Adjacent-channel interference
Adjacent-channel interference occurs when there is another channel received with a high field strength close to the channel received.

High-level signal interference
High-level signal interference occurs close to the transmitter at high field strength. The receiver protects its input by reducing the field strength. This has the effect of attenuating the weaker signals from other transmitters, i.e. they become quieter.

Overmodulation
Some transmitters increase the modulation level in order to achieve a greater range or higher loudness level. The disadvantages of this process are greater distortion factor and greater susceptibility to multipath interference.

Ignition interference
High-frequency interference sources (such as the ignition of a spark-ignition engine, the operation of a switch, or switching operations on the commutators of electric motors) produce reception interference.

Reception improvement
A large number of functions for improving received power are implemented in modern automotive sound systems. An overview of the most important functions is provided in the following.

Radio Data System
Radio Data System (RDS) is a digital data transmission system for FM radio. This format is standardized throughout Europe. It provides the tuner with extra information in addition to the desired audio signal by using alternative received frequencies with the same modulation. This enables, for example, the tuner to switch continuously to the frequency with the least interference. Table 2 provides an overview of the information transmitted.

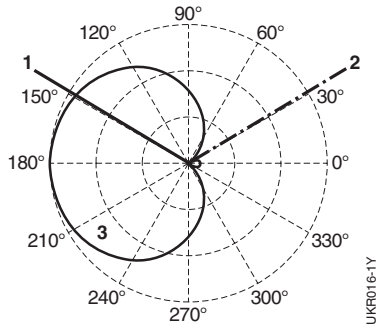

Table 2: RDS codes

Code	Information transmitted
PS	Name of the station received
AF	List of alternative frequencies on which the station also broadcasts
PI	Identifies the broadcast station
TP, TA	Traffic-program station identification, traffic-announcement identification
PTY	Identification of the station type
EON	Signals traffic announcements on a parallel station
TMC	Standardized traffic information
CT	Time (for synchronizing the clock in the vehicle)
RT	Text transmission (e.g. title of music track)

Digital Directional Antenna
The "Digital Directional Antenna" (DDA) system developed by Bosch uses the signals from two antennas to calculate a synthetic antenna with a new directional characteristic. This permits suppression of interference caused by multipath reception as shown in Figure 4.

Digital Diversity System
The reception characteristics of FM radio are heavily dependent on location. A Digital Diversity System (DDS) has a number of antennas at its disposal so that it can switch between them in order to enhance reception. The Digital Diversity System integrated in the digital receiver uses exactly the same signal for its switching strategy and the signal is available as the audio signal after demodulation.

Figure 4: Optimized antenna signal
1 Direct signal,
2 Reflection,
3 Directional diagram.

High-cut
Interference caused by such effects as fading and multipath reception has a greater effect on higher audio frequencies. For this reason, modern automotive sound systems have a facility for detecting such interference and reducing the level of the audio signal at higher audio frequencies when there is interference.

SHARX
SHARX is a function which automatically adjusts the bandwidth of the intermediate-frequency filter for FM reception to suit reception conditions. If different stations transmit at frequencies that are very close to one another, this function significantly increases the clarity of separation by reducing the bandwidth and allows virtually interference-free reception. If there are no adjacent channels, the bandwidth can be increased and thus harmonic distortion reduced.

Automatic interference suppression
A further measure for improving reception is automatic interference suppression, which suppresses interference signals generated by interference sources from both the present vehicle and other vehicles. To this end, the demodulated signal, which contains interference pulses, as well as the useful signal, is blanked for that moment of interference and the gap created is filled.

Traffic telematics

Transmission paths

Traffic telematics refers to systems that transmit traffic-related information to and from vehicles and, generally, which analyze this information automatically. Both unidirectional broadcasting (radio) and bidirectional mobile communications connections are available as transmission paths. Analog and digital radio provides only the path into the vehicle, with the information received identical for all receivers. Mobile communications connections on the other hand enable messages to be specifically received by way of individual requests and thus information to be exchanged between a vehicle and appropriate service providers in both directions.

The transmission paths also differ in the bandwidth limiting the information volume that is available and the transmission costs. The available bandwidth in mobile communications has increased by several orders of magnitude with each generation in recent years through the developments of GPRS (General Packet Radio Service), UMTS (Universal Mobile Telecommunication System), and finally LTE (Long Term Evolution). While data transmission by radio does not involve additional costs for receiving sound radio, costs are generally incurred for the information volumes on the mobile communications channel in proportion to the data volume.

In the future communication with “roadside units” in accordance with the standard WLAN 802.11p (Wireless Local Area Network) will serve as a further transmission path providing a high bandwidth with no additional transmission costs.

Standardization

The standardization of message content is an important precondition to enable the evaluation of information from various sources by different on-board terminals.

RDS/TMC standard
The widespread RDS/TMC standard (Radio Data System/Traffic Message Channel) for FM radio comprises content regarding the type of traffic disruptions (e.g. traffic jam, full road block), the causes (e.g. accident, icy roads), the expected duration, as well as identification of the road sections concerned. A numeric coding for traffic junctions, expressway sections and geographic regions already exists in many countries. However, it limits the messages for the most part to the major roads (expressways and highways).

TPEG standard
It is now also possible, via the TPEG standard (Transport Protocol Experts Group), to transmit traffic forecasts and recommended alternative routes. A limitation by numeric, predefined junctions and road sections within the road network, as used in TMC, is no longer necessary when the AGORA-C standard is used. This standard allows messages for any road to be coded without transmitters and receivers having to use identical-version reference tables. However, because of the bandwidth required, transmission is only possible via digital channels.

Information recording

The benefit of traffic telematics is dependent on the quality of the messages and how up-to-date they are. There are different data sources for recording information about traffic flow. "Historical" data are additionally used so as also to offer – independently of current messages – the best possible route planning.

Local information
The first data sources for automatically determining the traffic situation were induction loops integrated in the road surfaces which can record the average speed and number of vehicles at individual road points and transmit the data to an evaluating control center. This form of recording was supplemented by the introduction of sensors on expressway bridges which also collect this information.

Area-wide information
In order to receive area-wide information instead of local measurements, newer approaches resort to floating-car data or floating-phone data. The basic idea is to infer traffic situations from the movement data of many cars or mobile phones.

Floating-car principle
In the case of the floating-car principle, the in-car navigation device transmits the car's position and speed by mobile communications to a control center, which then calculates the current traffic situation by statistically analyzing these data.

Floating-phone principle
In the case of the floating-phone principle, the movement patterns of mobile phones are analyzed. This principle exploits the fact that every mobile phone is constantly transmitting information on the current reception situation to its base station. Characteristic patterns can be derived from the changed messages which are accompanied by the mobile communication device's change of location. These patterns are then used to infer the position of the device. Statistical processes are used first to evaluate whether the devices in question are moving devices in vehicles and then to infer the traffic situation from them.

Benefits of the floating processes
The two floating processes are used not only to detect the traffic disruption itself, but also to determine and forward reference values for the delay caused by the disruption.

The movement profiles of the vehicles can also be collected, assigned a time, and compressed. This practice produces so-called hydrographs which reproduce for individual road sections the average driving speeds depending on the day of the week and the time of the day. In this way, recurring traffic disruptions such as slow-moving traffic and regular rush-hour traffic jams are depicted. The vehicle-navigation system can use these hydrographs as "historical" data as a function of the current time to specify a route and journey time adapted to the expected situation.

Dynamic route guidance
Through the standardized coding of traffic messages, it is possible also to display these messages in the vehicle in comprehensible text form for the driver. Furthermore, the computers in route-guidance systems can determined on the basis of the standardized coding whether a better alternative route exists in the event of disruptions. The relevant messages are filtered out from those available using the vehicle location and, if necessary, its movement along a route. If the associated amount of time lost is communicated as well as the actual disruption, this time lost can also be included in the route computation. In the event of alternative route guidance, the driver is instructed that the route has been recalculated on account of traffic announcements received. Further route recommendations will follow in accordance with the new route (see Vehicle navigation).

Furthermore, subscription traffic services not only transmit the more serious traffic jams and disruptions, but also indicate for all higher road categories the

existence of restricted driving speeds identifiable from the floating data. Thus, for example, the traffic situation can be made transparent by a color-coded, high-detail display of the traffic flows in the vehicle navigation's map display even when route guidance is inactive.

Vehicle-vehicle communication

Vehicle-vehicle communication is currently being tested as the logical next step in traffic telematics. The ultimate aim is to further increase road safety and to reduce economic losses due to traffic disruptions. A system of direct information transfer between vehicles can be used to send warnings about, for example, broken-down vehicles, approaching emergency vehicles, the location of the tail end of a jam, right through to relevant individual maneuvers such as hard braking. This gives the driver in the receiving vehicle time to react in an suitable way to the present situation.

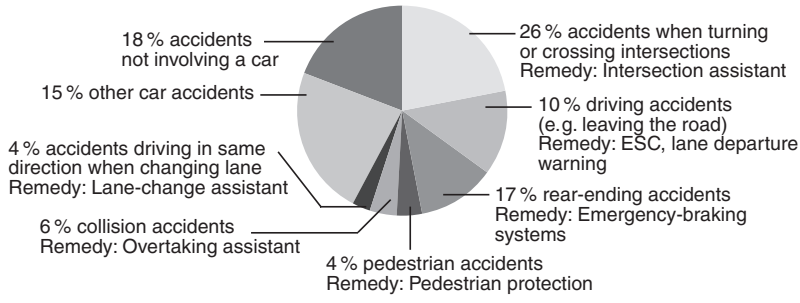
The standard WLAN 802.11p (Wireless Local Area Network) serves as the basis for direct vehicle-vehicle communication. The basic principle behind the warning functions is the timely and correct communication of precise location information between the transmitting vehicle and a receiving vehicle. This involves both the continuous transmission of movement messages and the additional transmission of an extra warning message when disruptions and events are detected. The process of regularly repeating or even passing on received messages to other vehicles ensures that all the affected vehicles can be reached.

To prepare for market launch, engineers are currently testing the functionality and efficacy of the systems under everyday conditions in a variety of field tests conducted in for example Germany and the USA.

Driver-assistance systems

Introduction – driver assistance

Driver-assistance systems in modern vehicles can basically be divided into the categories comfort/convenience systems and safety systems. Comfort/convenience systems relieve the driver in performing monotonous, repetitive driving tasks. Typical examples are automatic turn-signal resetting after turning or Adaptive Cruise Control (ACC). Safety systems, on the other hand, are intended to support the driver in critical driving situations so that an accident is avoided or its consequences are lessened. Typical examples are driving-dynamics control (Electronic Stability Control, ESC) and airbags. As the specified system categories increasingly interact in the face of the increasing level of system networking in vehicles and driver support by comfort/convenience systems is intended to provide increased safety (avoidance of critical situations already in advance), there is increasingly a flowing transition between comfort/convenience and safety systems. For further details, refer to the descriptions in the section "Comfort/convenience and safety systems".



Critical driving situations

Driver-assistance systems aim to make the vehicle capable of perceiving its surroundings, interpret them, identify critical situations, and assist the driver in performing driving maneuvers. The aim is to identify critical situations early, i.e., already before they occur, and anticipate and defuse them, or at best to prevent accidents during critical situations or at worst to minimize as much as possible the consequences of an accident.

In critical driving situations, just fractions of a second are often decisive in determining whether an accident occurs or not. According to the study in [1], approximately 60 % of rear-end collisions and approximately 30 % of frontal impacts could have been avoided if the driver had reacted only half a second earlier. Every second accident at an intersection could be prevented by faster and correct driver reaction.

At the end of the 1980s, when the possibility of highly efficient and partially automated road traffic was presented as part of the EU "Prometheus" project, the electronic components for this task were not in existence. The highly sensitive sensors and powerful microcomputers now available have brought such vehicles driven by highly automated means a step nearer to realization.

Figure 1: Operating areas of passenger-car safety functions in accidents involving personal injury by accident type
(Analysis of GIDAS accident database [2]).

The first driver-assistance systems which facilitate semi-automated vehicle guidance in specific traffic situations have been on the market since 2013 (e.g., traffic-jam assistant). Here the environment sensors scan the vehicle's surroundings and detect relevant objects. The driver-assistance systems follow a cascade of intervention and generate warnings or directly perform the maneuvers required (automatic steering or braking interventions). All this is done at those crucial fractions of a second faster, since a computer-controlled system can essentially react faster than a person.

Accident situation and actions

Accident research plays a significant role in the development of driver-assistance functions. Accident research at Bosch provides support among others in the design and development of new vehicle-safety functions while taking into account current traffic-accident occurrences. Assessments are conducted as to the effectiveness of these systems – i.e., of the potential for accident avoidance – and their effects on future accident occurrences.

To assess the effectiveness of passenger-car functions of driver assistance, an analysis of accidents involving personal injury was conducted for Germany on the basis of the accident database GIDAS (German In-Depth Accident Study [2]) (Figure 1). In Germany in 2015 there were 305,659 accidents involving personal injury, 82 % of which involved a passenger car [3].

Around 26 % of accidents involving personal injury in which a passenger car is involved occur during a turning or crossing maneuver. Here different intersection-assistant functions will be able in future to reduce accidents.

Every tenth accident involving personal injury (10 %) can be put down to driver error; in many such cases involving passenger cars, accidents can already be avoided or the consequences of the accidents lessened with driving-dynamics control (ESC) and lane departure warning.

A further 17 % of all accidents involving personal injury and passenger cars arise when one vehicle rams into another vehicle driving in the same direction. Collision-warning systems can counteract these accidents in an initial stage (e.g., Adaptive Cruise Control). In a further stage collision-avoidance systems prevent the accident by actively intervening in the driving dynamics, for example through brake intervention with the emergency-braking system (Automatic Emergency Braking, AEB).

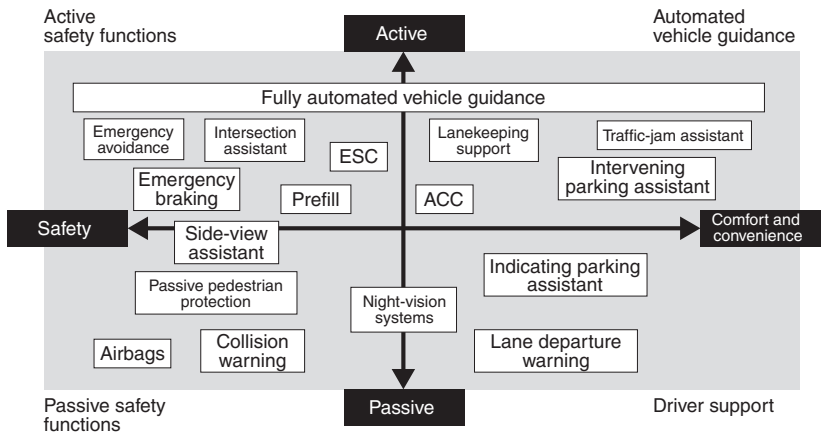
Accidents involving unprotected road users such as pedestrians or cyclists demonstrate a high degree of complexity. The first emergency-braking pedestrian-protection functions for passenger cars are already available on the market. These operate in up to 4 % of all accidents involving pedestrians. Research is currently being conducted into extending these pedestrian-protection systems to further reduce the occurrence or the consequences of such an accident by means of automatic avoidance maneuvers.

Collision accidents which usually occur during overtaking and can be positively influenced by overtaking-assistance systems amount to 6 %. An additional reduction in accidents by 2 % or in total 4 % can be expected when the driver is supported when changing lanes by an assistance system.

In spite of the already high traffic-safety standards, according to the accident research conducted by Bosch up to 40 % of accidents involving personal injury and passenger cars still do not involve the operation of a vehicle-safety system – accident research is helping here to develop further vehicle-safety functions or to advance their market acceptance.

Applications
Driver-assistance systems have a wide range of applications. They can be divided into active systems which intervene in the driving dynamics and into passive system with no intervention in the driving dynamics.

As already mentioned, a further distinction is made between comfort/convenience systems to reduce the burden on the driver (driver support) with the long-term goal of fully automated driving and safety systems with the aim of accident avoidance or mitigation of accident consequences.



Comfort/convenience and safety systems
Figure 2 shows according to the selected system the range of driver-assistance systems and functions.

Passive safety functions
Passive safety functions (Figure 2, bottom left quadrant) contain the actions for mitigating the consequences of accidents such as airbag deployment and the functions for passive pedestrian protection (specific design of the front of the vehicle to mitigate the consequences of collisions with pedestrians).

Driver support
Systems for reducing the burden on the driver (driver support) without active vehicle intervention (Figure 2, bottom right quadrant) are the preliminary stage to fully automated vehicle guidance. These systems give the driver tips on vehicle guidance. The parking assistant with short-range sensors (ultrasound sensors) aids the driver in looking for a parking space and actually parking, while specific infrared video sensors can be used to good effect to improve driver vision during nighttime driving. In the case of the lane-departure warning system, a video camera uses the road markings to detect the direction of the lane ahead of the vehicle and warns the driver if he/she changes lane without activating a turn signal. The warning can be issued acoustically through the car radio's speakers or mechanically in the form of steering-wheel vibrations.

Automated vehicle guidance
The automated vehicle-guidance systems (Figure 2, top right quadrant) include lane-keeping support, which prevents the vehicle from leaving the lane by means of specific intervention in the lateral guidance. Lane-keeping support is therefore a

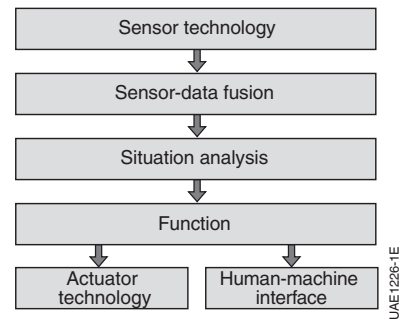
Figure 2: Systematic classification of driver-assistance systems (with selected example functions)
Prefill: Brake prefill.

further development of the lane-departure warning system. Adaptive Cruise Control (ACC) is also one of the automated vehicle-guidance systems. A further development of this system relieves the burden on the driver in slow-moving congested traffic – first by braking the vehicle to a complete stop, and then by moving it forward again at low driving speed (ACC Stop & Go). The traffic-jam assistant as a further development also permits lateral guidance at low speeds. Significantly higher requirements are imposed on the functions which are intended to facilitate automated longitudinal and lateral guidance on expressways/highways (highway assistant). The next conceivable development step is full longitudinal and lateral guidance in the urban range, i.e., in unstructured environments, at medium speeds (City ACC). Such a system is the last development stage before highly automated vehicle guidance (see Degree of automation).

Active safety functions

The active safety functions (Figure 2, top left quadrant) concern all the active emergency measures for avoiding or mitigating the damage caused by accidents. In the event of a collision danger that can no longer be averted by the driver, these systems in their maximum configuration enables computer-aided maneuvers to be carried out. Collision prevention or mitigation of the consequences is achieved by automated braking (emergency braking, intersection assistant) or steering (emergency avoidance) here. The intermediate steps consist of a brake prefill when a danger is detected, short hard braking (kinesthetic warning signal to the driver) or a steering pulse. ESC is an example of an active safety system on the vehicle-stabilization level.

Standard architecture for driver-assistance systems



Driver-assistance systems can be subdivided in accordance with a distributed standard architecture (Figure 3) into the submodules sensor technology, sensor-data fusion (with the aim of creating an environment model), situation analysis (with the aim of understanding a traffic situation and its further development), function (with the aim of action planning), actuator technology, and human-machine interaction.

The sensor layer consists of various sensors defined and designed in response to the functional requirements in type and parameterization. In the sensor-data fusion module the environment is modeled in accordance with the function specification (non-moving environment, function-relevant moving objects) on the basis of the sensor measured values.

In the following situation analysis the criticality with regard to function-relevant scenarios is checked on the basis of environment modeling. Thus, the position of the object and the actual position of the vehicle are predicted into the future by way of example for an emergency-braking function and the risk of collision is evaluated.

The criticality measurements derived in this way serve as the criterion in the following function module for a decision on whether to deploy the function. The function module typically uses a finite state machine which as well as thresholds for the criticality measurements also checks whether the function-specific system limits are adhered to (e.g., in the event of the vehicle being subject to high yaw rates an emergency-braking function would not be triggered for the situation where vehicles are driving in the same direction). In the event of a critical situation the function module runs through a cascade of intervention. This ranges, depending on the

Figure 3: Standard architecture for driver-assistance systems

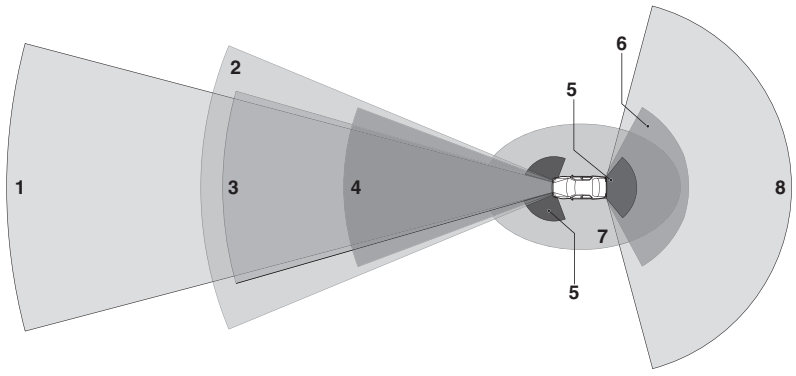
situation and function, from early driver notification and warning (visual, acoustic, haptic) to an automated steering or braking intervention to avoid a collision or mitigate the consequences of an accident. The corresponding actuators and the human-machine interface are now activated in accordance with the function-specific warning cascade.

Typical approaches for the environment-sensor system, sensor-data fusion and function are described in more detail in the following on the basis of the standard architecture introduced.

Environment-sensor system for electronic all-around visibility

Using "electronic all-around visibility", numerous driver-assistance systems are achievable – both for passive and for active intervention purposes. Figure 4 shows the detection ranges of the all-around visibility sensors presented below.

Long range



Mainly long-range radar (LRR) sensors are used for long-range applications. Today's sensors have an operating frequency of 76.5 GHz and a range of approximately 250 m. Lidar sensors are also used (e.g., for adaptive cruise control) primarily in Japan. These sensors operating in the close infrared range have ranges of between 150 and 250 m.

Medium range

In the medium range mid-range radar (MRR) sensors with an operating frequency of 24 GHz can meet the exacting demands with regard to range and angle resolution. Since 2005 video sensors have also been used in the medium range. They increasingly play a central role in driver-assistance systems as they enable numerous driver-assistance functions to be implemented due to the large information content of image data (among others thanks to stereo video, optical flow, object classification, see Computer vision) and a very good cost-benefit ratio. For example, infrared cameras in night-vision systems support the driver by detecting situations in the dark.

Figure 4: Detection ranges of sensors for vehicle allround visibility

The detection ranges shown as circle segments indicate the beam angle, however the sensor range decreases as the angles get bigger.
1 Long-range radar up to 250 m, horizontal beam angle 30°,
2 Front-end mid-range radar up to 160 m, horizontal beam angle 45°,
3 Night-vision camera up to 150 m, horizontal beam angle 32°,
4 Video, stereo video up to 80 m, horizontal beam angle 41°,
5 Ultrasonic sensors up to 5 m, horizontal beam angle in each case 120°,
6 Rearview camera up to 15 m, horizontal beam angle 130°,
7 Close-range cameras up to 10 m, beam angle in each case 130°,
8 Rear-end mid-range radar up to 100 m, horizontal beam angle 150°.

Close range
Ultrasonic sensors with higher scanning ranges than previously can form a "virtual safety shield" around the vehicle within certain limits (range smaller than 20 m). This shield can be used to implement a number of functions. The signals from objects inside this safety shield serves as the database of various safety and comfort/convenience systems. Even the driver's "blind spot" can be monitored by these sensors.

Since 2008 multi-beam lidar sensors have been used to monitor the range up to 8 m ahead of the front of the vehicle for automatic emergency-braking functions and have been rapidly taking hold in the volume segment.

Ultra-close range
The parking assistant monitors the ultra-close range with the aid of ultrasound technology. Today's sensors have a range of up to 5 m. These sensors are therefore suitable for a variety of parking functions. Rear-end video sensors (in their simplest form) can assist the ultrasound-based ParkPilot system during parking maneuvers.

Sensor-data fusion
In the event of long-range functional requirements a number of sensors (based on different sensor principles) can be used with an overlapping field of vision in order among other things to increase the field of vision and improve the accuracy and reliability of object detection. This procedure is known as sensor-data fusion (see also Sensor-data fusion). Thus, the camera mounted at the front end can, depending on its functionality, also be used to extend the measured values of the long-range radar. This enables not only the distance to an object to be measured, but also the object itself to be classified. The object class enables the system to draw conclusions about the position and nature of future object movement and thereby helps to increase the reliability of the function. Connecting the video system to the long-range radar creates synergy effects. This significantly increases the beam angle of the ACC system or lane-keeping support and makes object detection even faster and more reliable.

Future driver-assistance systems will incorporate a large number of environment sensors. Because the sensor data typically arrive at different frequencies and asynchronously and are subject to different time delays, a common time allocation must first be established in the fusion module. This is achieved typically using ring memory structures and time stamps. The vehicle's surroundings are modeled on the basis of the sensor data. Grid approaches are increasingly being used to model the non-moving (stationary) surroundings [4]. Moving (dynamic) objects are typically modeled as objects with various function-relevant attributes (such as position, expansion, speed) and time-stabilized by means of an algorithm for state estimation (with Kalman filter [5]). Hybrid approaches which combine object models and stationary grids are still in the research stage [6].

Test and hedging
The primary motivation behind active-intervention systems is increasing driving safety, as is the aim for example with an emergency-braking system (AEB) for automatic collision avoidance.

An important aspect of such systems is the risk of incorrect automatic interventions, for example an unauthorized emergency brake deployment. In the worst case this could result in accidents and consequently the increase in system safety would be undermined. It must therefore be possible through suitable measures to rule out such unauthorized interventions with absolute reliability.

In order to determine the achievable benefit and rule out potential risks, comprehensive tests are therefore part and parcel of the development of new driver-assistance systems. How such tests are conducted and the complexity of such tests currently differ depending on whether the purpose is to test the aimed-for effectiveness in critical driving situations or the hedging against unauthorized interventions.

Because critical driving situations, e.g., the rear-end collisions addressed by AEB, fortunately only occur very rarely in ordinary road traffic, the effectiveness is instead analyzed without endangering

persons on enclosed test sites and with dummy vehicles.

In contrast to these benefit cases, whose parameters can generally be well described from an accident analysis, the hedging against unauthorized interventions must essentially be conducted for all relevant ambient conditions and driving situations. For this reason, the vehicle manufacturers and system suppliers conduct very extensive vehicle tests for the purpose of releasing the system [7].

The main reason for the extensive endurance tests lies in the complexity of the environment sensors used, the wide variety of traffic situations, and the high requirements imposed on the safety of autonomous driving-dynamics interventions. This is because, even in a driving situation that is non-critical for the human driver, "phantom" objects may be detected (e.g., a cloud of exhaust gas incorrectly interpreted by a camera as an obstacle). Because unauthorized braking or steering interventions involve a high risk potential, it is essential to ensure that even very rare cases of such incorrect deployments are discovered before the release of the system. This is the reason for the extensive driving tests.

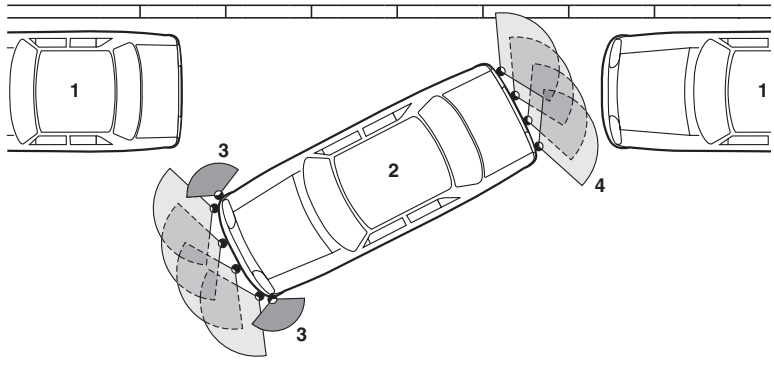
Ultrasonic sensor system

Ultrasonic sensor

Application

Today's parking-aid and maneuvering systems (see Parking-aid systems) use ultrasound-technology short-range sensors with a detection range of up to 5.5 m. They are integrated in the bumpers of motor vehicles and serve to calculate distances to obstacles and to monitor the vehicle's surroundings when parking and maneuvering (Figure 1). Sound or even visual alerts are issued to the driver as the vehicle approaches an obstacle.



The sixth-generation ultrasonic sensor from Bosch is characterized by digital signal processing, which prevents the systems of different vehicles from influencing each other, and by blindness detection (in the event of icing or fouling) and improved short-range detection. These sensors facilitate comfortable parking in very small parking spaces and maneuvering in tight situations. They also permit the use of a parking-aid assistant, which either issues instructions to the driver for optimum parking or steers the vehicle into the parking space while the driver only needs to take care of longitudinal guidance of the vehicle (see Parking-aid assistant).

Sixth-generation ultrasonic sensors also support emergency-braking functions at low speed by detecting the presence of very near objects and reacting quickly to suddenly appearing obstacles (e.g., pedestrians). In the higher speed range the ultrasonic sensor can also be used to monitor the blind spot (see Blind-spot detection).

Ultrasonic-sensor design

Figure 2 shows by way of example a fourth-generation ultrasonic sensor. It is comprised of a plastic case with integrated plug-in connection, an ultrasonic transducer (aluminum pot with diaphragm onto the inside of which has been glued a piezoceramic element), and a printed-circuit board with transmit and evaluation electronics. They are electrically connected to the ECU (e.g., of a parking aid) by three wires, two of which supply the power. The third, bidirectional wire is responsible for activating the transmit func-

4 Detection range of the ultrasonic sensors in the rear area.

tion and returning the evaluated received signal to the ECU [1].

Ultrasonic-sensor operating principle

The ultrasonic sensor receives a digital transmit pulse from the ECU the parking aid for example. The transmit electronics then induce the aluminum diaphragm to oscillate with square-wave pulses of approximately 300 µs duration at resonant frequency (around 48 kHz) with the result that ultrasonic pulses are emitted. No reception is possible during the relaxation time of approximately 900 µs. The diaphragm, which has meanwhile returned to rest, is made to vibrate again by the sound reflected back from an obstacle. These renewed oscillations are outputted by the piezoceramic element as analog electrical signals and amplified and converted into a digital signal by the sensor electronics (evaluation electronics).

Ultrasonic sensors usually have for the described application a selective emission characteristic (Figure 3) with a wide horizontal sensing range and a narrow vertical sensing range (see Detection characteristics).

Distance measurement with ultrasound

The ultrasonic sensors emit ultrasonic pulses and receive the sound reflected by an obstacle (Figure 4). The piezoceramic element generates an analog electrical signal, which is evaluated in the sensor.

Echo-sounding method

Following the echo-sounding method (Figure 5), the ultrasonic sensors detect the time taken between the ultrasonic

pulses being emitted and the echo pulses being reflected back from obstacles. The distance l between the transceiver probe and the nearest obstacle is derived from the propagation time t_e of the first echo pulses and the velocity of sound c according to the following equation:

$l = 0.5\ t_e\ c$,
where
t_e propagation time of ultrasonic signal,
c velocity of sound in air ($c \approx 340$ m/s).

Detection characteristics
To enable the system to cover as large a spatial area as possible, the detection characteristics must meet special requirements. In the horizontal direction a wide detection angle is desirable to be able to detect as many objects as possible. In the vertical direction, on the other hand, a compromise is required. In order to avoid interference from ground reflections, the detection angle must not be too wide. However, existing obstacles must be reliably detected. Figure 3 shows the emission characteristic of a sensor in the horizontal and vertical planes. A nearly seamless scanning range is produced by the overlapping scanning ranges of mul-

tiple sensors. Figure 6 shows an example of the scanning range of a 4-channel system.

Newer-generation sensors also allow for a variation of the vertical detection angle within certain limits, thus permitting optimized adaptation to the geometry of the bumper and vehicle without resulting false warnings in the event of bumps.

Distance calculation

The geometrical distance a between an obstacle and the front of the vehicle is determined using the triangulation method from the results measured (distances b and c) from two ultrasonic sensors, mounted at a distance d from one another (Figure 7). The distance a is calculated from the following equation:

$$a = \sqrt{c^2 - \frac{(d^2 + c^2 - b^2)^2}{4d^2}} \quad .$$

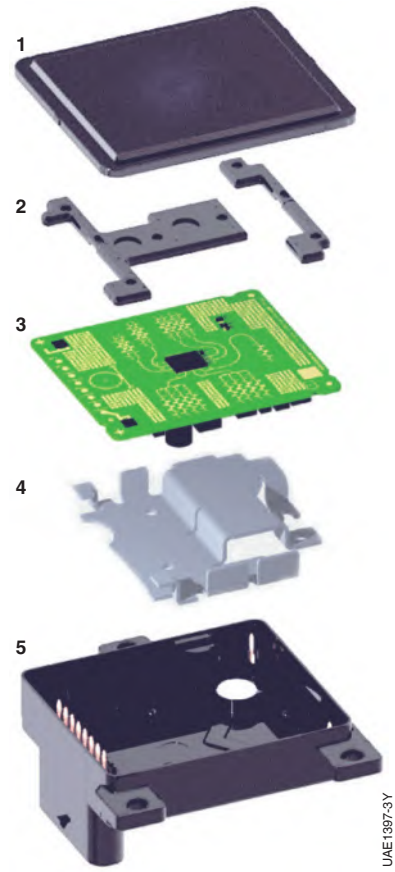
Radar-sensor system

Application

Radar technology has since 1999 been used with increasing regularity in motor vehicles and supports drivers in their driving tasks. The radar sensor detects objects in front of the driver's vehicle (e.g., other vehicles, pedestrians, roadside structures) and measures their distances, relative speeds and transverse offset to the driver's vehicle. On the road to autonomous driving the radar sensor thus makes a significant contribution to sensing and interpreting the surroundings and the driving situation.



In the early days the radar sensor was used primarily for adaptive cruise control (ACC). This system uses the measurements, adapts the vehicle's driving speed to the traffic in front, and thereby relieves the driver in their driving tasks (see Adaptive cruise control).

The radar sensor's strengths lie primarily in its fast, precise, and weather-independent measurement of distance and relative speed, as a result of which it is particularly suitable for active and passive safety functions. These are for example the Predictive Emergency Braking Systems (PEBS, or Automated Emergency Breaking, AEB), pre-crash detection, lane-change assistant, and blind-spot monitoring. The radar sensor is, aside from the video-sensor system, one of the cornerstones of vehicle-environment sensing on the road to autonomous driving.

Figure 1 shows a radar sensor as a schematic exploded view.

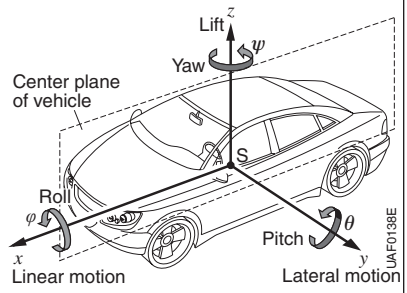
Radar principle



Sensing of objects

The electromagnetic waves emitted by the radar device are rebounded against metal surfaces or other less well reflecting materials and are picked up again by the radar's receiving section. The radial distance from the radar sensor to the objects in the sensing range can be measured from the propagation times of these waves. The Doppler shift of the reflected electromagnetic waves enables the radial relative speed of all the detected objects to be measured directly. The spatial position is determined with the radial distance and one or more angle estimations based on the evaluation of three or more sending and receiving antennas.

Typical objects in the vehicle surroundings generate for the most part a number of reflexes, which depending on the configuration of the radar sensor are also measured separately. The upshot of this is that in the real environment for each measurement cycle several hundred reflexes are detected and forwarded for interpretation to the higher system layers.

Figure 2: System of coordinates

ψ Yaw angle,
φ Roll angle,
θ Pitch angle,
S Center of gravity.

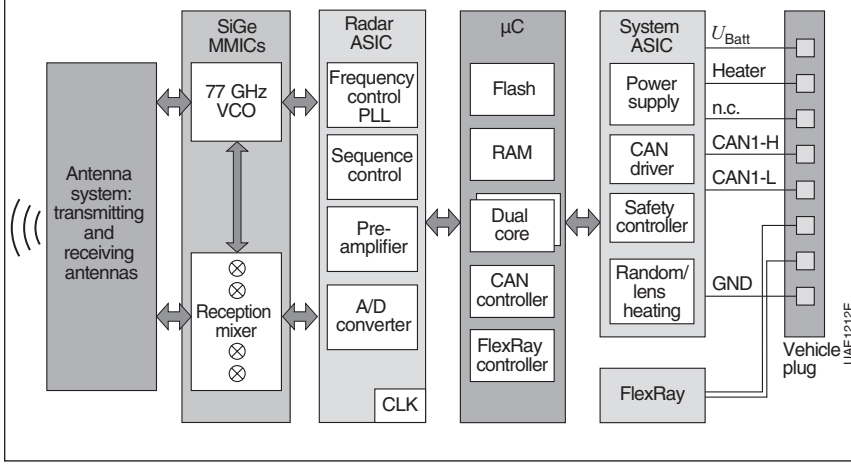
Measured variables in the system of vehicle coordinates

All measured variables are converted to the system of perpendicular and cartesian vehicle coordinates. This is defined according to ISO 8855 [1] as follows: The coordinate datum is usually at the vehicle's center of gravity; the x-axis runs horizontally along the vehicle longitudinal axis and points forwards; the y-axis is vertical to this and points horizontally to the left; the z-axis points upwards (Figure 2).

Technology

Development of radar sensors

Aside from the antenna, the high-frequency electronic components constitute the core of radar sensors. Up to around 2010 the dominant components were GaAs semiconductors (gallium arsenide) for use in high-frequency technology beyond 10 GHz. In the Bosch LRR2 (produced between 2004 and 2013) discrete Gunn diodes made of GaAs were used to generate the 77 GHz carrier frequency. The greatest innovation in the Bosch LRR3 (produced from 2009 onwards) was the switch from discrete high-frequency components to highly integrated MMICs (Millimeter-Wave Integrated Circuits), which have integrated frequency generation, frequency regulation, and also demodulation completely in an SiGe MMIC (silicon-germanium MMIC). This has both reduced the costs dramatically and increased the performance of the radar sensor. The SiGe technology generates on a classic silicon wafer bipolar mixed structures with germanium components which permit very high cut-off frequencies and thus make the silicon-based technology ready for use at 77 GHz. The combination of SiGe technology with classic CMOS technology (BiCMOS technology) on a wafer also permits further high integration for example for signal processing in the same IC.



Future development
The increasing reduction of the structure sizes for the pure CMOS processes, which is driven in particular by smartphones, servers, and desktop computers, in the meantime enables the frequencies around 77 GHz to be generated with sufficient efficiency without using SiGe structures. Added to this is the ever more pronounced penetration of the automobile market by radar sensors and the accompanying massive increase in numbers. This now permits the use of the high one-time costs of manufacturing 28 nm, 22 nm or even 16 nm structures for the radar-sensor semiconductors in the automotive sector. The trend towards high integration is thus continued and the future will in part belong to the "single-chip radar" – MMIC together with signal processing and large computer components in an RFCMOS IC (radio-frequency CMOS).

Measurement methods
The received signals are compared with the transmitted signal. Due to the propagation time of the radar waves the received signals are a superposition of the reflected transmitted signals per object and noise created in the reception path. The reflected waves per object are delayed on account of the propagation time and shifted in frequency via the Doppler effect. The transmitted waves are modulated to enable a received signal to be uniquely assigned to a transmitted signal. Whereas previously pulse modulation was used with pulses of a magnitude of 0.5 to 20 ns (corresponding to a distance resolution of 0.15 to 6 m), the predominant method since 2010 has been frequency modulation (also called FMCW, frequency modulated continuous wave), which during transmission alters the instantaneous frequency of the waves over time and requires less hardware outlay.

A further improvement in the detection of objects is made possible by so-called fast FMCW modulation, also known as chirp sequence.

FMCW modulation
Figure 3 shows the block diagram of an FMCW radar. A 77 GHz VCO (voltage-controlled oscillator) supplies the transmitting antenna. The receiving antenna transmits the signal reflected by the object to the reception mixers, which mix the received signal with the current transmitted signal of the VCO and thus transform to lower frequencies in the range from virtually 0 Hz up to several MHz. The high-

Figure 3: Block diagram of a 4-channel FMCW radar
SiGe MMIC: mm-wave-IC, integrated circuit (silicon-germanium technology).

est occurring frequency depends on the maximum propagation time of the signals and the gradient of the frequency ramp. The signals are amplified, digitized, and to determine the frequencies subjected to a high-speed Fourier analysis (see Fourier transform).

Frequency generation
The operating principle of frequency generation is explained in the following. The frequency of the 77 GHz VCO is compared continually by PLL closed-loop control (phase-locked loop) with a stable quartz-based reference oscillator and regulated to a prespecified setpoint value. The PLL is altered during a measurement in such a way that for the transmit frequency f_S a linearly rising frequency ramp is created over time – followed by a linearly falling frequency ramp (Figure 4). The mean transmit frequency is f_0.

Measurement without relative speed
The signal reflected and received from a vehicle driving in front f_E is delayed according to the propagation time, i.e., it has in the rising ramp a lower frequency and in the falling ramp a frequency f_E higher by the same amount Δf_{FMCW}. The amount of the frequency difference Δf_{FMCW} is a direct measure of the distance d, depending on the gradient s of the ramp and the speed of light c:

$$\Delta f_{FMCW} = |f_S - f_E| = \frac{2s}{c} \cdot d \ .$$

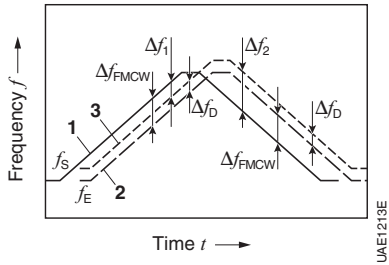
Measurement with relative speed
If there is additionally a relative speed Δv to the vehicle traveling in front, the receive frequency f_E is, on account of the Doppler effect, increased (when approaching) or decreased (when the distance increases) in both the rising and falling ramps by a specific, proportional amount Δf_D:

$$\Delta f_D = \frac{2 f_0}{c} \cdot \Delta v \quad \text{(approximation for } v << c\text{)}.$$

In other words, there are two different difference frequencies Δf_1 and Δf_2. For the rising ramp:

$$|\Delta f_1| = |f_S - f_E| = \Delta f_{FMCW} - \Delta f_D$$
$$= \frac{2}{c} \cdot (s\,d - f_0 \Delta v).$$

For the falling ramp:



$$|\Delta f_2| = |f_S - f_E| = \Delta f_{FMCW} + \Delta f_D$$
$$= \frac{2}{c} \cdot (s\,d + f_0 \Delta v).$$

Their addition produces the distance d, and their subtraction the relative speed Δv of the objects:

$$d = \frac{c}{4s} \cdot (\Delta f_2 + \Delta f_1),$$

$$\Delta v = \frac{c}{4 f_0} \cdot (\Delta f_2 - \Delta f_1).$$

Figure 4: Distance and speed measurement with a linear FMCW radar

Fast FMCW modulation (chirp sequence)

In the case of fast FMCW modulation many similar FMCW ramps are sent in sequence in a measurement, hence the term chirp sequence. An individual ramp is much shorter with a duration in the region of 10 to 50 µs. This results in a much higher (in terms of amount) ramp gradient such that the amount of the frequency difference Δf_{FMCW} is now much greater than the shift Δf_D due to the Doppler effect; the observed difference frequency Δf is therefore dominated by the distance. For a target distance of 100 m and a gradient of 300 MHz in 10 µs the distance-related frequency shift is 20 MHz. Facing this is a Doppler shift of 41 kHz for a fast target with a relative speed of 80 m/s (= 288 km/h) and a mean transmit frequency of 76.5 GHz.

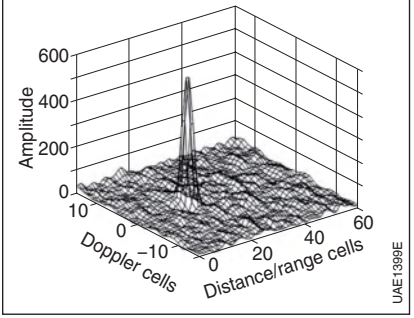
The fast Fourier transform of the received signals of a ramp produces a discrete frequency spectrum whose frequency cells can be assigned to a distance. These are therefore called distance or range cells.

The Doppler effect is then evaluated by evaluating each distance cell across all ramps, again with fast Fourier transforms. This corresponds to a sampling of the Doppler effect, the individual ramps defined the sampling times and influence the determination of the Doppler frequency. Accordingly the acquired signals are evaluated with a two-dimensional Fourier transform, with the time signal as the matrix of the dimension (number of samples per ramp) × (number of ramps). The two frequencies are accordingly proportional to distance (ignoring the Doppler effect) and relative speed of the object. Figure 5 shows a sequence of FMCW ramps, Figure 6 a two-dimensional spectrum with an object.

Figure 5: Sequence of FMCW ramps

Advantages and disadvantages

The major advantage of this method is the higher number of simultaneously detectable objects and the simpler allocation of distance and relative speed via the two frequencies.



The major disadvantage is the substantial increase in outlay. For the above example due to the Nyquist condition an A/D converter sampling rate of at least 40 MHz is required, 51.2 MHz produces for a ramp duration of 10 µs exactly 512 sampling values. To achieve suitable Doppler acquisition and a higher signal-to-noise ratio, it is necessary to evaluate for example 128 ramps – compared with two ramps a data volume that is higher by a factor of 64. For this reason, hardware units are usually used with calculate the Fourier transforms very quickly and with little power loss.

Antenna system and determining the angle

The antenna system (see Figure 1) has not only to transmit and receive the high-frequency signals, but also to determine the spatial position of the objects. This is required to assign the objects to lanes and to determine object characteristics.

Figure 6: Two-dimensional spectrum with an object

Standardized values at the axes.

Determining the relative position of the objects

Radar systems determine the relative position by estimating the angle under which the receiving antenna locates an object. Two, or better still more than two receiving antennas are required for this purpose. This can be done by directing a single radar beam (scanning) and also by several parallel, overlapping radar beams.

The gains of the complex amplitudes (phases and amounts) which are measured for an object in neighboring beams allow a conclusion to be drawn about the relative reception angle to the radar-sensor axis. In practice four radar beams are frequently used, enabling an angle accuracy of up to 0.1° and a separability of up to 3° to be achieved.

Patch-array-antenna system

There are many ways of technically realizing the antenna system. The most common variant is the patch-array-antenna system with antenna elements which are realized in microstrip technology.

Design

The patch-array-antenna system, in contrast to the lens-antenna system, as a rule has a bistatic design. The transmitting antenna in this system consists of a large number of single patches arranged in rows and columns which are wired in such a way that superposition produces a concentrated radar beam along similar lines to concentration by a lens.

The receiving antenna typically consists of a number of single patches arranged in columns which are electrically separated from each other and arranged next to each other. The offset of the individual reception columns generates a phase shift between the received signals of a detected object which is used to determine the angle. A reception column can in an individual case also consist of a number of wired columns.

Determining the angle

Angle evaluation utilizes the dependence of the antenna characteristic in amount and phase on the direction to the object of the outgoing or incident waves. To evaluate the outgoing waves a number of transmitting antennas are required which exhibit a directionality compared to its characteristic, for example via different directions of maximum radiation (this results in different amounts, often used for monopulse methods) or via different positions (this results in different path lengths to the object and thus in phase differences, often used in “phased array”). A number of receiving antennas can be used and evaluated in the same way.

If both a number of transmitting antennas and a number of receiving antennas are used for angle evaluation, the term used, based on communication technology, is MIMO systems (multiple input multiple output). This enables the direction to the object to be determined even more accurately.

Variants of radar sensors

In the past a distinction was made between short-range radars (SRR, usually in the 24 GHz frequency band) and long-range radars (LRR, in the 76 GHz frequency band). In the meantime the applications are merging and sensors are increasingly covering both ranges such that mid-range radars (MRR, in the 76 to 81 GHz band) will dominate the market, supplemented by a long-range radar. Short-range radars have a typical range of 20 to 50 m and a beam angle of up to 160°. Long-range radars have ranges of approximately 300 m and beam angles of up to 100°; mid-range radars have ranges and beam angles in between.

Vehicles in the future will often have five or more radar sensors all round the outer skin, placing a virtually continuous envelope around the vehicle and providing the opportunity for further assistance functions to make driving safer and more comfortable.

Homologation

Radar sensors are in accordance with the requirements devices which transmit and receive radio waves. Their operation is therefore governed by country-specific regulations worldwide. So-called homologation ensures that for each country in which radar sensors are to be operated the legal requirements are satisfied and the sensor receives type approval.

Radar sensors are usually approved by the manufacturer, e.g., Robert Bosch GmbH. The vehicle manufacturers then refer in the Owner's Manual or on specially set-up websites to type approval by the manufacturer.

Homologation covers both the technical aspects (such as frequency range, transmitted power, directional characteristics) and the labeling of radar sensors. Using the EU as an example, a radar sensor must among other things carry a specifically sized CE mark in a visible location on the sensor. Homologation must both be completed before the radar sensor is put on the market for the first time and, depending on the country, also be renewed on a regular basis.

Lidar-sensor system

Functions and applications

Previous applications
The use of lidar sensors (lidar, Light Detection And Ranging) for applications in motor vehicles began in Japan and in the USA around the year 2000, initially for adaptive cruise control (ACC). Since 2008 a low-priced multibeam lidar has tapped into the mass market when used for a rudimentary, automatic emergency-braking function. Since 2018 a multilevel laser scanner for an expressway/freeway traffic-jam assistant and an improved emergency-braking function have been in series production (for the first time including pedestrian protection as per the NCAP standard; NCAP, New Car Assessment Programme, [1]).

Future applications
Since 2010 lidar sensors with constantly increasing resolution and range have been in development. Above all the development of powerful lasers and low-noise, high-resolution image receptors have led to the situation today where comparatively cheap solutions are available. By 2025 – driven by functional safety – a dramatic increase in the number of lidar sensors for highly automated driving functions is expected (SAE levels 4 and 5, see Future of automated driving). Derived from this is the need for a redundant sensor design with wherever possible different physical measurement principles. In other words, lidar sensors will in future closely accompany video and radar sensors. Examples of the first driving functions in development with lidar are the urban automated taxi and the first expressway/freeway pilots in the truck and passenger-car sectors.

Operating principle

Distance measurement
Lidar sensors operate with laser beams in the infrared range (IR). A light beam emitted by a transmitting module is reflected by an object and detected by a receiving module. The time of flight between transmission and reception produces the distance between the object and the lidar sensor (see Measurement principles).

Intensity measurement
As well as the time of flight the intensity (power) of the reflected light can also be measured. The amount of reflected power essentially depends on the distance to the object and its IR reflectivity (see Time-of-flight principle, Power balance). It is therefore possible using additional model assumptions to extrapolate from intensity to reflectivity, an additional object characteristic.

Image build-up
Distance measurement is used to measure a distance value between the lidar sensor and an object located at the solid angle captured by the light (e.g., distance to the vehicle traveling in front).

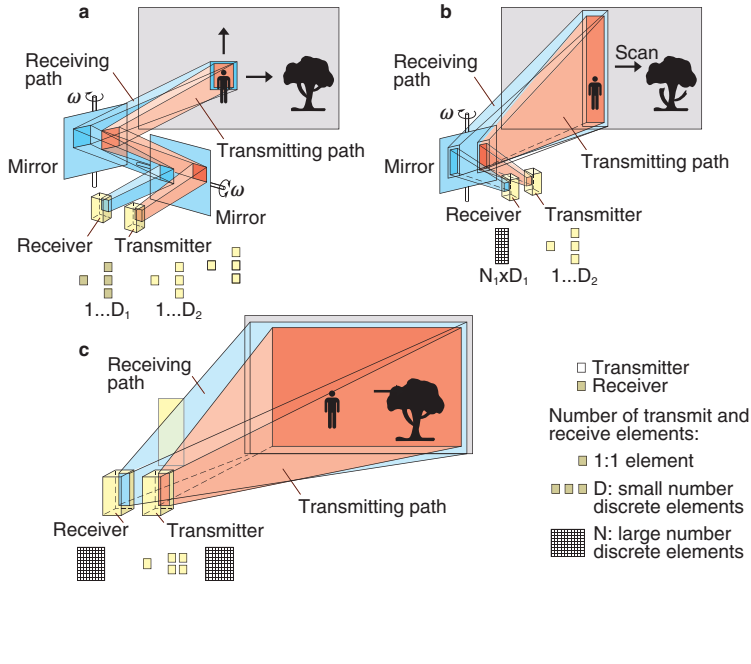
To resolve the surroundings spatially as a three-dimensional image, it is necessary to capture many solid angles within a desired field of vision independently of each other. There are two known fundamental principles for this purpose. Firstly, the number of transmitting elements or receiving elements can be increased by further, spatially independent pairs. Within a pair there can be transmitting and receiving elements in any ratios (see Methods for increasing the number of pixels, Single-beam, Multibeam, Flash lidar). Secondly, the light beams can be deflected via a scanner in a horizontal or vertical direction (Figure 1, see also Methods for increasing the number of pixels, Macro-, Micro-scanner).

Depending on the distance and resolution, the captured objects must be detected in great detail in a high-resolution 3D image. In this way, contours of

vehicles, persons, and other objects, including in particular the road surface and infrastructure, can be detected in great detail. At short distances to the sensor even body language and hand gestures of persons can be resolved.

The lidar sensor captures an intensity image as well as the 3D image. Unlike a video camera, however, it contains only light from a narrow IR wavelength range (only "one color"). Depending on the wavelength range, such intensity images can be similar to the capture in a video camera or the human eye, but also differ significantly. Furthermore, retro-reflectors (e.g., rear reflectors) appear unusually intensive due to the active measurement principle. The intensity resolution (image dynamics) is much lower than a video camera.

Environment perception (perception)



Lidar sensors supply on the detection level a large number of 3D pixels, also called a 3D point cloud, which are for the most part enriched by additional attributes (typically time stamp, pulse intensity, pulse length).

More abstract environment descriptions can be created using software algorithms on the basis of this 3D point cloud. Typical features on the object level for lidar sensors:

– objects (dynamics, 3D contour),
– lanes,
– open spaces,
– roadside structures,
– object classification (type, dynamics, object height, and derived from this ability to drive over small obstacles on the road).

Figure 1: Design variations of lidar sensors

a) Spot scan with 2D deflection,
b) Vertical flash with 1D deflection,
c) Full flash.

The lidar is additionally used to
– estimate proper motion,
– locate the vehicle within the area around the vehicle,
– have the area around the vehicle mapped by map providers.

Additional and monitoring functions
For use in highly automated driving functions sensors must in future adhere not only to rigorous requirements relating to functional safety (functional safety, focus on E/E faults), but also relating to very high availability of the intended function (SOTIF, Safety of the Intended Function).

It is possible to derive from functional safety and SOTIF a series of additional and monitoring functions which the lidar sensor itself can conduct. Required monitoring functions are:
– detection of contamination,
– detection of dazzle/glare,
– estimation of weather conditions,
– estimation of visibility and range,
– estimation of extrinsic calibration (i.e., of the time-varying installation parameters).

Required additional functions are:
– control of a heating system (to de-ice the optical window),
– control of a cleaning system (to clean the optical window),
– control of a cooling system.

Advantages of lidar
The lidar sensor has significant advantages over the video camera:
– high distance accuracy even over long distances (200 to 300 m),
– full range of functions at night or in unlit parts of the surroundings,
– capture of all object geometries (mono camera: only trained object classes; stereo camera: only sufficiently large object surfaces with texture),
– capture and classification of small objects, e.g., shed load and its height and resulting ability to drive over it.

It has significant advantages over radar:
– high angle accuracy over all distances (radar: angle uncertainty on stretched objects; objects with incorrect angle, caused by interference),
– detection of objects with virtually all geometries, sizes, and surface properties (radar: reflectivity sometimes too low depending on view angle, size, material),
– classification of objects based on contour capture (radar: object contour cannot be seamlessly captured),
– detection of lanes (radar: no detection of road surfaces and lanes).

Disadvantages of lidar
Lidar sensor has some disadvantages compared to the video camera:
– lower image resolution (number of distinguishable object classes is lower),
– lower intensity resolution (detection of classification based on texture, e.g., characteristic object classes, texts, only possible with video camera),
– intensity contains only a small proportion of the color spectrum (identical IR gray-scale value for non-identical color).

It has significant disadvantages compared to radar:
– lower robustness against adverse weather conditions, particularly fog, sometimes spray (but not mist/haze, moderate rain, snowfall),
– direct glare from the sun (essentially only at the solid angle of the sun),
– less accurate speed measurement (this is done only by way of one measurement, but is derived in terms of time from the position change).

Properties and use

Ranges
Comparable to other environment sensors in the motor vehicle, lidar sensors can also be classified according to their typical detection range. The following details of ranges always relate to weakly reflecting objects (worst case). The maximum range can typically be taken as double the value.

Near-field lidar
Near-field lidar has a range of almost 0 m to around 30 m and ideally a field of view approaching a hemisphere (180° horizontally and 180° vertically). The angle resolution is typically 0.5 to 2°. If a number of such lidar sensors are distributed around the vehicle, uninterrupted monitoring of the near field is possible. This facilitates for example highly automated parking and safe lane changing on expressways/freeways. However, due to the availability of other low-priced alternative sensors (video, radar, ultrasonic), there are as yet no known equivalent lidar developments.

Mid-range lidar
Mid-range lidar has a range of around 0.5 m to 80 m and, depending on the application, a field of view of around 50 to 150° horizontally and 10 to 20° vertically. The angle resolution is typically 0.15 to 0.25° horizontally, 0.15 to 0.85° vertically. A sensor mounted on the front of the vehicle supports semi-automated ranging systems (expressway/freeway assistant, traffic-jam assistant) and emergency-braking functions, based on radar and camera. Highly automated driving functions can only be realized with them in a very limited speed range and in very simple driving scenarios. For semi-automated driving functions mid-range lidar has been in series production (at Denso) for over 20 years in small and fluctuating quantities. Since a further manufacturer (Valeo) arrived on the market in 2017, numerous manufacturers have been announcing their arrival on the market with larger quantities for the period between 2021 and 2023.

Long-range lidar
Long-range lidar has a range of around 1 to 150 m and a field of view comparable to mid-range lidar. The angle resolution is horizontally and vertically around 0.08 to 0.15°. With three to six sensors distributed around the vehicle highly automated driving functions in the urban environment are possible. A front sensor (if necessary extended to include a rear sensor) facilitates highly automated driving functions on expressways/freeways. Here lidar is on an equal footing with radar and camera. A number of development projects since 2010 having been focusing on this lidar class, which is among the fundamental components of the highly automated driving functions.

Ultra-long-range lidar
Ultra-long-range lidar has a range of around 200 to 300 m and a field of view of 50 to 90°. The angle of resolution is horizontally and vertically below 0.05°. A sensor mounted at the front permits high driving speeds well above 100 km/h and full monitoring of large intersection areas. Lidar bears the main responsibility for these tasks compared to radar and camera.

Even if the development activities, apart from one exception, are in their infancy, the first sensors will be ready to go into production by 2023.

Properties
Distance accuracy
Some properties are shared by all lidar classes to a large extent. Thus distance accuracy registers for the most part between 5 and 15 cm. The frame rate registers for the most part between 10 and 25 Hz.

Image resolution
The image resolution is very different, ranging between some 1,000 and several 100,000 pixels. Here each pixel contains as a 3D pixel at least one piece of distance information and one piece of direction information, frequently one piece of intensity information (comparable to the infrared image of an infrared camera), less frequently additional classification information.

Disadvantageous properties
The most important disadvantageous properties of lidar sensors are today their size (depending on the principle and range up to two liters volume) and their still high cost.

Measurement principles

Time-of-flight principle
Distance measurement via time of flight
The fundamental principle of every lidar sensor is the time-of-flight principle (TOF). A modulated light beam is emitted at a time t_1 by the transmitting module and scattered on an object (Figure 2). Some of the scattered light falls at the later time t_2 back into the receiving module. The time of flight ($t_F = t_2 - t_1$) is proportional to double the distance r between the transmit-receive unit and the object. The distance is calculated via the speed of light c_0 in air at

$$r = 1/2\ c_0\, t_F .$$

Power balance
The lidar equation descriptions the relationship between the light emitted by the lidar and the received utilizable light. The receiving power $P(2r)$ is dependent on six factors:
– the transmitting power P_0,
– the reflectivity R_O of the object,
– the optical losses T_S in the transmitting path,
– the optical losses T_E in the receiving path,
– the receiving aperture D, and
– the distance r.

The following applies:

$$P(2r) = P_0 R_O T_S T_E D^2/(2r)^2$$

If the object surface (horizontal or vertical) is smaller than the diameter of the transmitted beam, the power drops even more sharply with the distance. Thus:

$$P(2r) \sim 1/r^4.$$

Significant losses occur due to scatter and absorption through optical elements, contamination, and the atmosphere (Figure 3). Fog, mist/haze, and spray can result in a substantial scatter of the light. The atmospheric losses are taken into consideration in the optical losses in the transmitting and receiving paths.

Dynamic range
The dynamic range of the receiving power $P(2r)$ is calculated at constant transmitting power P_0 from the reflectivity of the objects and the distance range to be measured at around 100 to 160 dB.

To adapt to the large dynamic range required, some receiving circuits operate primarily in saturation, with the result that only edge detection is possible. In other words, the very high gain of the analog receiving power leads to an almost digital switching performance. Other systems perform a dynamic adjustment of the receiving-power gain, e.g., increasingly with rising time of flight. An adjustment of the transmitting power can also be made.

Signal-to-noise ratio
To safely identify the useful signal, its power must be clearly above all the noise outputs in the system; the signal-to-noise ratio (SNR) must be large enough. Aside from all the electronic noise sources the Sun and artificial light sources constitute a significant noise source.

A widely used method to increase the signal-to-noise ratio is statistical improvement by accumulation of several individual measurements. This accumulation can take place both directly in the detector (PMD, Photonic Mixing Device; SPAD, Single Photon Avalanche Diode) and also in the digital domain.

Wavelength and eye safety
Few wavelength ranges are well suited for lidar sensors. These are derived from the availability of suitable transmitting and receiving components, from eye safety (in accordance with DIN EN 80625-1, [2]), invisibility to humans, and damping by the atmosphere. Important factors for eye safety are wavelength, beam shape, and modulation.

Essentially all popular lidar sensors operated in the infrared range (IR). The demand for a light source that is invisible to humans leads to a wavelength above 850 to 880 nm.

A first atmospheric window then extends up to around 930 nm. 905 nm represents a good compromise between low-priced lasers and silicon detectors whose quantum efficiency decreases rapidly above 850 nm. The limits of the maximum permissible radiation to comply with eye safety are at 905 nm still really low because infrared light close to visible light still strikes the retina virtually undamped. Nevertheless, this is the most widespread wavelength today.

A second atmospheric window for which lasers are available is at 1,300 nm, a third at 1,550 nm. For both wavelengths it is necessary to use other detector substrates (InGaAs, InP) whose maturity, costs, and noise performance are comparatively unfavorable. The limits of eye safety are however much higher because infrared light is to a large extent absorbed by the aqueous humor. The advantage becomes a disadvantage in the detection of wet objects or some objects with a high water content. In all, system performance at these wavelengths has not been examined sufficiently and there is no lidar of this type in series production.

Modulation methods
The signal-to-noise ratio is very much dependent on the type of modulation. Because noise increases with the measurement period, pulse modulation for lidar sensors particularly with medium and high range is the type of modulation favored in practice.

In all direct and indirect pulse time-of-flight methods the amplitude of the light is modulated. Similarly to radar, FMCW modulation methods in which the wavelength is modulated will in future be used for lidar (see FMCW modulation).

Direct pulse time-of-flight method
With the direct pulse time-of-flight method (Figure 4) a comparatively strong, short pulse of light is emitted (typically up to 100 W pulse height, 2 to 15 ns pulse duration, pulse repetition rate up to 200 kHz). The pulse of light reflected by the object (minimum power a few 10 nW) is identified by means of a pulse-detection method and its chronological position and frequently also the signal shape are determined.

Background light is only received in a small time window. The distance is calculated from the chronological position of the received pulse relative to the emitted pulse via the speed of light.

One particularity of the direct pulse time-of-flight method is that even a number of received pulses can be determined in succession. Objects can also then still be detected by means of this so-called multi-target capability (per pixel) if previously a less relevant detection was already determined (e.g., due to noise, spray, fog, reflection, glass).

The reflectivity can be inferred from the signal shape. But a classification can also be made as to for example whether the reflection comes from a hard target (object) or a soft target (atmospheric interference, e.g., fog). Sometimes the signal shape is also used to improve the distance estimation (e.g., walk-error compensation; walk error is an apparent time-of-flight error which occurs for different receiving power levels during a threshold-value comparison). Only the direct pulse time-of-flight method permits a signal classification to determine object properties, contamination or atmospheric interference (Figure 5).

Pulse detection

Two methods are customary for pulse detection. Technically more complicated, but more favorable (lower-loss) with regard to the information content is digital sampling of the received signal with an A/D converter (Figure 6a). The sampled signal can be specifically searched after detections, particularly by means of a correlation analysis (matched filter).

Technically simpler, but involving greater information loss is pulse-edge detection (Figure 6b), realized by a threshold-value comparison that is high-resolution in terms of time (TDC, Time-to-Digital Converter).

The lidar block diagram differs for both pulse-detection methods in one component only (Figure 7a). All the components operate in the high-frequency range (around 1 GHz).

Indirect pulse time-of-flight method
In the case of the indirect pulse time-of-flight method (Figure 7b) a long, wherever possible square-wave pulse with high amplitude is emitted (a few 100 ns pulse duration, 100 W to 100 kW pulse height). The receive pulse is integrated in the receiver in two exposure sections. The contain the phase relation and thus the time of flight between the transmitted and received pulses. This produces the time of flight.

Figure 6: Pulse detection by means of analog-to-digital conversion

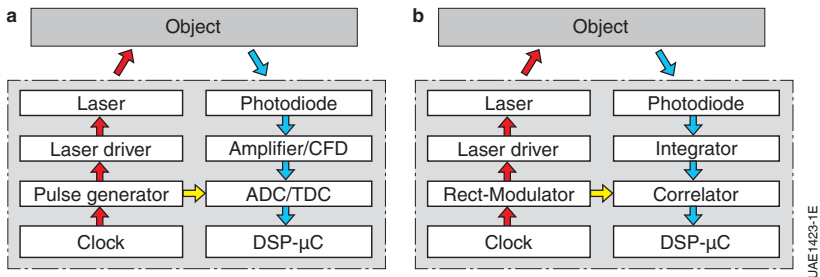
t_S Calculated mid-point (center).



The first exposure section corresponds to the transmission duration so that as the distance to the object increases an ever-decreasing proportion of the reflected light still shines into the gate window and consequently can be integrated (Figure 8, S1). This component falls linearly with the distance of the object. If the object distance is above the distance of the corresponding transmission duration (upper distance limit), no more light can be integrated. This first partial measurement is still ambiguous with regard to object reflectivity and object distance.

The reflectivity of the object can be determined with the second exposure section. This component rises linearly with the distance of the object (Figure 8, S2). Its time duration corresponds to at least twice the transmission duration so that the entire reflected pulse is always recorded.

Both partial measurements in total contain the information about the reflectivity of the object and also an offset by the background light. The background light is therefore determined in a third partial measurement without pulse lighting and subtracted from the integrated value.

The requirements imposed on the dynamic range of the receiver are particularly high for this technology because in addition to the utilizable light the background light is also integrated over a rela-

tively long period of time whose intensity is much lower. The signal-to-noise ratio is lowered by the additional background light. In all, no systems with very high ranges can be realized today with this method.

Realization variants

There are three realization variants. In the first variant two quickly switchable CMOS imagers (see Imager) are used to carry out one of the two partial measurements each. The received light is distributed via a beam splitter to the two imagers. The distance images are calculated in a downstream stage on a processor. Because the imager is based to a large extent on standardized camera imagers, very high resolutions up to several megapixels can be achieved. The drawback is that incorrect measurements occur due to the time interval between the two partial measurements if the object under consideration performs a rapid movement (movement artefacts).

The second variant implements the principle of beam splitting and distribution to two imagers by means of polarization. A Pockels cell is used instead of two rapidly switchable imagers to rapidly switch the light. The Pockels cell in the process in a few 10 to 100 ns turns the polarization direction of the received light through 90°. The two imagers are each provided with a polarization filter, both filters being turned through 90° to each other. By rotating the polarization direction, one imager receives with the rotation an increasing proportion of the light output from near objects, while the other imager receives that from far objects. The object distance can be calculated from the ratio of the two light outputs.

In the third variant the measurement principle is implemented directly in a special CMOS imager in which each pixel consists of two taps (sensor ranges). One tap takes on one of the two partial measurements. The level of sophistication of these imagers is still comparatively low in terms of pixel size, quantum efficiency, and noise. The more complex circuits and lines on the imager reduce the space factor and consequently give rise to comparatively low resolutions (some 1,000 to 10,000 pixels).

The high pulse power of the light source and the homogeneous light distribution today pose a major technical challenge for all indirect pulse time-of-flight methods and owing to the high costs are currently not competitive.

H Background light.

CW phase measurement method

In the CW phase measurement method (CW, Continuous Wave) the light is continuously emitted and sinusoidally modulated in amplitude. The received signal is by φ_d out of phase (Figure 9). The phase displacement corresponds to the time of flight and thus the distance to the object. The background light is received in a small time window.

The intensity of the emitted light can be taken as sinusoidal. To determine the received signal in full, it is necessary to determine the amplitude, the phase relation, and the offset. Usually this is carried out by integrating the received signals via four phase windows corresponding to the relative phase displacements 0°, 90°, 180°, and 270°.

Central elements of the CW phase measurement method are CW modulation and correlation with the received signal (Figure 10). The received signal is processed at low frequency. Sampling takes place due to the fact that the light converted into charge carriers is integrated according to its relative phase relation in four charge-storage elements. The charge-storage elements are activated and deactivated over a number of measuring cycles. The three unknown variables phase relation (distance), amplitude (intensity), and offset (background light) can then be determined from the charge ratios of the four partial measurements.

Four voltage measurements are conducted using two successive measurements and two taps (per pixel) (Figure 11). Each measurement integrates the charge carriers via a phase of 180°, the two taps being in phase opposition (charge-carrier swing). The two measurements are in quadrature. The phase relation and thus the distance can be determined from the voltage values.

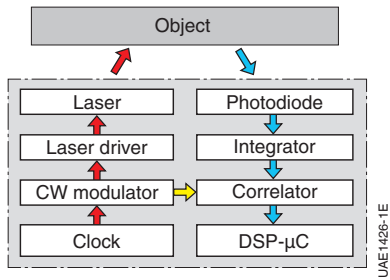
The calculation of the phase relation can already be implemented in the imager. The four partial measurements are either simultaneously realized in four taps of one pixel or in two partial measurements with two taps per pixel. The rapidly switchable taps of each pixel are also known as charge-carrier swing or photonic mixing device (PMD).

To prevent the pixels from being saturated by strong background light, direct components can be removed in part (SBI, Suppression of Background Illumination).

The emitted light output can be limited to 1 to 100 W by the integrating method. The duration of a measurement is some ten milliseconds. The modulation frequency is typically 10 to 20 MHz.

Significant drawbacks are the lack of multi-target capability, the low immunity to interference, and the insufficient dynamics of the imagers. For applications in motor vehicles the development of PMD cameras was driven on by some manufacturers until around 2015 and then to a large extent stopped.

Figure 10: Block diagram of CW phase measurement method



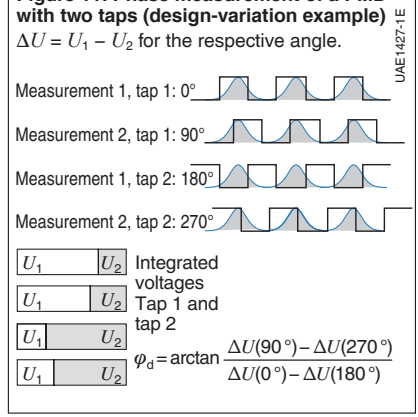


Figure 11: Phase measurement of a PMD with two taps (design-variation example)

$\Delta U = U_1 - U_2$ for the respective angle.

FMCW measurement method
In the FMCW measurement method the wavelength of the emitted light is changed (e.g., ramp). The received light is optically interfered with the transmitted light and consequently the light frequency (≈ 200 to 350 THz) is downmixed into the baseband. Frequency lines in the baseband correspond to the object detections, to which as well as the distance a speed can also be assigned (see FMCW radar).

The usual mechanical approaches can be chosen for beam deflection. Research is also being conducted in electronic beam deflection.

Methods for increasing the number of pixels

Basic principles
If the number of spatially resolved pixels is to be increased, more time-of-flight measurements must be carried out in different directions accordingly. The individual measurements can take place either chronologically in parallel or iteratively, i.e., in succession. Receiving arrays are customary for chronologically parallel measurements. In chronologically successive measurements the beam is deflected in different directions (scanning). A deflector is required for this purpose.

The speed of light is a physical limit on the number of iterative measurements. If frame rate f and maximum range r_{max} are specified, this produces the maximum number of individual measurements

$$N_{max} = c_0 / f\, r_{max}.$$

Example: For 10 Hz image rate and 300 m maximum range 100,000 pixels are obtained. Without further parallelization this amounts to the maximum number of independently measurable pixels.

To realize high-resolution lidar sensors with high range, it is therefore necessary to combine both principles of iterative and parallel measurement.

Solid-state lidar sensors
Single-beam, multibeam, and flash lidar belong to the class of solid-state lidar sensors which operate without mechanically moving components. Figure 12 shows combination options for partitioned transmitting and receiving elements in a solid-state lidar. The number of pixels increases with the number of partitions.

Single-beam lidar (single fixed beam)
In the simplest variant the transmitted beam is focused by a transmitting optic on the desired detection range (i.e., solid angle) and a corresponding receiving optic directs the collected light into an individual receiving element (see Figure 12). Thus no spatially separable distance measurements are possible inside the solid angle. Only one 3D pixel per measuring cycle is generated.

Multibeam lidar (multi fixed beam)
By duplicating components of single-beam lidar it is possible accordingly to measure numerous solid angles separately (see Figure 12). A high degree of duplication has a detrimental effect on costs compared to more highly integrated systems and consequently such systems for the most part only measure three to five solid angles. It is only advisable to use such systems in applications where rough volume elements are to be checked for the fundamental presence of an object. Multibeam lidar is used very successfully for a rudimentary but effective emergency-braking system.

Flash lidar
In this variant of highly integrated, high-resolution lidar the transmitted beam is widened as for single-beam lidar to the entire detection range. The detector consists of a high-resolution imager (FPA, focal plane array, up to 256 x 256 pixels). Each pixel of the imager is able to perform a time-of-flight measurement (Figure 12).

Long ranges in conjunction with large fields of view and resolutions above some 10,000 pixels lead to comparatively high costs and reach the limits of eye safety much earlier. There are also disadvantages with regard to spatial separability.

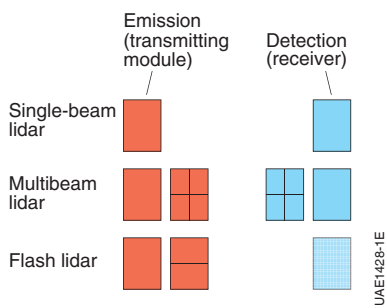
Macro-scanner with rotor
In this variant a single-beam, multibeam or flash/part-flash lidar is placed on a motor-driven, rotating platform and rotated about the rotor axis (rotor scanner, Figure 13). In the case of flash lidar the transmitted beam is widened to the entire detection range. In contrast, in the case of part-flash lidar, the transmitted beam only covers part of the detection range such that for complete coverage an additional scanner (see Macro-scanner with deflecting mirrors) or an electronic scan is required. The electronic scan is performed through sequential activation of laser lines or laser columns of a laser array (VCSEL, vertical-cavity surface-emitting laser).

The vertical resolution is achieved by a vertical partitioning of transmitting or receiving elements or both. The number of transmitting and receiving elements determines the vertical resolution. The individual measurements can take place chronologically in parallel or iteratively. The horizontal resolution is achieved by rotation. The measurements must accordingly take place iteratively. In total a resolution of several 100,000 3D pixels can be achieved.

Transmitting and receiving modules can be laterally or vertically arranged in a rotor scanner (Figure 13). The number of transmitting and receiving elements determines the vertical resolution.

Advantages and disadvantages
Disadvantages are the higher costs of the mechanical drive, the additional wireless power and data transfer to the rotor, and heat-dissipation challenges. On the other hand, this variant has the advantage of

Figure 12: Combination options for partitioned transmitting and receiving elements in a solid-state lidar



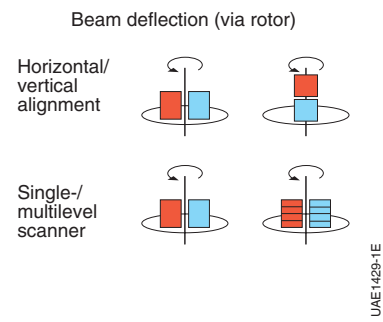


Figure 13: Rotor scanner

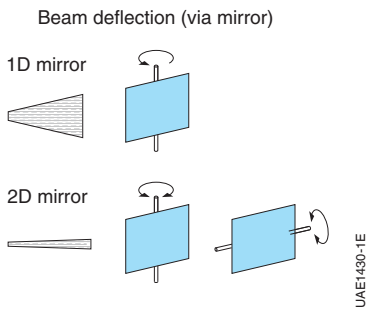
a horizontal field of view up to 360° and very homogeneous performance over the entire field of view.



Macro-scanner with deflecting mirrors
In this variant the transmitting and receiving beams of the single-beam, multibeam or part-flash lidar are directed via one or more moving mirrors. In view of the many possibilities two typical system configurations will be described.

In the first configuration the beams of vertically partitioned transmitting and receiving elements are deflected via a rotating mirror that rotates about a vertical axis. The horizontal field of view is limited by the size of the mirror and the vignetting of the housing to 90 to 120°. The resolution is several 100,000 3D pixels.

In the second configuration the beams of individual or few transmitting and receiving elements are directed via two oscillating mirrors with an orthogonal oscillating direction. The beam thus follows the established Lissajous figures. The number of possible pixels is reduced by around 40 % compared to a rotating scanner.

Figure 14 shows two typical configurations of a mirror scanner. A vertically extended beam is directed via a rotating mirror (1D mirror) and only horizontally deflected. In the second configuration a focused beam is directed via two oscillating mirrors (2D mirrors) and deflected in both principal directions.

Figure 14: Configurations of a mirror scanner

Micro-scanner
To miniaturize oscillating mirrors 1D or 2D MEMS micro-mirrors (Micro-Electro-Mechanical Systems) have been analyzed in the last few years. For long ranges these small mirrors (usually under 1 cm diameter) have proven to be an “optical eye of a needle”, which could only be brought under control with the aid of highly voluminous and highly complex optics. In all, micro-mirrors offer no advantages for the currently pursued approaches. But they could play a role again in the context of FMCW lidar.

Video sensors

Application

People use their sense of sight to discern the information pertaining to environment detection. Consequently it is natural to develop driver-assistance systems on the basis of video data. There are now a multitude of assistance functions and the demands on the video cameras also change, depending on the application.

Indicating display systems
The first applications were indicating display systems, such as for example rear-view cameras. In these systems importance is attached to high-contrast images and color reproduction. The images are often reprocessed to obtain the desired impression in the display.

Image-processing systems
As well as indicating display systems there are systems which use computer-based image-data processing (computer vision) to extract relevant objects and determine the driving situation. It is no longer necessary for the images to be perceived to be realistic by people; instead, they must depict relevant objects for the algorithms so that they are easily distinguishable.

Cameras for image recognition can be used for purely informative systems, as with road-sign recognition. But cameras also serve to control actuators, such as
– for automatic headlamp dimming,
– for brake interventions for vehicle-to-vehicle ranging and for accident avoidance,
– for steering interventions, e.g., in parking functions, lane-keeping support or evasive steering support,
– or as sensors for automated or autonomous driving.

The higher the degree of automation, the greater the demands on the performance of the cameras. This is achieved through the interaction of the elements of a camera described in the following. The two main components are the image sensor and the objective (see Figure 1).

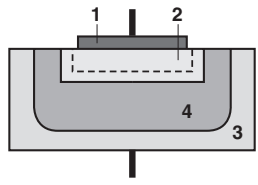
Image sensor



Basic principles of photosensing

Aside from a few special applications, image sensors (imagers) are today manufactured using CMOS technology (complementary metal-oxide semiconductor). This technology enables transistors to be embedded in every pixel for control purposes.

In the image sensor many photodiodes are arranged in a rectangular pixel grid. A layer of p- and a layer of n-conducting semiconductor material meet in a photodiode (Figure 2). An electric field is created at the junction between the two layers, the space-charge region. At the same time this space-charge region demonstrates a certain capacitance which behaves in inverse proportion to its thickness.

Photodiodes typically work by being charged to a certain potential (output voltage) and then being exposed to light. When photons shine into the semiconductor, electron-hole pairs are generated. Here, the quantum efficiency η describes how many electron-hole pairs are generated by one photon. The photoelectric current is proportional over many factors of ten to the incident luminous flux and is linear over a wide dynamic range. The photoelectrically generated charges now discharge the photodiode capacitor. The residual voltage is measured once the photodiode has been exposed to light. The difference between this voltage and the output voltage is a measure of the quantity of incident light.

Figure 2: Photodiode
1 Contact, 2 n silicon substrate,
3 p silicon substrate, 4 Space-charge region.

If so many photons shine in that the space-charge region is completely discharged, further photons no longer lead to a linear reduction of the voltage and the photodiode is saturated. Efforts are usually made to operate the photodiodes in their linear range. This can be achieved under bright lighting by reading out the voltage already after a short exposure time and by coupling the photodiode to an additional capacitor. However, large capacitors provide a lower voltage drop per photoelectron such that dark scenes and the associated low voltage drops are more difficult to measure.

Design

Photodiodes and metal-oxide capacitors can be manufactured on a chip with standard semiconductor processes like CMOS. Large photodiodes have a large surface for collecting photons, meaning that they also exhibit low shot noise in dark scenes. Shot noise arises because only integer electrons can be measured. Stochastically a pair of photons more or less meets the photodiode in any exposure. Depending on the quantum efficiency only a part of the photons is converted into electrons that can be read out. Both processes lead to fluctuations even with homogeneous lighting viewed macroscopically.

The ratio of light-sensitive volume to lateral face is high for large photodiodes such that cross-talk between adjacent photodiodes is easier to handle than for small photodiodes.

Large photodiodes use a lot of silicon surface area, impacting on the sensor costs. The pixels are therefore for the most part designed to be as small as possible to obtain a still acceptable dark sensitivity. The trend towards higher sensor resolutions, i.e., more pixels, provides for ever larger sensors in spite of ever smaller individual pixels. Where in 2010 sensors with a quarter megapixel (VGA resolution) and 5 µm pixels were customary, in 2020 sensors with 2 megapixels of 3 µm each or 8 megapixels of 2.1 µm each are the norm.

Activating the image sensor

Aside from the photodiode, each pixel also includes transistors to control the image sensor. These transistors can for example charge the photodiode to the output voltage are direct the residual voltage to the readout electronics. The setup of a simple pixel with three electrodes is shown in Figure 3. Modern pixel designs often contain further transistors to obtain additional functions or improved behavior.

The control electrodes of the transistors (gate) are connected to each other in lines and therefore can only be switched jointly (Figure 4). The readout lines are connected to each other in columns. If a voltage is applied to the control line to read out a line, all the pixels in this line are simultaneously connected to a readout line.

Each column has its own readout electronics; an entire line can therefore be evaluated in parallel. The voltage is initially analog-amplified. The gain is adjustable for many image sensors and influences the sensor's noise performance.

Evaluating the sensor signal

The pre-amplified signal is then converted in an analog-digital converter (A/D converter) into a number of fixed bit depth. If the analog voltage is above the reference voltage for the highest digital value, a saturation occurs in the digital output. The saturation threshold of the A/D converter is selected in so that the photodiode still operates in its linear range.

A/D converters with high bit depth can show higher dynamics between the brightest and darkest value, but are costlier to produce and are sometimes prone to higher noise. Through the noise contributions of all the analog components only a limited dynamic range can be sensibly used from a single readout.

As at 2020 converters with 10 and 12 bits are widely used in series applications.

Images with high dynamics
Additional techniques are often used in order also to be able to depict scenes with higher dynamics (high dynamic range, HDR) with low noise and without over- or underexposed areas.

Dual conversion gain
One possibility here is "dual conversion gain". A second capacitor can be connected via a resistor to the photodiode for this purpose. The resistors can be realized for example by means of a half-closed transistor. While the photodiode discharges immediately when exposed, the voltage follows the supplementary capacitor with a delay. At the end of the exposure the photodiode and the supplementary capacitor are read out separately. The small capacitor of the photodiode exhibits already with low luminous fluxes a high voltage drop and is suitable for dark image areas. The large capacitor is saturated much later and can be used for bright image areas. For the most part the digital values of both readouts (capture) are already offset against each other on the image sensor.

Split-pixel technology
If the dynamics are still insufficient, a sensor with split-pixel technology can be used. Here photodiodes with high and low sensitivity are arranged in pairs and again offset against each other. Usually the sensitive pixel is much larger and absorbs through its surface area more photons than its insensitive counterpart.

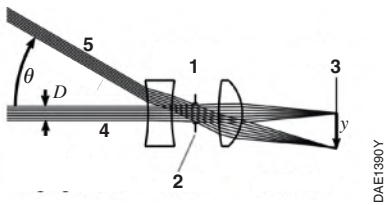
Multiple exposure with different exposure times
To further increase the dynamics, it is also possible to record in succession and offset exposures of different lengths. In moving scenes, however, artifacts may appear in the form of multiple edges.

Exposure modes
Rolling-shutter mode
Automotive image sensors are for the most part operated in rolling-shutter mode. Here a count variable points at the line currently to be processed. This counter is incremented at a fixed rate, the line rate. Initially, the current line is charged to the output voltage (reset). Then the pixels accumulate the photons and discharge. In a fixed line spacing after the reset line the pixels are connected to the evaluation electronics and converted into digital brightness values. The exposure therefore "rolls" over the sensor.

The advantage of this method is the simple and favorable implementability. The disadvantage is that each line was exposed with different start and end times. Objects may appear distorted as a result.

Global-shutter mode
In global-shutter mode the entire sensor is simultaneously charged to the output voltage. Each photodiode is connected to a light-protected capacitor (shielded cap) belonging to the pixel. At the end of the exposure time all the capacitors are simultaneously disconnected from their photodiodes. The voltages can then be read out in succession.

The advantage of this operating mode is that all the pixels are exposed simultaneously and no motion artifacts appear. It is more complex and therefore more expensive to process shielded caps.



Color filters
To be able to distinguish colors, photodiodes with different color sensitivity must be arranged on the sensor. In practically all applications photodiodes are damped in a regular pattern with different color filters. This pattern is also called a mosaic. The Bayer pattern is the most widely used pattern in photography. It consists of repeating lines of 2×2 pixels. A green filter is applied to two diagonally opposed pixels; the other two pixels are sensitive in the red and the blue (see Figure 9).

Human color perception is likewise based on receptors for red, green and blue. As a result, the camera perceives color spectra similarly to the eye and can reproduce realistic images.

As well as the Bayer pattern there are other color patterns, which can contain for example colorless pixels. Colorless pixels are sensitive to all colors, therefore collect more photons, and have above all in dark scenes advantages in the signal-to-noise ratio. The same applies to magenta, yellow and turquoise (cyan), which transmit in each case two of the three additive primary colors red, green, blue.

If a sensor is offered with a specific number of pixels, this number refers to the sum total of all pixels. There are therefore far fewer pixels available per color channel. The color channels are for the most part interpolated in image preprocessing (see Demosaicing) in order to have available at each location a brightness value for all color channels.

Objective

The objective reproduces light from an object on the image sensor. In the case of a sharp reproduction a point-shaped light source is focussed on a dot or as small a spot as possible on the sensor. The object-side angle of the incident beam bundle to the optical axis is called the field angle, the distance between the pixel and the optical axis the image height (see Figure 5). A reproduction is characterized by among others the following properties:

Field of view
The field of view is the maximum object-side angle at which an object can still in order to still be reproduced. Objectives are designed for a maximum angle up to which they reproduced sharply. Furthermore, the sharpness and brightness of the reproduction often diminish dramatically and the reproduction can no longer be used. Only areas which are reproduced both within this maximum angle and within the sensor size are reproduced in the camera.

Sensors are rectangular, i.e., the size differs in the horizontal, vertical, and diagonal directions. Connected with this are different fields of view in these directions.

Projection model
The projection model describes how object-side field angles are translated into image heights. Two important projections are the pinhole-camera model and the equidistant projection model.

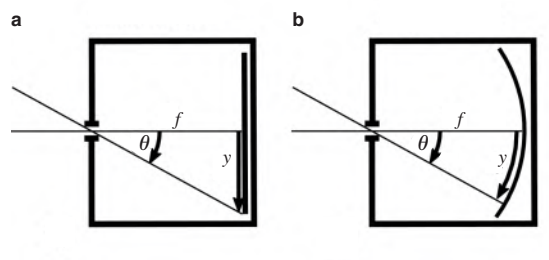
Pinhole-camera model
The eponymous pinhole camera consists of only an aperture and a film plate (Figure 6a). A pinhole camera translates straight edges into straight lines in the image. Real objectives with lenses are designed in such a way that the carry out the same translation of field of vision into image height as a pinhole camera. The reproduction function is given by

$$y = f \tan \theta.$$

Here y is the image height on the sensor, f the focal length, and θ the field angle. The focal length can be understood in the formula as the enlargement ratio. It should be chosen in the design of the objective in such a way that the desired field of view is reproduced on the sensor. The derivation of the reproduction function, i.e., the change of the image height per angle, is called enlargement. It is often given in the unit pixels per degree. In pinhole cameras the enlargement increases as the field angle increases and diverges at ±90 °; a sensor of infinite size would be necessary. It is therefore clear that real wide-angle objectives must deviate from the pinhole-camera model and follow a different projection model.

Equidistant projection model
Wide-angle and fisheye cameras often use the equidistant projection model (also called the F-theta model). As an example it is possible to image an equidistant camera as a modified pinhole camera with a curved image (Figure 6b). Here the image height is given by

$$y = f\,\theta.$$



The angle θ must be applied in rad. In this model identical angle changes are translated into identical changes of the image position. The enlargement is constant. Straight lines are generally shown with a barrel distortion.

Distortion
Because many other parameters must also be taken into account in the design of an objective aside from the projection, real objectives rarely follow one of the projection models exactly. The relative deviation of the projection of an objective from a model is called distortion. If no projection model is specified, the pinhole-camera model is assumed for the most part as the reference. Through the clever design of the distortion it is possible to place a high level of distortion in image areas in which a degree of camera performance is required.

Luminous intensity
The luminous intensity of an objective is traditionally described by the f-number familiar from photography. The f-number is determined with a parallel (collimated) beam bundle on the optical axis, which fills the aperture entirely. The f-number is the ratio of focal length to the diameter of the beam bundle (see Figure 5). The smaller the f-number, the greater the luminous intensity of the objective.

Relative illuminance
In most cameras the illuminance decreases with increasing field angle. The ratio of brightness on the sensor at the optical axis to brightness in the field is called relative illuminance. This is caused for example by an angle-dependent increase of reflections or by cutting off part of the beam bundle by means of lens edges (vignetting). The distortion also affects the relative illuminance. A change of enlargement also changes the object-side solid angle from which a pixel collects light.

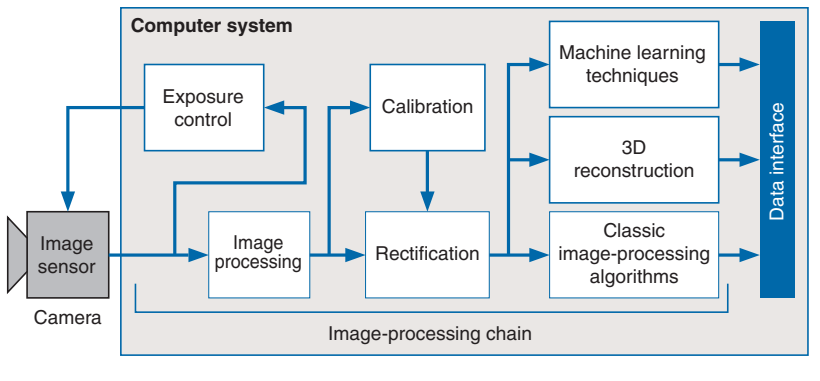
Sharpness

A measure of sharpness widely used in technical optics is the modulation transfer function (MTF). The MTF describes the loss of contrast (Michelson contrast) incurred by a periodic object with a sinusoidal brightness characteristic in the reproduction. A sharp objective can itself reproduce fine structures with high contrast whereas a blurred (unsharp) objective already creates noticeable contrast losses with rough structures. The characteristic period in which the MTF must be measured can vary from task to task: Should for instance only the outer shape of a road sign be recognized or text on the sign?



Computer vision

Image-processing chain

The term computer vision (CV) comprises the processing of an image-data sequence by a computer system. The object of image-data processing is to detect and classify objects which are relevant to a specific application. In the field of driver-assistance systems intelligent camera systems are used in which the captured image data must be processed in real time and only the limited computing resources of an electronic system embedded in the vehicle are available.

The block diagram (Figure 7) shows the schematic representation of computer vision for a driver-assistance system. The individual processing steps in their entirely are called the image-processing chain. A digital representation of the environment captured in the range of vision of a camera is created with the aid of the image sensor (imager). This image representation is the database of computer vision and thus forms the input data stream of the image-processing chain. The first processing steps comprise the algorithms of image processing and exposure control fed back to the image sensor. Calibration supplies as a supporting algorithm static and dynamic parameters for rectification. Rectification is followed by the parallel processing of the classic image-processing algorithms, the 3D reconstruction, and the machine learn-

Figure 7: Image-processing chain

ing techniques. To finish, the results of the image-processing chain are transferred via a data interface to the following processing steps on the computer system.

Exposure control

The exposure time of the image sensor is dynamically adapted to the light conditions of the captured scene with the aid of exposure control. In this way, a sufficiently high range of contrast can be guaranteed at any timed in the image data generated by the image sensor. To this end, exposure control uses brightness information from the currently captured image data to optimize the exposure time for the subsequent capture. The image-data stream generated by the image sensor has a frequency of typically 30 Hz or 30 fps (frames per second).

In camera-based driver-assistance systems an HDR image sensor (high dynamic range) is usually used in which differently exposed captures are fused into an overall image with a higher dynamic range. The simplest case here is the combination of an overexposed capture with an underexposed capture. This operation, known as HDR recombination, happens either directly on the image sensor or as part of the subsequent image processing.

Scenes with rapidly changing brightness values such as tunnel entrances and tunnel exits pose a challenge for exposure control.

Image processing

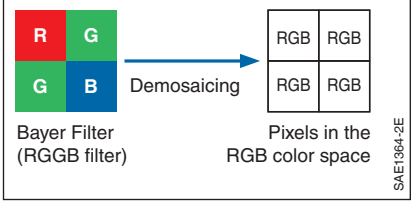
The algorithms of image processing are based on the image data received by the image sensor, which are also called raw data. The typical component parts of image processing, also known as “image signal processing”, are shown in Figure 8

Image processing comprises the following blocks: demosaicing, noise reduction, edge preservation, tone mapping, and color-space conversion. Aside from these blocks there are further processing steps which are typically dependent on the image sensor used, the available computing resources, and the available computing unit.

Demosaicing

An image sensor has a color filter to be able to represent the color information of a captured scene. Each pixel in the image sensor's raw data therefore represents a color value in digital form. An RGGB filter, also known as a Bayer filter, is typically used as a color filter (color filter array). A red, green and blue component is interpolated in the RGB color space for each individual pixel (Figure 9) by demosaicing with the aid of the neighboring pixels. There is generally no reduction of the image resolution by the demosaicing. Numerous publications with algorithms of

Figure 9: RGGB color filter and demosaicing



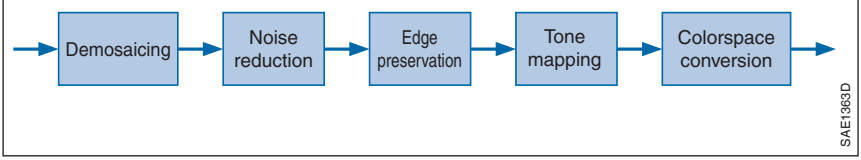


Figure 8: Component parts of image processing (image signal processing)

all manner of complexity are known in the literature to calculate the RGB values [1].

Aside from the RGGB filter, other color filters which typically contain pixels without color information are used for image sensors in camera-based driver-assistance systems. These intensity pixels (clear pixels) are more light-transmitting than color pixels and therefore produce an altogether higher image brightness and as a result a higher-contrast reproduction of dark scenes.

Typical color filters with intensity pixels in the field of driver assistance are for example RCCC (i.e., one pixel with red filter and three intensity pixels) and RCCG (i.e., one pixel with red filter, one pixel with green filter, and two intensity pixels).

Noise reduction

Noise reduction serves to suppress image noise and thus to reduce unwanted signal components, improving the signal-to-noise ratio of the image-data stream. Two-dimensional filter operations are generally used for noise reduction and applied for each pixel. A typical example of a filter for noise reduction is a Gaussian filter [1]. Small image structures like noise for example are suppressed by the use of the smoothing filter. From a signal-theory standpoint the Gaussian filter thus equates to a low-pass filter.

Edge preservation

The image data were smoothed by the filter operations of the previous processing steps. An algorithm for edge preservation is used in order nevertheless to obtain a detailed image with clearly discernible and sharp edge information. There are numerous established techniques for preserving edge information; these techniques are mostly based on filter operations which ideally sharpen only the edges, but influence or smooth the remaining image data as little as possible. A typical example of an edge-preserving smooth filter is a bilateral filter [1].

Tone mapping

The adaptation of contracts within the image data is referred to as tone mapping. This operation can for example increase the range of contrast in dark image areas to facilitate the recognition of existing details there. There are all manner of established global and local algorithms for tone mapping [1]. In most techniques the color value of a pixel is replaced with the aid of a reproduction rule by a different color value. For global techniques a location-independent reproduction rule is used for the full image. In the often more complex local techniques the reproduction rule is dependent on the position of a pixel.

Color-space conversion

In the case of color-space conversion the image information in the RGB color space is carried over for each pixel to a different color space because other color spaces are better suited for some computer-vision algorithms. For example, the YUV color space facilitates through the separation of brightness information (luminance Y) and color information (chrominance U and V) a simplified processing of algorithms which only process luminance values.

Typically, algorithmic techniques for 3D reconstruction only work on the brightness information of an image. Machine learning techniques are typically in a position to work on the basis of information from both the RGB color space and the YUV color space. For color-space conversion there are very many different and in part also internationally standardized conversion rules [1].

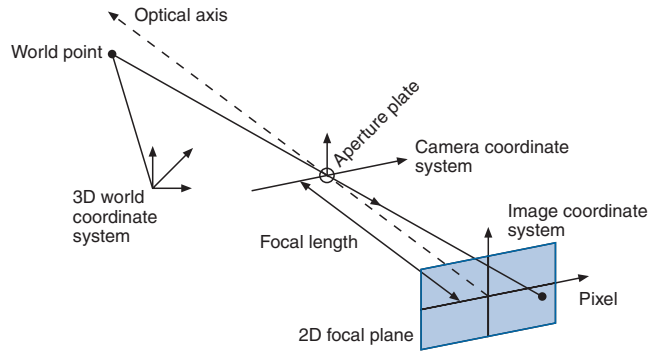
Calibration
The calibration of a camera system is required to describe the relationship between a point in the real world and its projection on the focal plane.

Static calibration
The theoretical basis for static calibration is an idealized camera model which describes the mathematical relationship between a point in the real world and its projection on the focal plane. The simplest form of a camera model is the pinhole-camera model. In this model the captured scene is projected through an idealized pinhole without perspective distortion onto the focal plane (Figure 10). The idealized needle hole is also called the pin diaphragm. The pinhole-camera model is typically used for a front-camera system with an aperture angle of less than 120°. The equidistant projection model (fisheye-camera model) is generally used for a rearview camera with a larger aperture angle of more than 180°.

To describe the relationship between real world coordinates and image coordinates, the pinhole-camera model has parameters which are determined during calibration with the aid of pairs of points and are available for coordinate transformation. The connection between coordinates in the world coordinate system and image coordinate system is established with the aid of the camera coordinate system (Figure 11).

Intrinsic parameters
The relationship between camera coordinate system and image coordinate system is described by the intrinsic parameters of the camera model. These parameters include the focal length and the position of the optical center of the camera. On the simplified assumption that the camera only has one single thin lens, the optical center describes the point behind the focal plane in which all the beams of a parallel incident beam bundle cross. The intrinsic parameters are thus camera-specific and describe the internal geometry

Figure 10: Pinhole-camera model



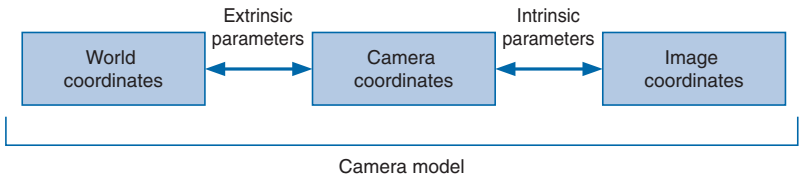


Figure 11: Relationship between real world coordinates and image coordinates

of a camera. The intrinsic parameters are typically determined after the production of a camera and stored in a non-volatile memory inside the camera.

Extrinsic parameters
The relationship between world coordinate system and camera coordinate system is described by the extrinsic parameters of the camera model. A translation and rotation of world coordinates using the extrinsic parameters results in the corresponding camera coordinates. Consequently, the position and orientation of the camera can be described in three-dimensional space via the extrinsic parameters. The extrinsic parameters are determined after the camera is installed in the vehicle because these are dependent on its installation location. An external calibration target is typically used to determine the extrinsic parameters. For the mathematical relationships and the transformations using the intrinsic and extrinsic parameters reference is made at this point to further technical literature [2].

Dynamic calibration
As a result of the vehicle's proper motion the field of vision of a camera installed in the vehicle changes without the captured scene also inevitably changing. Dynamic calibration is required to record the resulting dynamically changing vehicle parameters and reproducing their effects on the transformation of world coordinates into image coordinates. The determined dynamic vehicle parameters are then passed on to the following algorithms. The dynamic parameters included on the one hand the longitudinal and lateral motion component of the vehicle, i.e., typically the inherent speed and the current steering angle, and on the other hand the rotary motions and the associated motion angles about the three vehicle axes:
– pitching about the transverse axis and the associated pitch angle,
– rolling about the longitudinal axis and the associated roll angle, and
– yawing about the vertical axis and the associated yaw angle.

The required parameters for the inherent speed, the steering angle, and the yaw angle are as a rule made available via the vehicle bus (e.g., CAN bus). The pitch and roll angles can be determined with the aid of algorithms for image-based proper-motion estimation. Image-based determination of the dynamic vehicle parameters is also called visual odometry.

Rectification

As already mentioned with calibration, an idealized camera model is used for the mathematical description of the relationship between a real point in the world and the associated pixel. In this model the pair of points (real point and pixel) and the optical center lie on the same optical beam. Furthermore, straight lines in the real world are also reproduced without distortion as straight lines.

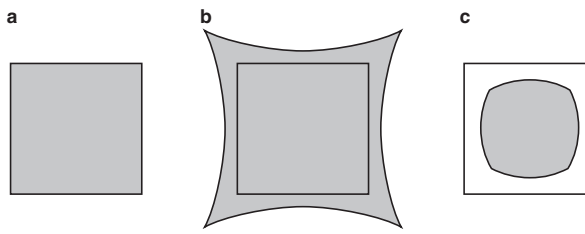
With real cameras the assumption of distortion-free reproduction is typically not fulfilled, i.e., a straight line in the real world is reproduced crooked. The larger the aperture angle or the field of view of the camera, the greater the distortion of the optical reproduction by the objective and the more crooked real straight lines will be reproduced. Algorithms for rectifying the image are used to correct the distortion of an objective. Thanks to the use of rectification straight lines are again reproduced as straight lines and the assumption of the idealized camera model is valid again.

Radially symmetric distortions

Numerous models of varying complexity are known from the literature to describe the distortion of a real objective [2]. The simplest form of mathematical description in the form of a polynomial is radially symmetric distortion. This manifests, depending on the objective design, as pincushion or barrel distortion. With pincushion distortion the enlargement of the optical reproduction increases towards the image edge, with barrel distortion the enlargement decreases towards the image edge (Figure 12).

A frequently used mathematical representation of the radially symmetric distortion $\Delta r'_{rad}$ as a function of distance r' to the optical axis is:

$$\Delta r'_{rad} = A_1 r'^3 + A_2 r'^5 + A_3 r'^7$$



The parameters A_1, A_2, and A_3 determine the type of distortion: pincushion or barrel. Because the distortion is always specific for a particular objective, the parameters as a rule derive from an exact measurement of the objective after its production.

Further distortions

As well as radially symmetric distortion there are further distortion models, such as for example asymmetric and tangential distortion, which is caused as a matter of priority by a the lenses inside the object being brought out of center. There is no detailed description of the associated complex mathematical relationships at this point and reference is made to further literature [2].

Because a camera in the vehicle is often installed behind the windshield, the distortion caused by the window glass must also be taken into account in the rectification.

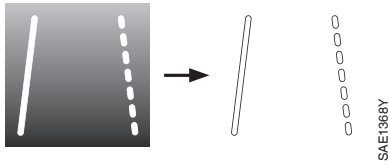


Figure 12: Radially symmetric distortion
a) No distortion,
b) Pincushion distortion,
c) Barrel distortion.

Classic image-processing algorithms
The algorithms of classic image processing are based exclusively on mathematical techniques and are divided typically into a feature extraction and a downstream object formation. The classic image-processing algorithms included in the field of driver-assistance systems typically line detection and light detection.

Line detection
For line detection the conditioned and rectified image-data stream is initially processed using a cut-off filter. This filter operation produces a gradient image from the original brightness information. In terms of signal processing a cut-off filter corresponds to a high-pass filter which emphasizes brightness jumps between neighboring pixels and suppresses brightness changes. Retained in the resulting gradient image are thus lines which exhibit at their edges a large brightness jump, such as for example a white line marking on dark gray asphalt, areas of consistent brightness are suppressed. An algorithm frequently used for edge detection is the Canny algorithm, which typically uses the Sobel operator as a filter kernel for partial derivation in the horizontal and vertical directions [1]. The Sobel operator is defined here as a 3×3 filter matrix. A typical application of the Sobel operator is shown in Figure 13. Based on the gradient image pixels with a similar gradient vector and similar intensity are brought together in line segments. After a plausibility check which contains all manner of assumptions for a valid line marking, relevant line segments are linked with valid lane markings and output as line objects. Included in the plausibility-check assumptions are for example alignment, strength and bending radius of a line as well as the parallelism of several lines. The presented algorithm facilitates the detection of all the line-based lane markings, such as for example continuous and dashed lines and line markings in different colors.

Figure 13: Application of the Sobel operator

Light detection
Light detection is as a rule used as an input variable for different light functions, such as for example automatic high-beam control. The lights of oncoming vehicles and vehicles traveling in front must be detected in a nighttime scene for this purpose. A CCL algorithm (connected-component labeling) is generally used here. This algorithm facilitates the bringing together of neighboring pixels whose brightness value is above a defined threshold value. This process is also known as clustering. In this way an image-data sequence can be segmented, i.e., pixels which belong to a vehicle light are brought together in a cluster and continued in the following as an individual characteristic (Figure 14). For the detected points of light a series of additional attributes is also established, such as for example size, center point and brightness of the respective group.

The detection of the points of light is followed by their plausibility check using different assumptions, such as for example the brightness and position of the point of light in the image. In this way relevant light objects thus detected as vehicle lights are formed and separated from irrelevant light sources, such as for example reflective road signs.

The algorithmic further development of light detection comprises, aside from the detection of front and rear headlamps, also the stop, turn-signal, tail, and hazard-warning lamps of other vehicles as well as the detection of the rotating beacons of emergency vehicles. The recognition of traffic lights also poses a further challenge for light detection.

3D reconstruction

The aim of 3D reconstruction is to restore the depth information of a captured scene because this information is lost by the camera system and the associated transition from the real three-dimensional space to the two-dimensional space of the focal plane. By restoring the depth information it is possible to create a detailed environment model in the area of the captured scene. In this way the drivable corridor ahead of the vehicle (freespace) can be determined and on this basis a precise trajectory planning can be created for the ego vehicle. A precise 3D reconstruction also facilitates – in complex scenarios, for example in roadworks areas on expressways/interstates – longitudinal and lateral vehicle guidance. A detailed environment model is absolutely necessary for autonomous driving functions. An exact calculation of the road surface is also made possible by 3D reconstruction. Irregularities such as for example potholes or speed bumps can be detected by means of this surface estimation.

Optical flow

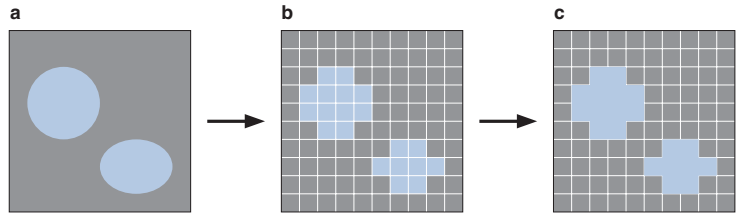
The optical flow is an algorithmic process on the basis of which the depth information of a scene can be reconstructed.

Flow calculation

The basic principle for the optical flow is provided by a set of features which is made up of a defined number of features. A feature typically consists of two pixel sums within a defined window size, e.g., 5×5 pixels. The difference between the two pixel sums is compared with a threshold value. The result of this comparison is then in the simplest case 1 or 0, depending on whether the difference is greater or less than the threshold value. This type of feature is also called a Haar-like feature because of its similarity to Haar wavelets from signal processing. Figure 15 shows by way of example a set of features with six features in a window size of 5×5 pixels.

Figure 14: CCL algorithm

a) Real points of light,
b) Reproduction on points of light,
c) Bringing together in a cluster by the CCL algorithm (connected-component labeling).



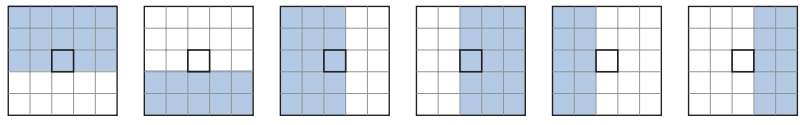


Figure 15: Set of features by way of example for 5 x 5 pixels

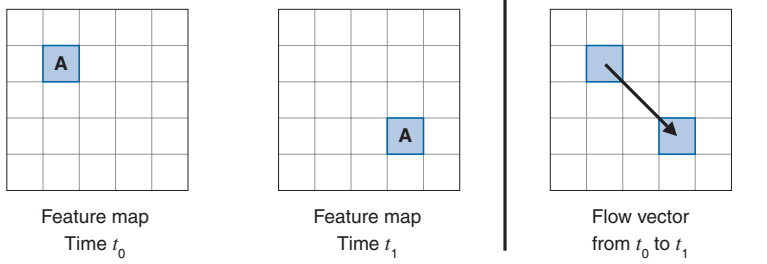
The examples show features for detecting horizontal edges and vertical edges.

Aside from the Haar-like features presented here there are also numerous other feature types known to science, such as for example HOG (Histogram of Oriented Gradients) or SURF (Speeded Up Robust Features). The feature size is variable and impacts directly on the computing complexity of the chosen algorithmic approach.



Now feature calculation is performed for each pixel within an image. Aside from the central pixel, all the pixels located in the window are included in the calculation. Based on the results of the feature calculation, each pixel is assigned a signature, e.g., 101100 for the six features from Figure 15. The aim of feature calculation is to generate as clear a signature as possible for all pixels belonging to relevant structures in the image, such as buildings, marker posts or vehicles of all types. During the feature calculation for an entire image a feature map containing all the relevant signatures is created on the basis of the original image data.

If now a feature map is calculated for two consecutive images, the pixels belonging to a structure visible in both images have the same unique signature, i.e., they correspond. This also applies if the ego vehicle moves and the position of a signature shifts from image to image. Signature-based correspondence creation, i.e., the location of identical signature values in different images, is one of the core algorithmic components of the optical flow. Starting out from the image position of a signature A at time t_1, it is thus possible, referred to the position of the same signature A at the previous time t_0, to determine a vector, which is also called the flow vector (Figure 16).

The sum total of all the flow vectors in an image is also called the flow field. In this vector field properly moving objects, such as for example a crossing pedestrian, can be clearly detected because the flow vectors on a properly moving object clearly differ from the vectors of the environment. Because the optical flow does not contain any object assumptions, i.e., the algorithm does not know what pedestrians or other properly moving objects look like, the optical flow facilitates a generic object detection.

Within the framework of scientific papers numerous algorithms for calculating the optical flow have been published in the past few years which aside from the algorithmic complexity also differ in how many flow vectors can be calculated from the image data. A distinction is essentially made here between algorithms which frequently generate very many flow vectors on the basis of interpolation and in this way can create a dense flow field and algorithms which only generate a fraction of the flow vectors and can therefore create only a sparse flow field.

Figure 16: Optical flow
A Signature.

Structure from Motion

The position of a three-dimensional world point in the two-dimensional focal plane can be calculated with the aid of static calibration. For a known pixel, however, it is conversely possible to calculate only a straight line in three-dimensional space on which this point lies. The straight line is also called the line of sight. All the world points which are on this line of sight are projected onto a common point in the focal plane. The depth information of a point in the real world is therefore lost in the reproduction in the two-dimensional space of the focal plane, i.e., based on a pixel the distance of the corresponding point in the real world cannot be determined.

To determine the depth information of a point in the real world, it is necessary to capture this point from two camera perspectives. It is thus possible to calculate two non-identical straight lines in three-dimensional space at whose crossing point ultimately the real world point is situated. Algorithms for calculating the optical flow use as explained previously two captures at different times for the creation of the flow vectors. When the ego vehicle moves, the two capture times correspond to two camera perspectives at different times.

For a static structure in the real world it is now possible to determine two non-identical lines of sight on the basis of which the real distance of the structure can be calculated. For this purpose, aside from the flow vector, the parameters for the vehicle's proper motion must be know, for example how far the vehicle has moved between the two capture times. It is thus possible to calculate depth information for all structure in the real word for which a unique signature has been allocated and which consequently can be found in the image data of both capture times.

A depth map of the captured scene is created in this way. This flow-based technique of 3D reconstruction is also called “Structure from Motion” (SfM).

A drawback of flow-based 3D reconstruction is however the dependence on the ego vehicle's proper motion, i.e., when the ego vehicle is stationary, flow-based 3D reconstruction of the captured scene is not possible.

Stereo vision

Another algorithmic technique for reconstructing the depth information of a scene is stereo vision, i.e., a scene is captured at the same time by two image sensors. This equates to human sight with two eyes. Like the optical flow, this technique too is based on signature-based correspondence creation. To this end a feature calculation is performed in the first step as with the optical flow in order to generate signatures that are as unique as possible for real structures. Because of the assigned signature a structure in the real world can then be found in a captured image. Stereo vision, however, does not use like the optical flow the signature-based correspondence creation on the basis of two consecutive images of the same camera, but on the basis of two images captured at the same time by independent cameras. If the position of a signature A is known for the optical flow at time t_1, this signature A referred to the time t_0 may have moved in any direction horizontally and vertically.

For stereo vision a simplification can be assumed under certain preconditions so that there must be a signature in both camera images within the same image line, which is then called the epipolar line. With the aid of simplification by the principles of epipolar geometry the algorithmic effort for the correspondence search can be significantly reduced. To be able to apply the simplification, it is necessary to establish and maintain the stereo normal case for a stereo camera system (Figure 17).

The stereo normal case requires firstly a parallel alignment of the focal planes of two identical cameras, i.e., cameras with

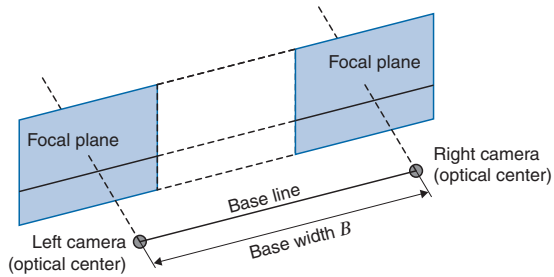
identical intrinsic parameters. In addition, the focal planes must be parallel to the base line, which connects the optical centers of the cameras. The length of the base line between the optical centers is also called the base width of a stereo system. In addition to the parallel alignment of the cameras the optical centers of both cameras must be at the same height. To completely satisfy the simplified epipolar geometry, the pixels of an image line in the left camera image must correspond to the same image line in the right camera image. Therefore a distortion-free image of the individual cameras is required as well as intrinsic and extrinsic calibration.

The function of a camera system in the vehicle must be guaranteed over a wide temperature range and is subject to constant vibration and aging effects. To this end a camera system always has production-related manufacturing tolerances and installation-related installation tolerances. To be able to guarantee compliance with the stereo normal case also for a stereo system installed in the vehicle, as a rule an algorithmic component extending beyond the mentioned intrinsic and extrinsic calibration and rectification is required to establish and maintain the stereo normal case. This component is also called stereo calibration.

A world point P captured by both cameras is now reproduced taking account of the stereo normal case in the focal planes of both cameras on the identical image line, i.e., on an epipolar line (Figure 18). The horizontal distance between the pixel and the optical center of the left camera taking account of the focal length f and the base width B of the stereo system is governed by the following relationship:

$$x_L = \frac{f}{Z} X .$$

By analogy, the horizontal distance between the pixel and the optical center of the right camera is governed by the following relationship:



$$x_R = \frac{f}{Z} (X - B) .$$

The difference between the horizontal position of the pixel in the left camera image and the horizontal position of the pixel in the right camera image is called the disparity d and describes the relationship between the reproduction of the world point P and the depth Z:

$$d = x_L - x_R = f \frac{B}{Z} .$$

The depth Z corresponds to the distance between the world point P and the optical center of the reference camera system,

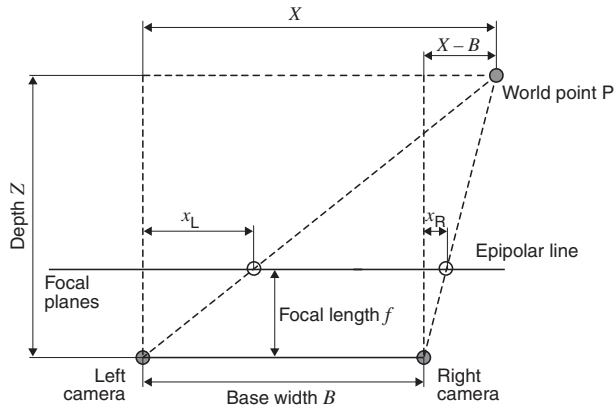
Figure 17: Stereo normal case

i.e., in this case the left camera. The distance to the world point P is thus inversely proportional to the disparity d. In this way it is possible to calculate the disparity for all the visible and clearly corresponding world points in the two images and create a disparity map which contains the depth information of the captured scene. Generally: The greater the disparity the closer an object is and the smaller the disparity the further away an object is.

Comparison of optical flow and stereo vision

Stereo vision has a number of advantages over 3D reconstruction based on the optical flow, but also disadvantages for an application in the automotive sector. The stereo-based measurement method is constantly available compared with the optical flow and is not dependent on the vehicle's proper motion. The depth calculation of the flow-based method on the other hand requires as accurate an estimation of proper motion as possible and knowledge of the capture times of the individual images because these have a direct bearing on the accuracy of the depth estimation.

Stereo vision offers a direct geometric possibility of depth calculation and therefore as a rule delivers greater measuring accuracy.



A drawback of stereo vision is the need for a second camera, which typically entails much higher costs for a stereo camera system. The optical flow offers analogously to stereo vision the possibility of calculating depth information on the basis of the vehicle's proper motion with a generally cheaper mono camera system. For this reason the flow-based 3D reconstruction technique “Structure from Motion” is frequently also called “Motion Stereo” [2].

Machine learning techniques

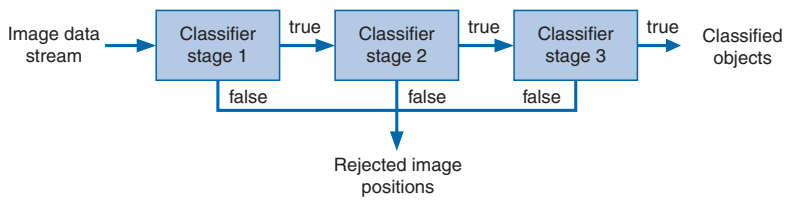
In the field of computer vision a typical task for an algorithm is to search for specific objects in the image, such as for example pedestrians, bike riders, motorcycles, cars, and trucks. Detecting these objects is a challenging task for a computer system, which is typically solved with techniques from the field of machine learning, which is a sub-area of artificial intelligence.

Machine learning techniques enable a computer system to process specific tasks without having been explicitly programmed for these beforehand. The algorithms learn on the basis of image-data sequences how they can best manage

Figure 18: Stereo disparity

a specific task. These image-data sequences involve so-called training data in which the objects to be detected were identified beforehand. The identification of objects is also known as labeling and is the basis for supervised machine learning. Based on the labeled training data the algorithm generates a mathematical model that enables its to detect relevant objects within an image with a high degree of probability. Not only does the algorithm detect these specific objects in the known training data, but it is also in a position to detect these objects in new and previously unknown image data. The greater the labeled training-data volume the more probable it is that the algorithm will detect a specific object hitherto unknown to it. What is important here is not only the amount of training data but also as high a variance as possible within the training sequences, such as for example the coverage of all manner of light and weather conditions.

Because the training data are typically stored on servers or a data cloud, the volume of training data is an important cost factor. Ideally, a computer system would detect and classify 100 % of all the relevant objects within a scene. However, this is not possible in the real world on account of their complexity. Thus, the aim of object detection is as high a detection rate as possible with at the same time a low error rate. With machine learning techniques the achievable detection rate is decisively dependent on the training-data volume used and thus the associated data costs.



Cascading object classifier

An example of the implementation of a machine learning technique is the cascading object classifier, which is typically based on a supervised learning technique. Here for each item of input data the labeled training-data volume is used to defined the result to which the classification must lead. Typically a cascading object classifier is used to detect and object class such as for example pedestrians, bike riders or motorcycle riders.

A cascading object classifier generally consists of a number of classifiers which are linked in the form of a decision cascade. This is then applied to each pixel of the incoming image-data stream. If the decision cascade has been fully run through, there is a very high probability that there is a relevant object at this image position. If the cascade has not been fully run through, there is a very high probability that there is no relevant object at the processed image position. The decision cascade is then canceled early and the current image positions are rejected. Through the early rejection of non-relevant positions the cascading structure facilitates an optimization of the total running time of the object classifier because all the existing classifier stages doe not have to be calculated for each image position (Figure 19).

Each classifier stage consists of a decision tree which in turn is made up of individual linked features. The feature type used involves in the simplest case, as in the implementation of the optical

Figure 19: Cascading object classifier

flow, Haar-like features. The manner of the links within the decision tree and the concrete elaboration of the features is determined by the previously specified learning technique (Figure 20). Numerous algorithmic techniques are known in the literature for implementing a cascading object classifier [3].

Deep learning

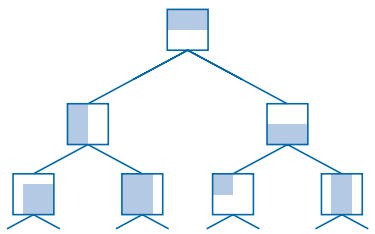
In the area of machine learning the basic relationship that a larger volume of labeled training data leads to a higher detection rate of the algorithms used applies. In particular, this applies to the deep-learning techniques which, when compared with classic machine learning techniques such as for example a cascading object classifier for an increasing volume of training data, can achieve a higher detection performance (Figure 21).

The deep-learning techniques are based on artificial neural networks the structure of which on an abstract level are based on the information processing in the human brain. The algorithms uses here a number of processing layers which process the incoming raw image data in stages. The deep-learning algorithms learn independently which calculation parameters must be used on which level to achieve an optimal detection result.

One implementation possibility for an artificial neural network is the deep neural network (DNN), in which data processing is performed in only one direction from input layer to output layer (Figure 22). The DNN thus works from a signal-theory standpoint exclusively on the forward path (feedforward). For the area of computer vision convolutional neural networks (CNNs), which are a specific form of deep neural network, are typically used. In the internal processing layers of a CNN discrete convolution operations are used which when compared with the general matrix multiplication of a DNN can be carried out with simpler filter operations and can thus be implemented with less effort in an embedded system. The processing layers between input and output layers are also called hidden layers.

Figure 22 shows a strongly simplified representation of a typical CNN architecture from the field of computer vision. The CNN network architecture depicted is based here on the previously rectified image data which are called in this connection the input layer. The convolutional layer is the central unit of the CNN architecture and contains an adaptable filter which is applied using discrete convolution to the input image data. In this way a specific activation threshold is determined

Figure 20: Classifier stage with Haar-like features



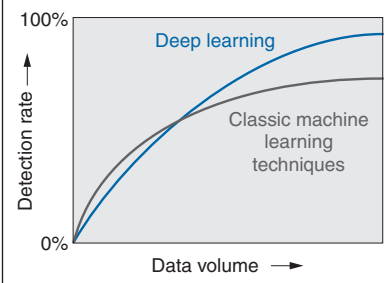


Figure 21: Relationship between detection rate and data volume

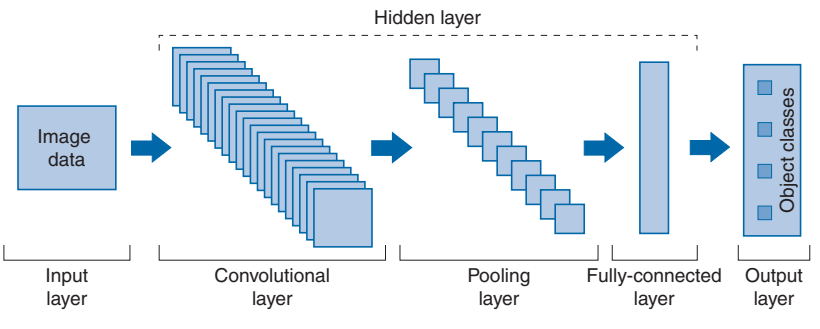
for each filter kernel corresponding to an artificial neuron. Depending on the CNN result the values of the filter kernels are independently optimized by the network, i.e., the neural network learns independently. In the pooling layer the existing data volume is decreased by combination of the filter responses and the size of the filter kernels is reduced. In the ensuing fully-connected layer all the neurons of the pooling layer are connected with all the neurons of the following output layer. In a CNN-based classifier the number of neurons in the output layer as a rule corresponds to the number of object classes to be classified.



There are as a rule in a CNN a number of interlinked units consisting of convolutional and pooling layers which thus form a multi-stage or else deep neural network. For the implementation of a CNN in a driver-assistance system the CNN network architecture is typically adapted to the architecture of a suitable hardware accelerator within the embedded system.

In the field of driver-assistance systems a CNN is as a rule taught in during the development process and adopted in series in a defined state. Training takes place under monitored condition, i.e., the object classes for the output layer of the neural network are specified during the learning phase. The validation of an algorithm based on deep learning is the object of the validation. This is based as a rule on a volume of validation data that are not dependent on the training data.

A CNN does not require any additional conditioning of the input image data when compared with other algorithmic techniques such as for example line detection based on cut-off filters. In the classic image-processing techniques the filter kernels must as a rule be developed on an application-specific basis; a neural network, however, learns these filters implicitly.

One of the typical applications for a CNN is semantic segmentation, which assigns one of the learned object classes to each pixel. In addition, a CNN facilitates the detection and classification of objects such as for example road signs, traffic lights, and lane markings and roadsides of all kinds (any boundaries). Single-task networks, which process only one of the tasks mentioned, and multi-task networks, which facilitate the performance of a number of tasks within a CNN, are possible here. The architecture of single-task and multi-task networks is likewise the object of current research in the field of computer vision.

Figure 22: Strongly simplified representation of a typical CNN architecture

Data interface
Objects and measured data are typically transmitted via the computer-vision data interface. The objects detected and classified by the classic image-processing algorithms and the machine learning techniques include for example lines, points of light, vehicles, and pedestrians.

In the case of measured data the depth map determined with the aid of 3D reconstruction is transmitted for example.

Sensor-data fusion

Introduction

Perception of the environment
People use their sense of sight when driving a car to discern the information pertaining to environment detection. Thus, the conclusion could be made that an autonomously driving vehicle only needs one video sensor to perceive the environment (or surroundings). Current autonomously driving platforms, however, have a multitude of sensors which operate according to different measurement principles. Perception of the environment is then conducted on the basis of the "fused measurements" of these sensors. Sensor-data fusion is concerned with the question as to how measurements from a variety of sensors should be combined to enable a scene to be optimally perceived. Sensor data thus refer to the acquired measured data and not the values from data sheets (e.g., measuring range, accuracy).

Sensor-data fusion in the automated-driving environment
Sensor-data fusion is essential in the field of automated driving for a number of reasons. Humans have as part of their evolution developed highly effective and efficient perception based on visual stimuli. We are currently not yet at the stage where we can emulate this so well and computation-efficiently that it can be implemented in a vehicle with limited energy resources. Current video sensors are stretched to their limits particularly in adverse-weather conditions, for example due to the low signal-to-noise ratio (SNR) and thereby limited detection capability.

Furthermore, an automated-driving solution must be better than a human and at the same time safe in order to be accepted by society. The processing overhead in perception can be reduced by having the scene measured very well and in such a way that the separability of interesting from uninteresting scene content is consistently as big as possible. This happens currently by using numerous sensors to measure the environment. In addition, fused measurements of numerous sensors also increase safety, above all in the event of a sensor failure.

Glossary
Special terms are used in the field of sensor-data fusion and will be explained here.

Sensor space
The sensor space contains the depiction of the environment based on the sensor measurements, e.g., pixels or images for a video sensor and point clouds for a lidar sensor.

Feature vector
This is a vector with features. With regard to a pattern a feature is a scalar by which a particular aspect of the pattern is described.

Inference
Inference denotes the acquisition of information by reaching a conclusion. Within the framework of a stochastic consideration it is concerned with the calculation of joint and conditional probabilities, e.g., in the case of a classifier the conditional probability of the class output is calculated depending on the feature-vector input.

Perception
Perception refers to a subconscious process of individual information and perception processing which gives rise in the consciousness of the information recipient to images of perceived partial aspects of reality.

Heuristics
Heuristics is the art of obtaining probable statements with only limited knowledge.

Sensors

There are currently in the automated-driving environment a number of types of sensors whose measured data are fused to perceive the scene. Each sensor measures certain specific properties of objects (e.g., of road signs, of a vehicle parked at the roadside, of pedestrians). Using these properties it is then possible to separate the objects from the background and differentiate them from each other – on the assumption that these differences are found in the sensor measurements.

Sensor types

Video sensors

Video sensors (image sensors, imagers) operate with electromagnetic waves in the visible-light range. A video sensor is able to convert photons to charge or to voltage. It generates a signal depending on the intensity and color composition of the light that is incident upon the sensor.

There are two types of objects: light sources and reflectors. In both case the composition of the light that comes from an object is dependent on specific object properties (e.g., surface structure).

Lidar sensors

Lidar sensors operate with infrared light. Unlike a video sensor, lidar is an active sensor. Lidar sends light beams with a certain distribution in the scene and receives the reflections back. The lidar uses the delay with which the emitted light after being reflected by the object is received by the sensor to measure the distance to the objects in the scene. A 3D representation of the scene is thus produced. The objects are then distinguished via their geometric structure. Modern lidar sensors are also able to measure the speed of objects.

Radar sensors

Radar sensors operate with electromagnetic waves in the radio range. Radar is likewise an active sensor, emitting a signal and measuring the reflection of the signal by objects in the scene. Essentially the distance to the object is measured by way of the delay.

Radar sensors also measure the speed of the object and properties of the reflecting object surface. Compared to lidar, radar typically delivers a sparser 2D range map and not a dense 3D representation of the scene, but the quality of the radar measurement is significantly less susceptible to weather conditions. Different technical approaches can be used to increase the resolution of radar sensors significantly.

Ultrasonic sensors

Ultrasonic sensors operates with sound waves above the audible frequency range. They are also active sensors. Ultrasonic sensors have a very short range compared to video, lidar, and radar, but are low-priced and robust against weather conditions.

Perception

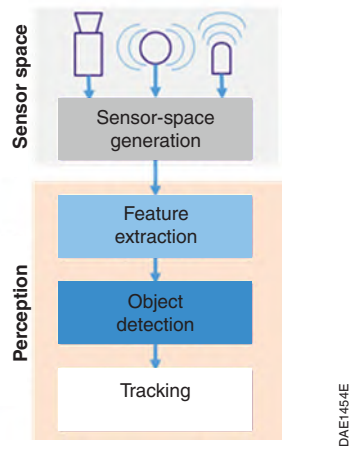
To perceive a scene, the information from the environment, just as it is measured by a sensor, is analyzed in a first step and relevant scene content (e.g., objects) is detected and tracked over time. In a second step the objects are placed in relation to each other. This second step generates additional information, which, together with the information extracted in the first step, describes the scene in full.

En route from the sensor measurement to the detected object the scene information passes through various processing steps (Figure 1). To improve object detection and tracking, information from a number of sensors is combined at different points along this processing chain.

Thus, sensor-data fusion is concerned with the processing of information which is obtained from the measurements of different sensors. The aim is to separate important scene content robustly and with high quality from unimportant content and to track the important content over time.

Representation of the driving scene

Currently most algorithmic solutions of the fusion tasks follow two architectures, which differ in the way in which information from the driving scene is depicted.



Grid approaches

Grid approaches are based on discretizing the driving scene into typically non-overlapping areas. At each point in

time a decision is made on the basis of the sensor measurements as to whether one of these areas is filled by an object. Individual areas can then be aggregated to objects in further steps [1].

Object-model approaches
Object-model approaches for their part use from the outset an explicit representation of the objects. This representation is of a geometric nature and is usually based on the principle of the enclosing polytope. It contains object properties such as size, orientation, position, and dynamics and is recalculated at each point in time on the basis of the sensor measurements.

Figure 1: Functional block diagram of early fusion

Fusion types

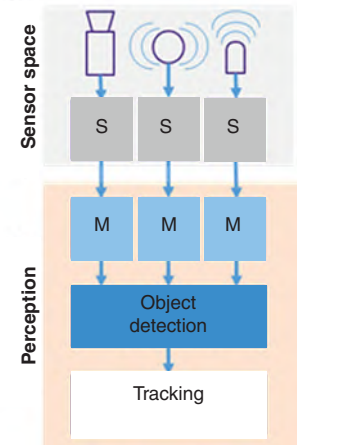
Depending on the position along the processing chain at which the information from the sensors is combined, a distinction is made between three types of sensor-data fusion.
– Early fusion: Here sensor measurements are directly combined with each other. This happens directly at the sensor output, prior to any further processing.
– Mid fusion: Here certain perception-related information-processing steps are carried out sensor-specifically first before the results of these steps are combined.
– Late fusion: Here objects are perceived sensor-specifically before they are combined.

Early fusion
En route from the sensor measurements to a detected object the scene information passes through a number of processing steps. In this way measurements from the sensor space are aggregated to feature vectors before it is decided whether and what kind of an object is situated at a certain point.

In the case of early fusion the sensor space extends across all the available sensors. Subject to this common sensor space is a model which describes how individual sensor measurements are to be combined with each other. The parameters of the model can be set on the basis of a-priori knowledge or learned from data. The block diagram of this type of early fusion is shown in Figure 1.

Traditional approaches
Traditional approaches to early fusion contain a separate step in which the sensor space is explicitly generated and the model parameters are set with reference to different considerations. This step is the basic principle on which the other information-processing steps function.

Learning method
If there is to be an underlying learning method, there is the possibility of combining the sensor-space generation with subsequent and likewise learning-based information-processing steps. Here the parameters of the respective algorithmic blocks are learned together. In this case the sensor space is only implicitly generated. Better results can be obtained by optimal mutual adaptation of the steps that are based on one another. However, it is in this case more difficult to follow which type of information is used where and what effect each step has along the processing chain. Neural networks offer the opportunity to implement such a procedure relatively easily.



Discussion
Perception functions like an information funnel. This extracts from the superset of scene information which the sensors measure only the information relevant to the automated-driving tasks. There information is filtered out at different points by different mechanisms. One of these mechanisms provides that potential object information with a reduced SNR is ignored. The upshot of this is that incorrect detections but at the same time also some correct detections are prevented.

Early fusion has the potential to achieve optimal perception performance. This is primarily because complementary information from all sensors is used without discarding object information with a reduced SNR from one sensor. Even if an object exhibits information with a low SNR for all sensors, there is in the case of early sensor-data fusion a good opportunity to detect the object by analyzing the dependencies between the measurements in different sensor spaces.

Early fusion also has certain drawbacks. For optimal results the sensors must be very precisely synchronized. This is often difficult because the times of measurement can differ very markedly from sensor to sensor. The calibration requirements are also very stringent in the case of early fusion and the hardware requirements increase because larger volumes of data have to be processed simultaneously. Calibration is the name of the process of determining sensor parameters. Furthermore, already the failure of a single sensor can lead to problems in the subsequent processing chain.

Another difficulty of a practical nature is that the sensor interface is not yet standardized. The ISO 23150 standard TC22/SC31 [8], which is intended to standardize this interface in future, is currently in the preparation stage. Not all the sensors make a raw-data interface available or meet the necessary synchronization and calibration requirements.

Figure 2: Functional block diagram of mid fusion
S Sensor-space generation,
M Feature extraction.

Mid fusion

In the case of mid fusion the sensor spaces of the individual sensors are examined for conspicuous regions and if necessary features are extracted before these are combined for object detection. Similarly to early fusion objects are in this way detected on the basis of an overall-sensor description of the scene; however, the search for conspicuous regions is sensor-specific. Figure 2 shows a typical block diagram for this type of fusion.

Discussion

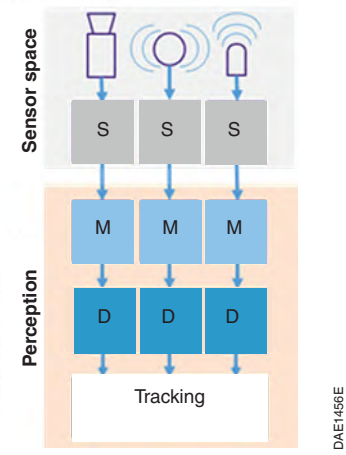
Mid fusion has the potential for improved performance with similar, but less pronounced drawbacks of early fusion. Thus the synchronization, availability, and hardware requirements are less stringent because not all the measurements of the various sensors have to be processed simultaneously. However, the difficulties relating to the interface also remain for mid fusion.

Late fusion

In the case of late fusion objects are first detected sensor-specifically before they are aggregated on an overall-sensor basis. One option of aggregation entails tracking the sensor-specifically detected objects jointly with the aid of a specially adapted measurement model over time. Figure 3 shows the block diagram of this type of fusion.

There are different heuristics to carry out the aggregation. Such approaches also work when the objects in the scene are sensor-specifically detected and tracked.

Discussion



Later fusion cannot achieve the performance of early fusion because information which would only be detected in the sensor network is discarded here. Late fusion cannot achieve the quality of mid fusion either because typically sensor-specific information in the low SNR range is ignored in order to reduce the number of incorrect detections. However, late fusion does not exhibit the drawbacks of early and mid fusion. Because it is objects and not sensor measurements or scene descriptions that are processed, the data rate is very low. The synchronization and calibration requirements are also low and sensor availability is non-critical because in the event of a sensor from the fused network failing the scene can nevertheless be perceived by having the objects of the other sensors analyzed.

Application of the fusion types

Late fusion is currently the most frequently used solution in the field of driver-assistance systems. The availability of greater computing capacities and the need for higher performance in the field

Figure 3: Functional block diagram of late fusion

S Sensor-space generation,
M Feature extraction,
D Object detection.

of automated driving means that the focus of development is on primarily mid fusion. Early fusion presents itself above all as the benchmark and for task with the highest performance requirements.

Information basis of object detection
Depending on how information is introduced over time in the decision problem of object detection, there are a number of ways of fashioning this step algorithmically. Deep neural networks with special architectures [2] play a particular role here.

Sensor-specific measurements (or features generated from them) can be jointly tracked across conspicuous regions. There is thus a history of sensor-specific information available to object detection. Alternatively, only information which was collected across overall-sensor conspicuous regions from sensor-specific measurements without a history is used. Particularly for early and mid fusion the decision about the procedure for object detection leads accordingly to an adaptation of the functional block diagram. The aggregation step can then solve different tasks, such as for example tracking or the consolidation of tracking results.

AI-based sensor-data fusion

Artificial intelligence
Artificial intelligence (AI) is concerned with the question as to how a machine has to be programmed or designed in order to complete tasks for which a human must use intelligence. Intelligence is defined as the capacity to acquire information (e.g., by perception or by inference), to store and use this information as knowledge, to handle this optimally, and to adapt to changes by learning. In general terms, the aim here is to support or even replace humans through the use of AI. Thus, AI is the cornerstone of autonomous driving.

Sensor-data fusion is important in order to detect and track objects within the framework of perception, where detection refers both to the division into important and unimportant objects (i.e., detection) and to the specification of the object type (i.e., classification). Different sensors can be used to measure the scene optimally and thereby establish the basis for optimal detection and tracking.

The tracking of objects and their detection are implemented as part of perception by AI algorithms. Usually the parameters of the algorithms that implement the tracking are defined on the basis of a-priori knowledge while the parameters of the algorithms that implement the detection are learned from training data. But there are also algorithmic solutions to the tracking problem which are based on learning approaches.

The algorithmic paradigms which make it possible to carry out detection and tracking and then in each case the most common approaches in the automated-driving context will be discussed in the following. Fusion approaches differ in how the combine and implement these algorithms.

Object detection

A decision problem is solved in order to detect objects. All the sensor measurements are analyzed and a decision is made whether these originate from an object. In practice the definition of an object is highly variable. Thus, an object can be understood to be part of a set, such as for example everything that moves, or standalone, e.g., a motorcycle. The term used here is detection when the important is separated from the unimportant, where what is important is problem-dependent.

Classifiers

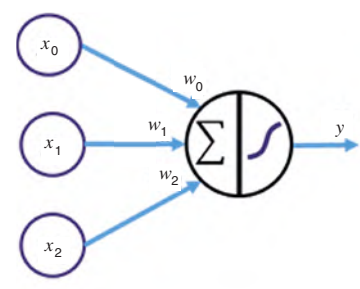
Decision problems are solved by classification algorithms. These algorithms implement classifiers. These are mathematical functions which constitute a relationship between an input and a discrete output. The input is a mathematical object (usually a vector) which contains a representation of the object, about which a decision is to be made. The output is connected with a label for a class to which this object belongs. In the case of object detection the sensor measurements (or quantities derived directly from them) constitute the input of the classification algorithms and the set of object types the output.

The mathematical expression of a classifier is an important design parameter. Of particular importance in view of their performance are neural networks (NN), where different types of classifiers exist. Neural networks are classifiers which are constructed by the combination of a number of simpler functions, i.e., neurons.

The parameters of a classifier can either be determined manually on the basis of a-priori knowledge or determined automatically. Automatic determination of the parameters happens as training as part of a machine learning process. The calculation of the output of a classifier for a given input is called inference.

Either data or rewards underlie the training. If exclusively input-output pairings (i.e., labeled data) are to be used during the training, the training is supervised. If the training is to use exclusively input data (i.e., unlabeled data), the training is not supervised. There is also the possibility of using a mixture of labeled and unlabeled data.

Linear classifiers and the perceptron



The simplest decision problem that a classifier could solve is binary. In this case the input of the classifier is to be assigned to one of only two possible classes. Because multiple-class decision can be made as a combination of a number of binary decisions, it is sufficient for the moment to consider the binary classifier.

The simplest binary classifier is based on a linear function $C : \mathbb{R}^N \rightarrow \mathbb{R}$, i.e., a first-order polynomial. This function assigns to each input vector $\vec{x}$ an output y as $y = \vec{w}^T\vec{x}$ where $\vec{w}$ is a vector with parameters.

A classification algorithm assigns the input to a class label. Because the function C supplies a real value at the output, within the framework of the classification algorithm the output y is to be mapped on a label set, e.g., {0,1}. This is done as a rule using a nonlinear function H. A linear binary classifier K thus consists of a composition of two functions $K = C \cdot H$, where C is a linear and H a nonlinear function. Figure 4 contains a graphical representation of a classifier.

The zero-level set of a linear classifier is a hyper level. Accordingly only such separating levels between the classes can be modeled in the input-vector space, which constitutes a significant limitation of linear classifiers in practice.

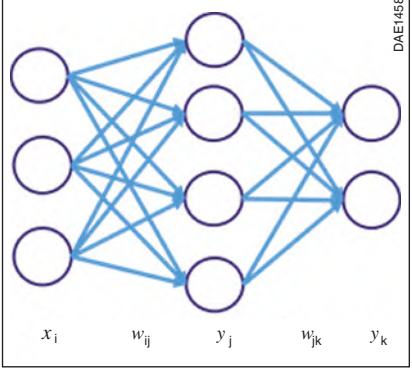
Figure 4: Graphical representation of a linear classifier

The perceptron is a linear binary classifier which uses the Heaviside function as nonlinearity. The Heaviside function is defined as:

$$H: \mathbb{R} \rightarrow \{0,1\}$$

$$H(y) = \begin{cases} 0, & y < 0 \\ 1, & y \geq 0 \end{cases}$$

Thus the input vector belongs to the class "1" when $y \geq 0$, otherwise it belongs to the class "0".



Deep neural networks

The perceptron originated from research conducted in the field of neuroscience as a model of an artificial neuron. In this context it is intuitive to combine neurons on the example of the brain in networks. Such networks can also model nonlinear interfaces and no matter which, however in practice only if they consist of neurons, where the nonlinearity in contrast to the Heaviside function is derivable like for example the sigmoid function:

$$S(y) = 1/(1+e^{-x})$$

Figure 5: Simple neural network consisting of three layers

x_i Neurons of the input layer,
w_{ij} Weights of the hidden layer,
y_j Neurons of the hidden layer,
w_{jk} Weights of the output layer,
y_k Neurons of the output layer.

Neural networks can be constructed by combining neurons in layers and building the layers on top of each other. The more layers are built on top of each other, the deeper a neural network will be. The simplest network consists of three layers:

– an input layer, whose task it is to make available only the input data of the network,
– a hidden layer, and
– an output layer, which consists entirely of neurons.

A simple neural network is shown in Figure 5. Thus the inputs x_i in the network are processed by the hidden layer:

$$y_j = \sum w_{ij} x_i ,$$

while the output layer y_k processes the outputs y_j of the hidden layer:

$$y_k = \sum w_{jk} y_j .$$

Such flat neural networks can already approximate all the possible nonlinear functions and are in this sense universal approximators. In practice, however, it has emerged that deeper neural networks process the information more efficiently than flat neural networks because they achieve comparable results with few parameters.

Compared to a flat neural network a deep neural network can aggregate information from the input at different abstraction levels and thereby eliminate interference factors, which have a detrimental influence on the decision quality. In the end the aggregation leads to the calculation of ever better features of the input data to the effect that these features become important supports for a good decision as to the class of an object. From this perspective a deep neural network consists of a feature-extraction transformation whose output is incorporated in a classifier, i.e., the output of the transformation is used as the input of a classifier.

Features which are derived from the input data by different calculations can simplify the classification problem. For example, motorcycles are to be distinguished from passenger cars on the basis of images. An important feature could

be the number of wheels. Thus, instead of analyzing pixels, the number of wheels is considered in order to decide on the class of the input object. However, the input must be transformed in order to reach the features that are of interest. The major practical advantage of deep neural networks is that this transformation is also learned during the training with the classifier parameters.

Supervised training

The case in which the training occurs on the basis of a set of labeled data is considered in the following because this method is currently through its performance the most widely used in the automated-driving environment and plays a particular role in perception.

The training is implemented as an optimization method. The parameters of the classifier are calculated as the argument of a function, which implements a specific measure, for which this function achieves its optimum. There are different measures which can be used. These measures are defined within the framework of learning theories.

Ideally a learning theory should result in a measure that minimizes the probability of an error relating to inference time. Because this is difficult or even impossible to determine, the measures usually consider the complexity of the classifier and the errors that it makes on the existing data record. The underlying intuition is that fewer complex classifiers generalize better. Where a classifier that generalizes wheel decides for new input data similarly well as for the data on which it was trained.

For deep neural networks an attempt is made in the case of preset complexity to minimize the error on the training data record. Because well designed deep neural networks are universal approximators, minimizing the error on the training record always works. However, the neural network then memorizes and cannot generalize. This contradicts the previous generalization assumption that the performance on the training data is reflected on previously unseen data. The result of this is that usual learning theories simply do not correctly grasp the generalization capacity of neural networks, which in turn compels the application of different heuristics. In order to that effect to maintain the generalization capacity, the quality on an additional data record, the validation data record, is observed during the training. The parameters of the neural network are set with the aid of the training data, but the training is interrupted as soon as the error on the validation data rises. There are also other different heuristics which improve the generalization capacity particularly for deep neural networks.

During the trainings an optimization problem is solved with the aid of a gradient method. Derivations are to be determined for this purpose. That is the reason why perceptrons, which use a non-derivable nonlinearity, are not suitable for neural networks.

For neural networks the training is conducted efficiently with the aid of the “backpropagation algorithm”. For deep neural networks special measures are to be taken to guarantee the successful convergence of this algorithm.

Tracking

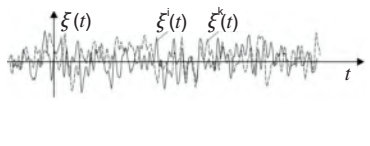
The sensors measure the scene in predefined time intervals. A measurement is available in each case at the end of a time interval. Through tracking an object is to be found again in each measurement and the properties of an object (e.g., its speed and orientation) observed over time. The tracking problem is aggravated by the fact that the movement of the object in the time interval between two measurements is unknown. In addition, sensor noise prevents a simple assignment of a measurement to an object.

The tracking problem is solved by the analysis of a chronological sequence of measurements. There are different approaches to conducting this analysis. Firstly, the modeling of the chronological sequence is to be considered as a discrete stochastic signal. The parameters of this model are established on the basis of a-priori knowledge.

What is notable in this connection is that certain object properties cannot be observed directly. This happens indirectly by way of an estimation of the attributes from the measured values over time.

Stochastic signal

A stochastic signal $\xi_t^{(k)}$ (Figure 6) depends on two parameters: the realization index k and the time index t. For a certain time index t_1 $\xi_{t1}^{(k)}$ is a random variable. A realization i corresponds to a time signals $\xi_t^{(i)}$.



A random signal can be described by the joint probability $p(x_1, x_2,\ldots, x_n)$, where $x_1 = \xi_{t1}^{(k)}$. For tracking applications in the field of automated driving x_1 is usually a vector (i.e., the state vector), which aside from the position of the tracked object at time t_1 can also contain the speed and other properties of the object.

To solve the tracking problem, it is necessary to calculate the state vector x_t at time t. For this purpose first the probability-density function $p(x_t)$ is determined and then x_t as the argument, for which $p(x_t)$ reaches the maximum. Assuming a Gaussian distribution x_t is calculated using the expectation operator.

The tracked object moves and does not change arbitrarily over time, its state vector at time t depends on the state vector at time t–1. Furthermore, the full history of the object is known and thus its current state can be better extrapolated. The probability of x_t can be calculated as a function of the full history of the object, i.e., what is sought is the conditional density $p(x_t | x_{t-1},\ldots, x_1)$.

This conditional density can be derived from the stochastic model $p(x_1,\ldots, x_n)$ of the tracking problem, i.e., inference is carried out in the model. The basis of inference is the property that a joint probability can be shown as the product of a number of factors, where each factor is either a conditional probability or a different joint probability.

Figure 6: A random signal – two realizations i and k are represented

Stochastic-graphical models

By showing a stochastic model in graphical form, it is possible to make an inference in an intuitive way. One method for this is to use so called stochastic-graphical models [3], also known as probabilistic graphical models (PGMs).

A graphical model reflects the way in which a joint probability can be represented as the product of conditional probabilities, together with the dependencies between different components (i.e., random variables) of the model. Each node represents a random variable or a set of random variables and each connection a dependency.

To solve the tracking problem it is assumed that the current state vector only depends on the previous one and only via it on all other previous states before last. The corresponding graphical model is shown in Figure 7.

Kalman filter

To solve the tracking problem it is not possible to observe the state vectors directly. Instead, each state is measured by a sensor and these measurements which are generated from the states are observed. Because the sensor measurements are subject to noise and the noise is not deterministic, each measurement is itself modeled as a random variable y_t. The complete graphical model of the tracking problem is shown in Figure 8.

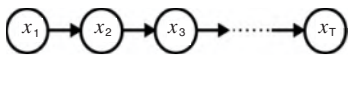
The tracking problem is now formulated as follows: Determine the state x_t from the previous state x_{t-1} (i.e., if the previous state is known) and all the observed measurements $\{y_1,\ldots, y_t\}$.

The algorithmic solution to this problem is the Kalman filter [3]. The Kalman filter operates on a number of simplifying assumptions. First, the assumption is made that all the random variables of the model in Figure 8 are subject to a Gaussian distribution. In this way the inference can be calculated in closed form. It is further assumed that the state process is a linear dynamic system: $x_t = Fx_{t-1} + v$, where v is Gaussian noise $N(0, V)$ with mean value 0 and variance V. Finally, it is assumed that the measurement model which connects the observations y_t with the states is also linear: $y_t = Cx_t + w$, where $w \sim N(0, V)$. The

parameters F, V, C and W can also be time-dependent.

On these assumptions x_t is estimated as a mean value of $p(x_t|y_1,\ldots,y_t)$, i.e., on the Gaussian assumption of the most probable realization of the random variable x_t. Thus x_t is estimated by the following relationship:

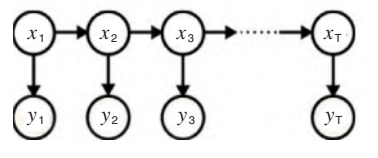
$$m_t = \int x_t \, p(x_t \,|y_1,\ldots,y_t) dx_t \,.$$



Tracking in practice

The Kalman filter as a rule delivers an acceptable solution to the tracking problem. In many cases, however, it is necessary to dispense with certain assumptions. If for example Gaussian assumption has to be dispensed with, the solution to the tracking problem must be provided by the particle filter or by variation approaches [3]. If the assumption of linearity falls away, the tracking problem can be solved by the extended Kalman filter or the unscented Kalman filter [3].

In practice it is often necessary to confronted the fact that the parameters F, C, V and W are time-dependent. The variances V and W should then be estimated from the scene via alternative paths from the available evidence. A similar produced is also followed to determine the measurement model.



The parameters of the state model F are themselves modeled as a random variable if they are time-dependent. The graphical model is adapted accordingly. In this case the inference is however even more difficult. Simplifications exist in the form of multi-model approaches. These conduct a discretization of the functional space of the state model. The most well known of these approaches is the Interacting Multiple Model (IMM) [4].

Figure 7: Stochastic-graphical model for the tracking problem

Compounding the situation is the fact that in practice usually a number of objects are to be tracked simultaneously. The association of new measurements with a specific object is then complicated. This association problem has various solutions, many of which are problem-dependent. The most well-known general approaches are “Nearest Neighbour”, “Joint Probabilistic Data Association”, “Multi Hypothesis” [5], and “Random Finite Sets” [6]. Of increasing practical importance in this connection is the “multi-Bernoulli filter”, which elegantly addresses this problem against the backdrop of stochastic-graphical models [7].

Vehicle navigation

Navigation systems

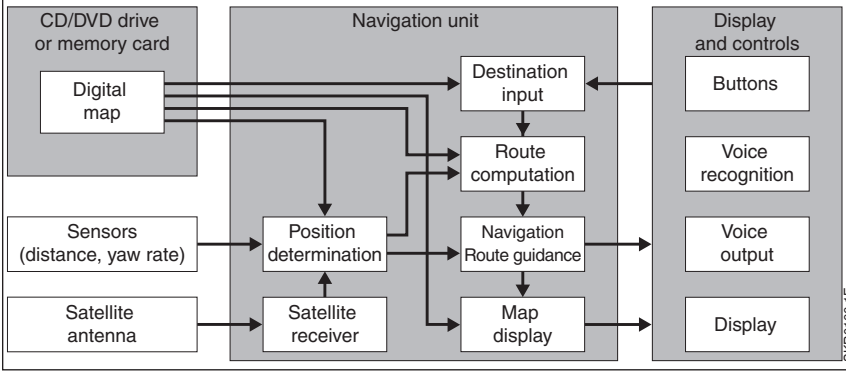
Determination of the position of a vehicle is based primarily on using the GPS satellite positioning system (Global Positioning System). The navigation system compares the determined position with a digital map and uses this map to calculate the route to the specified destination.

Vehicles can be equipped at the factory (original equipment) with permanently installed navigation devices (Figure 1). Portable navigation devices are also in widespread use. Compared with portable devices, permanently installed navigation devices in the vehicle provide better positioning quality and thus better route-guidance quality, since additional sensors for distance and direction signals (wheel-speed and yaw sensors) can be evaluated and the antenna can be mounted in a more favorable place for satellite reception. As original equipment, networking with other components is also common, i.e. integration in the operating concept of the vehicle is possible. Voice outputs can be issued via the audio system and muted for telephone calls. The route-guidance information can be displayed in the instrument cluster or in the head-up display and thus in the driver's primary field of vision.

Functions of navigation

Positioning

Satellite positioning system GPS



GPS is based on a network of 24 US military satellites which can be used globally for positioning (Figure 2). They circle the Earth in six different orbits at an altitude of approximately 20,000 km in twelve-hourly intervals. They are distributed in such a way that from every point on the Earth always at least four (for the most part up to eight) are visible over the horizon.

The satellites transmit special position, identification and time signals 50 times per second on a carrier frequency of 1.57542 GHz. The satellites each have on board two cesium and two rubidium atomic clocks which vary by less than 20 to 30 ns for the high-precision determination of the transmission time.

Position determination

The signals from the satellites arrive at the vehicle at different times on account of the different propagation times. The position of the receiver is calculated using the trilateration process. When the signals from at least three satellites arrive, the navigation device can calculate its own geographical position in two dimensions (terrestrial longitude and latitude). There is precisely one point which satis-

Figure 1: Navigation system

fies the distance conditions (signal propagation times). When the signals from at least four satellites arrive, this makes possible a three-dimensional position calculation (with altitude). Figure 3 shows this process in simplified form in only two dimensions.

Accuracy
The achievable accuracy is dependent on the position of the satellites that can be received relative to the vehicle. The greater the solid angle of the satellites to the vehicle, the better the possibility of position determination. The achievable accuracy is in the plane approximately 3 to 5 m, and for the determination of height approximately 10 to 20 m.

In deep urban canyons, satellite signals can only be received if the satellites are arranged to a large extent in a line, i.e. in the direction of the street/road. However, the solid angle formed by the satellites is then very small and position determination inaccurate.

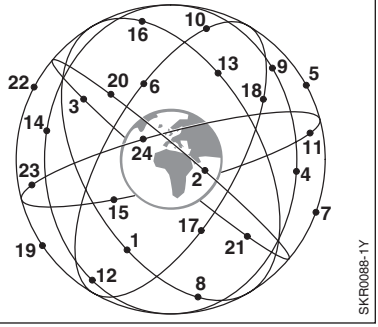
Errors in position determination may arise as a result of the reflection of the satellite signals, on metal-coated building fronts, for example.

Travel-direction determination
The direction of travel can be quickly sensed from the differences in the receive frequency of the satellites which are brought about by the Doppler effect. When a car drives towards a satellite, the GPS receiver of the navigation devices sees a higher frequency than the transmit frequency. It receives a lower frequency from satellites behind. This effect is sufficiently great from a driving speed of approximately 30 km/h to determine the direction.

Dead reckoning
Dead reckoning ensures position determination even if no GPS signals can be received, e.g. in tunnels. It adds cyclically recorded distance elements vectorially by magnitude and direction. The speedometer signal transmitted via the CAN bus is used to measure the distance. Changes in direction are recorded by a yaw sensor. In this way, the direction of travel is determined starting out from an absolute direction which was calculated with the GPS signals received last via the Doppler effect.

Map matching
The procedure known as map matching continuously compares the located position with the route on the digital map. In this way, the exact vehicle position can also be shown on the map, even if the located position is inaccurate (caused for example by the lack of a GPS signal and errors in dead reckoning). Route-guidance driving recommendations can thus be output at the best possible location. In addition, sensor errors and cumulative dead-reckoning errors can be compensated.

Figure 2: GPS satellite positioning system
1 to 24 satellites for determining the position of a vehicle.



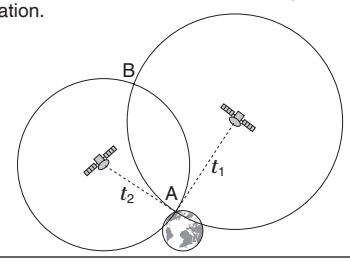


Figure 3: Position determination with GPS
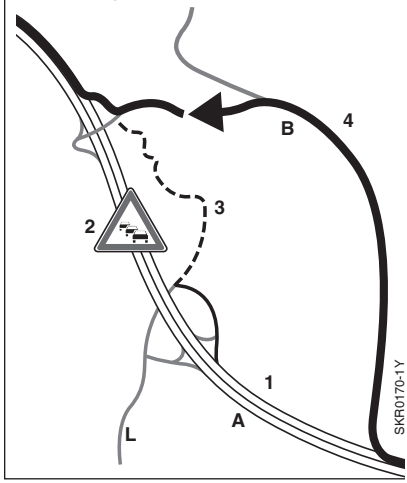
(Simplified two-dimensional view). Where the positions of the satellites are known, the possible reception locations for the measured signal propagation times t_1 and t_2 are on two circles around the satellites. The point of intersection A on the Earth is the sought-after location.

Destination entry
The destination is entered, for example, via the navigation-device panel with buttons, directly via the touchscreen, or by voice input. The user enters all the necessary details from a menu or in response to prompting by acoustically output instructions.

The digital map contains directories so that a destination can be entered as an address. Lists of all known place names are required for this purpose. In turn, all locations are allocated lists containing the names of the stored street names. To pinpoint a destination even further, the user can then also select road/street intersections, or the number of a building.

The destination can be quickly entered via the destination memory, with which already entered destinations can be called up again (e.g. the last destinations used or the destinations saved as favorites).



For airports, train stations, filling stations, multi-storey parking garages, etc. there are thematic directories in which these destinations (POI, Points of Interest) are listed. These directories make it possible, for example, to locate a nearby filling station or multi-storey parking garage (Figure 4).

In many navigation systems, destinations can also be marked in the map display (e.g. via the touchscreen).

Figure 4: Example of a map display with POI

Figure 5: Dynamic route guidance
1 Original main route, 2 Congestion,
3 Alternative route estimated by driver,
4 Best alternative route calculated by dynamic route guidance.
A Interstate/expressway,
B National highway,
L Secondary road.

Route computation
Standard computation
Starting from the current location, the navigation device calculates a route leading to the entered destination. The way in which the route is calculated can be adapted to suit the driver's preferences. He or she can stipulate different options such as, for example, optimizing the route
– based on driving time,
– based on an economic mean of driving time and driving distance,
– based on an estimated minimum fuel consumption,
– avoiding interstates/expressways, ferry crossings, or toll roads.

Route recommendations are expected within a few seconds of the destination being entered. A more critical scenario is recomputing the route if the driver departs from the recommended route. The new route recommendations must be supplied before the driver reaches the next intersection or junction.

Dynamic routing
Many radio stations transmit traffic messages not only as spoken text, but also in encoded form. The ALERT-C standard for

the Traffic Message Channel (TMC) is provided for this purpose. TMC content is transmitted via the Radio Data System (RDS) of FM radio.

The encoded messages contain, among other things, the location of a holdup, its extent, the actual length, and the reason for it. A navigation system can receive such an encoded message and determine whether a holdup is situated on a planned route. If this is the case, the route is recalculated, where the held-up section is evaluated with a longer driving time. A new route bypassing the holdup may be obtained (Figure 5). Further route recommendations will follow in accordance with the new route.

The TMC codes required for this are limited to interstates/expressways and major highways.

Route guidance

Route recommendations

Route guidance is performed by comparing the present vehicle position with the computed route. Route recommendations are mainly reproduced acoustically (voice output). This allows the driver to follow the directions without being distracted from the task of driving. Graphics, preferably positioned in the primary field of vision (e.g. in the instrument cluster), support the driver in understanding the directions. These graphics range from simple arrow symbols (Figure 6) through to the display of a map excerpt optimally adapted in size (Figure 4).

Figure 6: Pictogram as example of route guidance

Digital map

Map display

Depending on the system, the map is represented on color displays using scales as of approx. 1:2,000 in 2D, perspective 2D (pseudo 3D), or real 3D. This is helpful for obtaining a general overview of the route in the immediate locality or over a wider area. Additional information such as, for example, bodies of water, railroads and forests provide added orientation.

Digitization

High-precision official maps and satellite and aerial photographs provide the basis for digitizing the data. If the copies are insufficient or not up to date, on-site measurements/surveys are carried out. Digitization is performed manually from map material or satellite and aerial images. Names and classification of objects (e.g. streets, bodies of water, borders) are then integrated into the database.

Specially equipped vehicles drive along roads to record additional traffic-relevant attributes (e.g. one-way streets, passage restrictions, overpasses and underpasses, no turning off at intersections), after which the initial-digitization data are checked on site. The results from these recording vehicles are incorporated into the database and are used to produce digital maps.

Data memory

Because their storage capacity is at least seven times larger, DVDs have now superseded CDs as the storage medium for digital maps. On the other hand, new systems are mainly being supplied with hard disks or SD cards, where the latter clearly dominate in portable systems. These writable storage media open up the additional possibility of the navigation systems being able to adapt to their users' preferences.

Night-vision systems

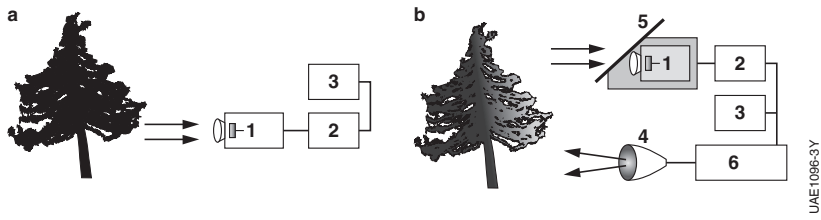
Applications

Darkness leads to two significant restrictions to a driver's sense of sight. Firstly, despite modern lighting technologies such as xenon and LED headlamps, only a very limited illuminated field of vision is available. For example, the range of a typical low-beam headlamp is just 50 to 60 m. The visibility range can be increased to over 150 m by using high-beam headlamps, this can only rarely be used during night driving, however, due to the tendency to cause glare for oncoming traffic.

Secondly, the capability to recognize objects in the dark by their color and contrast – which differ from those during daylight – is often greatly reduced. Pedestrians wearing dark clothing, for example, are frequently difficult to recognize even when they are within the range of the low beam headlamp. Night-vision systems and cutting-edge headlamp technologies help enormously in this respect to increase road safety.

Camera-based night-vision systems are classified into two different types based on their underlying spectral ranges: far- and near-infrared systems.

Far-infrared systems



Operating principle

Night-vision systems based on far infrared (FIR) have been used in military applications for years. They use heat radiation in a spectral range between 7 and 12 µm which is relatively far removed from the visible spectral range (hence "far infrared"). They were used for the first time in motor-vehicle applications in 2000 in the USA. They detect with a thermal-imaging camera the heat radiation that is emitted by objects (Figure 1a). These are referred to as "passive" systems since they do not need any additional radiation sources to illuminate objects.

The pyroelectric thermal imaging camera, or microbolometer camera, is only sensitive in the wavelength range of 7 – 12 µm. Because the glass in the windshield is not transparent for these wavelengths and the camera must be located on the outside of the vehicle.

Thermal imaging cameras use germanium lenses, or tex-glass with high amounts germanium and a corresponding transmission band. Currently available cameras have a resolution up to VGA resolution (video graphics array, 640 × 480 pixels). The camera signals are processed in an ECU. The generated video signal is output to a display (in the instrument cluster, in the center

4 Infrared headlight, 5 Windshield, 6 Vehicle.

console or in the windshield as a headup display), on which the thermal image can be viewed.

Image display
Hot objects are shown in the image as light contours against dark (cold) surroundings (Figure 2a), where the contrast improves the higher the temperature difference between object and air temperature. However, if a warm object (e.g., a person) is standing in front of a hot tail panel of a tourist bus, he will not be defined by the camera since the sensor is "dazzled".

However, the image display is rather unusual for the viewer since the appearance does not correspond to that of a normal reflected image.

Figure 2: Comparison of the appearance of far-infrared and near-infrared systems
a) Far-infrared system,
b) Near-infrared system.

Near-infrared systems

Operating principle
Near-infrared systems (NIR) are based on infrared radiation between 800 and 1000 nm near the visible spectrum (near infrared). Objects do not emit any radiation in this wavelength range. The area ahead of the vehicle must be illuminated with infrared headlamps (Figure 1b). They are referred to as "active" systems for this reason. An infrared-sensitive camera records the scene, i.e., the infrared radiation reflected by the objects. The image signal is transferred to a control unit that in turn forwards the processed image – as in the far-infrared system – to the display. The driver sees – in both systems – a current image of the road situation (Figure 2b) that plays out like a film.

Functioning principle
Near-infrared night-vision systems exploit the different spectral sensitivities of the human eye and electronic silicon-based images. The spectral sensitivity of the human eye is described by the $V(\lambda)$ curve (Figure 3) and comprises the wavelength range from 380 nm (violet) to 780 nm (red). The maximum sensitivity lies in the range of 550 nm (green). Compared to this, the spectral sensitivity of an imager reaches considerably further into the range of high wavelengths, only ending at around 1,100 nm.

Infrared headlamps
Halogen lamps, like those commonly used for automobile headlamps, have a infrared radiation content. This ranges from the limit of the visible spectrum (380 – 780 nm) up to wavelengths beyond 2,000 nm, with a maximum between 900 nm and 1,000 nm. The upper limit of the useful wavelength when a video camera is used is 1,100 nm, the sensitivity limit of silicon.

Conventional halogen high-beam headlamp models are used as infrared headlamps for this reason. In halogen high-beam headlamp models, visible light is blocked by an additional filter in the light path without significantly reducing the usable infrared part (Figure 3).

The emitted radiation cannot be perceived by the human eye.

The infrared headlamps that are used have a similar range and spatial characteristics to those of conventional high-beam headlamps, which means that the visual range achieved is comparable but without negatively dazzling other road users (Figure 4).

Suitable selection of the filter characteristic curve takes competing requirements into account. The spectral sensitivity of the imager decreases as the wavelength rises. In order to exploit its sensitive range, the filter edge for low wavelengths should lie near to the limit for visible light. On the other hand, in order to prevent non-permitted red impression for front headlamps, the filter edge should be shifted more towards higher wavelengths. Both requirements can be met by carefully selecting the transmission in the visible range, the position of the filter edge, and the edge steepness.

The infrared headlamps are either integrated into the headlamp module or mounted as external modules e.g. in the front apron of the vehicle.

Imagers

The extreme lighting conditions – darkness and very high intensity dynamics, e.g. due to headlamps of oncoming traffic – result in very high requirements for the projection properties of the camera lens, as well as for the imager. The sensitivity to darkness of the imager determines the visual range the system can achieve; the extent of dynamics is deter-

Figure 4: Range of vision of night-vision system

2 Spectral sensitivity of video camera,
3 Spectral transmission of filter.

mined to a great extent by the resistance to dazzling.

The CCD chip (Charge Coupled Device) features very high sensitivity to darkness, but as a rule it does not achieve the required intensity dynamics without additional measures. In addition, it tends in the case of large brightness differences in the image to override individual, bright image areas. The CMOS chip (Complementary Metal Oxide Semiconductor) has lower sensitivity to darkness, but doe achieve an intensity dynamic of over 100 dB. There needs to be compensation for every pixel of the fixed pattern noise of this technology. Adjustable, nonlinear characteristic curves mean that these imagers can be very easily regulated and adapted to changing lighting conditions.

Lighting up the road scene with radiation in the wavelength range between 700 nm and 1,000 nm (infrared) provides the imager of the camera with a useful signal that depends on the illumination strength and spectral reflective capabilities of the illuminated scene.

Activation strategy

One major aspect of the system is the automatic activation of the infrared headlamps. They emit light of high intensity that the human cannot perceive or can only perceive to a minor degree. To avoid damage to the eyes caused by unperceived exposure at short distances (e.g., mechanics working in the service workshop), the infrared headlamps are only activated automatically when a certain driving speed is reached with the low-beam headlamps switched on. If the speed falls below the threshold, it is automatically deactivated. This excludes occurrence of the critical combinations of long exposure and spatial proximity to the emission source. In addition, the infrared headlamps only light up if the adjacent low beam is also switched on. Through this, the blinking reflex is triggered when the headlamp is looked at, as a result of which the exposure of the eye is greatly reduced.

1st generation night-vision systems

The first system was introduced in 2000 in the American market in Cadillac cars and showed the image of an FIR camera in a head-up display (HUD). This was closely followed by NIR systems in the Japanese market, which also used a head-up display. Due to the high risk of distracting the driver caused by moving images in the primary field of view, these systems were withdrawn from the market after a few years. They could not make the breakthrough in the European market either.

In Japan these first NIR-based systems were initially introduced in 2003 in a simple version in terms of image display and with conventional CCD camera technology. In 2005 an NIR night-vision system with significantly enhanced performance was introduced in the Mercedes S-Class (Night Vision).

In German cars the processed image from the camera (in both far- and near-infrared systems) was displayed in the first systems on a graphics-capable monitor in the instrument cluster (Mercedes) or in the center-console area (BMW). When positioning the monitor in the vehicle, it is important to ensure that the monitor is as close as possible to the windshield and not too far removed from the driver's normal line of sight so that the driver does not have to divert his/her attention from the road and traffic for too long. Ergonomic tests featured the best results in relationship to read-off time and distraction in an arrangement with the monitor in the instrument cluster.

2nd generation night-vision systems

New image-processing procedures enable pedestrians to be reliably classified by reference to their typical outlines (head and shoulder area). This makes it possible not only to warn the driver acoustically but also still to highlight the detected pedestrian on the monitor in order to improve the driver's perception of a dangerous condition. This is particularly important in far-infrared systems, because the image on account of its strange appearance is more difficult to interpret than a near-infrared image.

This feature is important insofar as the majority of fatal accidents involving pedestrians happens at night. In this way, such systems can help to significantly reduce nighttime accidents involving pedestrians. Systems with pedestrian recognition are now fitted as standard in both technologies (near- and far-infrared systems) in German vehicles.

The further development of head-up display technologies offers the additional display of a warning when pedestrians are detected in the primary field of view. Displaying a warning symbol on the windshield represents and effective display format with minimal distractions.

An alternative for simpler systems is a cost-effective optical warning on the base of the windshield that displays the direction of the detected obstacle. These display formats would be a cost-effective alternative for lower classes of vehicles.

3rd generation night-vision systems

New headlamp technologies in the meantime permit the omission of the image display, and as a result the driver is not distracted by looking at the display. A pedestrian detected by the image-processing system can be lit or “flashed” with the aid of a small additional headlamp. This automatically directs the driver's attention towards the pedestrian, who now knows they have been detected.

New pixel-light concepts with numerous high-power LEDs whose light is diffracted by micro-mirrors make it possible to create light cones of almost any shape and facilitate continuous driving on high beam. If a pedestrian or an oncoming vehicle is classified by the imaging system, the light/dark boundary is automatically lowered to such an extent that dazzling no longer occurs.

Parking and maneuvering systems

Application

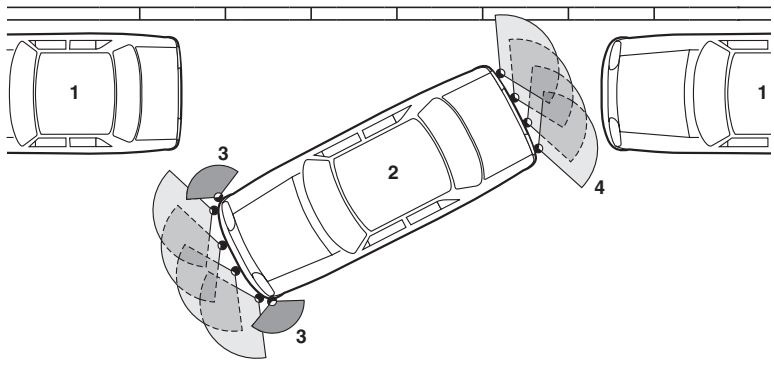
On virtually all motor vehicles, the bodies have been designed and developed in such a way as to achieve the lowest possible drag-coefficient values in order to reduce fuel consumption. Generally speaking, this trend has resulted in a gentle wedge shape which greatly restricts the driver's rear view when maneuvering. Obstacles are difficult to recognize. This also applies to obstacles beside the vehicle and objects in the driver's blind spot.

Ultrasonic parking aids were initially developed in the past to improve the overview around the vehicle. Thanks to new algorithms and the inclusion of video technology, these systems have undergone further development into maneuvering aids through to (semi-)automated parking systems.

A distinction is made between passive and active systems based on the system configuration. Passive systems warn or inform the driver about hazardous situations, while active systems intervene on a task- and situation-specific basis and steer the vehicle, such as into a parking space.

Ultrasonic parking aid

Parking aids with ultrasonic sensors support parking maneuvers. They monitor an area of approx. 20 cm to 250 cm behind and, if necessary, in front of the vehicle. Obstacles are detected and their distance to the vehicle is indicated by visual or acoustic signals.



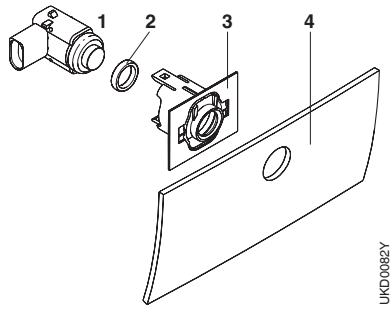
Numerous vehicle manufacturers offer parking aids as optional equipment; in many premium vehicles they are now fitted as standard equipment. Systems which can also be adapted to older vehicles are offered for retrofitting.

System

The parking aid essentially consists of ultrasonic sensors (see Ultrasonic sensor technology), the electronic control unit (ECU), and warning elements. The protection area is determined by the range and number of sensors and by their emission characteristic.

As a rule, vehicles with purely rear protection have four ultrasonic sensors in the rear bumper; some large vehicles, e.g. off-road vehicles (SUVs), also use six sensors. Front-end protection is provided by four

Figure 1: Scanning range of the parking system with rear- and front-end protection
1 Parked vehicle, 2 Parking vehicle, 3 Ultrasonic sensor at the front end,
4 Ultrasonic sensors at the rear end.



to six additional ultrasonic sensors in the front bumper (Figure 1). For vehicle integration, the installation angle and spacing of the sensors are determined specific to the vehicle. This data is taken into account in the control unit's calculation algorithms. Specifically adapted mounting brackets secure the sensors in their respective positions in the bumper (Figure 2).

The system is activated automatically when reverse gear is engaged. In the case of systems with front-end protection, the system is activated automatically when the vehicle speed drops below a threshold of approximately 15 km/h (manufacturer-specific). During operation, the self-test function ensures continuous monitoring of all system components.

Distance measurement
The ultrasonic sensors emit ultrasonic pulses and receive the sound reflected by an obstacle. The piezoceramic element generates an analog electrical signal, which is evaluated in the sensor. The distance between the vehicle and the detected obstacles is derived from the propagation time between the ultrasonic pulse being emitted and the echo pulses being reflected back from obstacles (see Ultrasonic sensor technology).

Figure 2: Principle of mounting an ultrasonic sensor in the bumper
1 Sensor,
2 Decoupling ring,
3 Installation housing,
4 Bumper.

Electronic control unit (ECU)
The ECU contains a voltage stabilizer for the sensors, a microcontroller, and all the interface circuits needed to adapt the different input and output signals. The software assumes the following functions:
– activating the sensors and receiving the echo,
– evaluating the propagation time and calculating the distance to the obstacle,
– activating the warning elements,
– evaluating the input signals from the vehicle (e.g. signal for engaged reverse gear),
– monitoring the system components including fault storage,
– providing the diagnosis function.

Warning elements
The warning elements display the distance from an obstacle. Their design is specific to the vehicle, and they usually provide for a combination of acoustic signal and optical display. Primarily LEDs, but also LCDs are currently used for optical displays.

In the case of vehicles with a display monitor in the center-console area or in the instrument cluster, the vehicle can be shown together with the obstacles detected by the system, e.g. from a bird's eye view. This generally improves the driver's view of the situation.

Ultrasonic parking assistant

The parking assistant is based on the ultrasonic parking aid and is designed along evolutionary lines in stages. Each stage is a self-contained function.

All the ultrasonic systems shown in the following are already in series production.

Parallel parking

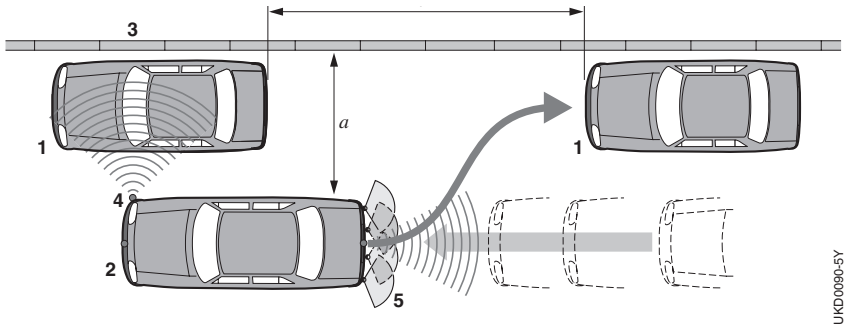
Information-providing parking assistant

After the system is activated by the driver, an ultrasonic sensor mounted on each side of the vehicle measures the length and depth of the parking gap as the vehicle drives past the gap (Figure 3). The length is obtained by evaluating the ESC speed signal (ESC, Electronic Stability Control, driving-dynamics control). The parking assistant then issues the driver with a signal as to whether the parking gap is long enough, tight or too short. If there is an obstacle in the parking space, this is rejected. This requires the above-mentioned sensors with a range of up to approximately 4.5 to 5.5 m.

Once the parking space has been measured, the determined geometry of the environment can be used to ascertain the optimal trajectory for the parking process. The parking assistant requires the signals from the steering-angle sensor (from the driving-dynamics control, ESC) for this purpose. During the parking process, the system can now give the driver a recommendation regarding how he or she should optimally turn the steering wheel in order to park in the space as smoothly as possible. During the parking operation, the trajectory is continuously recalculated and shown in a display. Figure 4a shows an example of a driving recommendation from the system.

Steering parking assistant

The next evolutionary stage is a system with automatic steering activation. A prerequisite is that the vehicle must have electrically activated power steering.



As before, the driver has to inform the system of his or her desire to park by pressing a button. After the system measures the parking space, the driver is notified whether the length of the parking space is sufficient. This can be accomplished for example by a corresponding graphics display in the instrument cluster (Figure 4b). Now the driver simply needs to put the vehicle in reverse and control the vehicle's linear motion (by braking and accelerating) – the parking assistant takes over the steering. When the parking process is done, the driver is notified accordingly.

One-step and multi-step parking

In the case of both the information-providing and the steering parking assistant, the system decides whether to park in one step or multiple steps, based on the length of the parking space. One-step parking is always selected if the parking

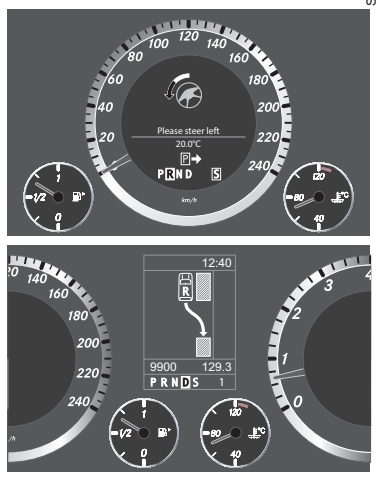


Figure 3: Parking assistant

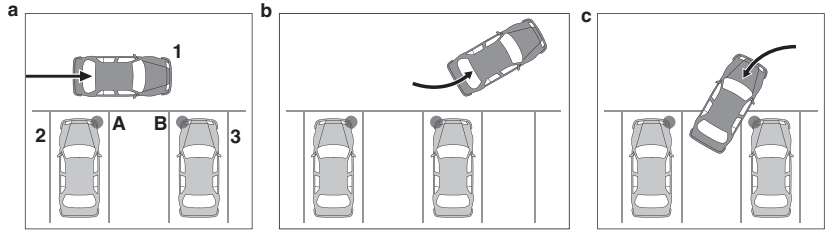
1 Parked vehicle, 2 Parking vehicle, 3 Parking space boundary (e.g., curb), 4 Side-detecting ultrasonic sensor, 5 Ultrasonic sensor in the rear area.
a Measured depth of the parking space, *l* Length of the parking space.

space is long enough. If the parking space is short, the parking assistant decides on multi-step parking, based on the length of the space and the vehicle's possible steering radius. Then the system prompts the driver to shift gears accordingly.

Figure 4: Display of the parking assistant of the multifunctional display in an instrument cluster
a) Display of the information-providing parking assistant,
b) Display of the steering parking assistant.

Perpendicular parking



Semi-automated parking is not limited to the parallel parking functions described, but also permits parking in spaces perpendicular to the direction of travel (Cross-Parking Assist, Figure 5).

As with parallel parking, the length of the parking space is measured as you drive by it. To do this, the corner of the vehicle on the left (marked as corner point A in Figure 5) is taken as the initial reference point for the parking maneuver. If there is also a vehicle to the right of the parking space, its corner (corner point B) is also taken into account.

Before beginning the parking process, the vehicle moves forward until it can calculate a parking trajectory. Then, after reverse gear is engaged, the vehicle parks along the trajectory, which is continuously recalculated and corrected if necessary. The signals from the rear ultrasonic sensors are continuously factored into the parking maneuver. Due to the limited detection range of the ultrasonic sensors, the driver is responsible for making sure the entire length of the parking space is free of obstacles.

As with the previously described parking assistants for parallel parking, for this function there are also information-providing and – if the vehicle is equipped with electric power steering – steering system versions.

Figure 5: Perpendicular parking

b) Preparation for parking,
c) Parking in the parking space.
1 Parking vehicle, 2 Left parked vehicle, 3 Right parked vehicle.
A Right corner point of the left parked car,
B Left corner point of the right parked car.

Assistant for leaving a parking space
In principle, the parking aid can also be used for leaving parallel parking spaces. To do so, the system first moves the vehicle into an appropriate starting position, so that the maneuver can be done in one step. The driver is responsible for paying attention to the traffic and accelerating or braking at the right moment. Simply touching the steering wheel turns off the function.

Maneuvering assistant
Traces of paint on parking-garage pillars and walls testify to frequent, sometimes costly collisions with vehicles. The system for warning about objects next to the vehicle helps prevent that.

Ultrasonic sensors mounted on the front of the vehicle at the sides detect permanent obstacles in the vehicle surroundings at a slow driving speed (up to 30 km/h) (Figure 6). The maneuvering assistant saves their positions, so that these are known even after the obstacles are no longer in the scanning range of the sensors. The side distance to the saved obstacles is continuously calculated using the steering angle sensor signal. If a risk of collision is detected, the driver receives an audible warning (side distance warning). A bird's-eye view of the situation can also be shown on the central display. This system was introduced to serial production in 2013.

Video systems

Rearview camera
Rearview cameras were already first introduced some time ago in Japan, but did not become prevalent in Europe due to the heavily distorted picture of the super-wide-angle lens. The breakthrough in Europe didn't come until there were systems to correct the image distortion.

Today's systems have a wide-angle camera installed in the rear end of the vehicle, usually in the recess of the handle to the trunk. The camera image appears in the center console display when driving in reverse. Newer systems with additional lines to help estimate the distance and display the predicted lane make it easier for the driver to maneuver (Figure 7).

The camera is intended only to provide information and does not provide the driver with any warnings.

Front-end camera
Visibility all around the front of the vehicle can also be provided by a video camera with a 180° wide-angle lens. It also provides a view of traffic from the sides, for example, when pulling out of a driveway (Figure 8). Since the driver is seated farther back in the vehicle, the view from there is not as good as from the camera installed in the front of the vehicle.

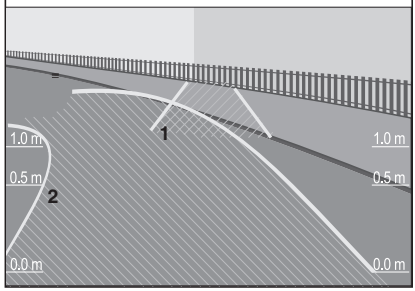
1 Trajectory without turning the steering wheel,
2 Trajectory calculated from the current steering angle.



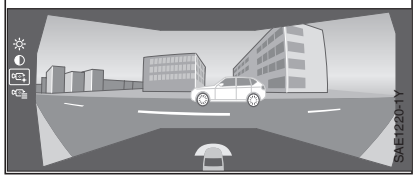


Figure 8: Driver assistance with front camera

View of the main road when driving out of a private driveway.

360° all-around visibility

The whole area around the vehicle can be detected using four super-wide-angle cameras installed around the vehicle (top-view system, Figure 9). The fields of view of the individual cameras overlap in the shaded areas. The four individual images are converted into one overall image using the stitching method. Projecting the four images into an imaginary bowl structure makes it possible to provide the driver with a bird's-eye view and a view from different directions of his or her own vehicle in the display.

K1 to K4 Cameras on the front, rear and sides of the vehicle.

Fusion of video and ultrasound technology
Further improvements can be achieved through data fusion of the ultrasound system's signals with the video camera's signals. For example, in addition to the lane information, distance information from the ultrasound system can be displayed in the image from the mono rearview camera as well, which cannot be used for measuring distance (Figure 10). By doing so, the driver receives even more meaningful information about the area by the rear of the vehicle.

More recent development steps
Further functions and options have been created through the further development of semi-automated parking by using intelligent image-processing algorithms (see Computer vision). The combination of intelligent camera systems with ultrasonic sensors form the basis for the automated parking and maneuvering assistance systems outlined in the following.

Parking maneuver assistant (park maneuver control)
Further development of the steering parking assistant has the vehicle now controlling linear motion as well. To initiate the parking maneuver, the driver needs only to put the gear in reverse; the system handles the rest. This system was launched into series production in 2014.

Remote-controlled parking assistant (remote park assist)
The driver drives past a parking space and receives a signal from the parking assistant is the space is sufficiently long. The driver gets out of the car and taps the "Parking" function on their smartphone. As long as the driver leaves their finger on the smartphone screen the car drives along the previously calculated trajectory into the parking space. If during the parking maneuver a critical situation arises (e.g., pedestrian crosses the trajectory), the driver simply has to take their finger off the screen and the car will stop immediately.

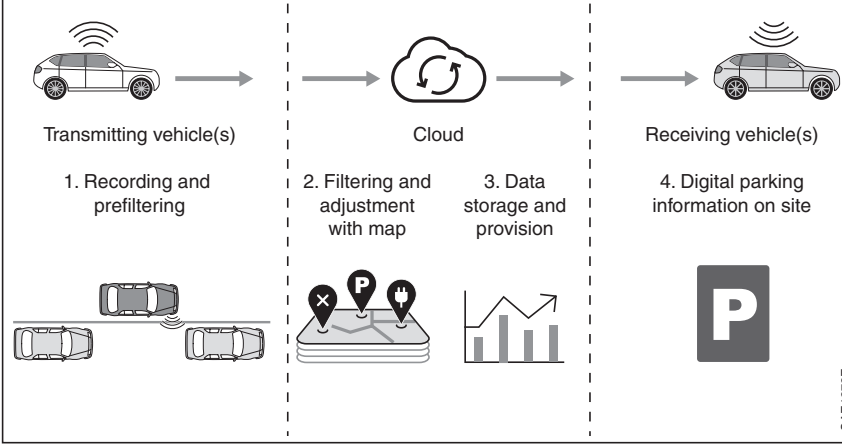
Home-zone park assist
In parking garages or parking lots with reserved parking spaces in the home environment it will in future be possible to teach the car a parking maneuver from a defined parked position to the driver's own parking space by driving the route and maneuvering the car into the parking space. The driver can then leave the car in the parked position and start the car by actuating a remote control as described above. The car then automatically drives the taught course to the parking space and parks up there. If the driver wants to use their car again, they can fetch it again from the garage with the same remote control. The car will then stop in the original parked position.

Highly automated, remote-controlled parking (remote park pilot)
This function is used above all for maneuvering into and out of tight garages or parking spaces. Because it is in principle possible to park a car without the need for a driver, the user can start the parking operation in front of the garage with a remote control, an intelligent remote key, or their smartphone by touching an operating element. The car then drives under automated guidance into the garage. The driver does not need to be present for this. This function calls for very robust environment recognition and high safety requirements.

This system was launched into series production in 2016.

Autonomous parking (automated valet parking)
A car that parks autonomously was presented to the public for the first time in 2007 as part of the American "Urban Challenge", a competition for automated driving in an urban environment. Here the car was parked at the entrance to a parking lot. The car found a free parking space itself and parked in it.

With this new function too the car is parked in a predefined drop-off area in front of a parking garage or a basement garage. For the subsequent parking maneuver the driver gets out of the car and selects the “Find parking space” function on their smartphone. The the car drives under fully automated guidance into the parking garage, finds a parking space itself, and parks in it. The same operating procedure can be used to fetch the car from the garage. For driving and maneuvering the car uses its own on-board sensor technology (ultrasonic and video-based systems) and signals from an infrastructure of the parking garage (see also Automated valet parking).



Such systems can have a significant influence on the infrastructure of future parking garages: The vehicles can be parked much more tightly since large spaces do not have to be kept for getting in and out. The storey height can be reduced. Long-stay parked vehicles can be “blocked in”.

Networking with the “Cloud”, Connected Parking

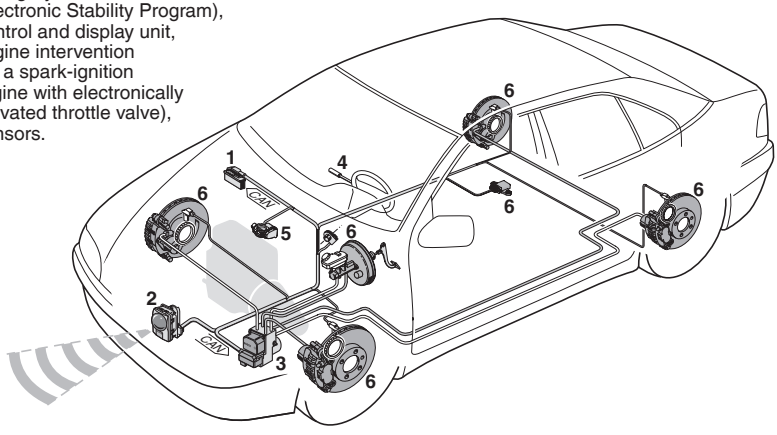
Looking for a parking space involves driving unnecessarily long distances. The resulting fuel consumption and exhaust emissions add up to a huge environmental impact.

Remedial action can in future be taken by a system which actively supports the driver in looking for a parking space. This system is based on the interaction between vehicles and infrastructure (V2I, Vehicle to Infrastructure Communication, Figure 11). Vehicles which are situated in an area with parking spaces (e.g., in an urban area) detect the geographical location of available parking spaces and their length with their on-board sensor technology and transmit this information to a “Cloud”. In the Cloud the data are filtered and the parking position is inserted into a map. All the relevant information is stored and made available to possible users. As shown in Figure 11 by way of example, the driver receives information on occupied and vacant parking spaces and parking paces with a charging station. Vehicles looking for a parking space can download the information from their surroundings from the Cloud and receive route-direction information to a neighboring vacant parking space or to a parking space as close as possible to the input destination in the navigation system.

Figure 11: Parking-space search with Vehicle to Infrastructure Communication

Adaptive Cruise Control

Function



Like the basic cruise-control system that has been available as a standard feature for quite some time, Adaptive Cruise Control (ACC, also known as Tempomat) can be categorized as a driver-assistance system. The vehicle-speed controller regulates the driving speed to the desired speed set by the driver using the operating unit of the cruise control. In addition to this function, adaptive cruise control senses the distance and the relative speed for the vehicle in front and uses this information with additional data from the driver's own vehicle (e.g. steering angle, yaw rate) to regulate the time gap between the vehicles. It thus adapts the speed to the vehicle ahead and maintains a safe distance. The adaptive cruise control is equipped with a long-range radar to detect vehicles that are traveling in front in the same lane or also obstacles that are moving in the sensor's sensing range, and necessitate that the vehicle be braked (Figure 1).

Design and function

Adaptive cruise control is a convenience system that relieves the driver of routine tasks, but not of his/her responsibility to maintain control of the vehicle. This is why the driver can override this function at any time through intervention or deactivation (e.g. by operating the accelerator or brake pedal).

Ranging sensor
Current ACC systems for the most part have a radar sensor which operates in a frequency range of 76 to 77 GHz (see Radar sensors). The radar beams emitted by the radar sensor are reflected by vehicles ahead and analyzed with regard to propagation time, Doppler shift, and amplitude ratio. These values are used to calculate the distance, speed, and angle position relative to the vehicles ahead. The evaluation and control electronics (radar-sensor check unit) are integrated in the sensor housing. They receive and transmit data via a CAN data bus from

Figure 1: Adaptive cruise control for a passenger car

4 Control and display unit,
5 Engine intervention (on a spark-ignition engine with electronically activated throttle valve),
6 Sensors.

or to other electronic control units that influence the engine torque and brakes (Figure 2).

There are also ACC systems that work with laser beams in the infrared range (see Lidar, Light Detection and Ranging). The functioning principle is similar, whereby the use of an optical beam means that restrictions compared to the radar systems must be accepted in poor weather conditions (fog, rain, snow) (see e.g. [5]).

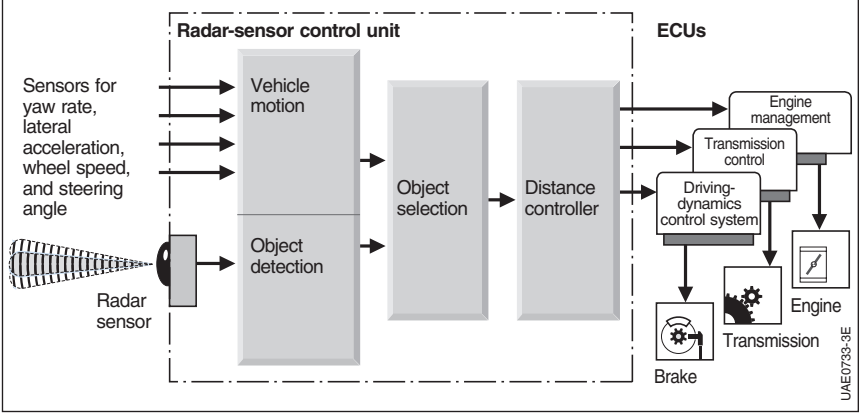
Course setting

To ensure reliable ACC operation no matter what the situation – e.g. also on curves/bends – it is essential that the vehicles traveling ahead can be allocated to the correct lane(s). For this purpose, the information from the driving-dynamics control (Electronic Stability Program) sensor system is evaluated with regard to the ACC-equipped vehicle's own cornering status (yaw rate, steering angle, wheel speeds, and lateral acceleration).

Setting options

The driver inputs the required speed and the required time gap; the time gap available to the driver ranges from 1 to 2 s. The time gap to the vehicle in front is calculated from the radar signals and compared with the required time gap specified by the driver. If the time gap is shorter than the required gap, the ACC system responds in a manner appropriate to the traffic situation by initially reducing engine torque, and only if necessary by automatically braking the vehicle. If the required time gap is exceeded, the vehicle accelerates until either the speed of the vehicle ahead or the desired speed set by the driver is reached.

Engine intervention



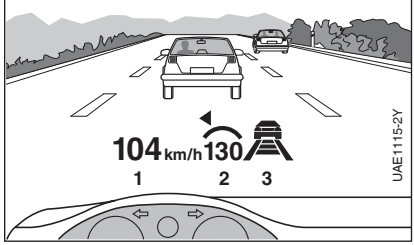
Cruise control is run via the electronic engine-performance control system (e.g. Motronic, electronic diesel engine control). This system allows the vehicle to be accelerated to the required speed or, if an obstacle appears, to be decelerated by reducing the drive torque.

Brake intervention

If the deceleration caused by engine control intervention is insufficient, the vehicle must be braked. For passenger cars the driving-dynamics control (Electronic Stability Program) is required for this purpose; this can perform a brake intervention. For commercial vehicles, an electronic braking system (EBS) is sufficient. Usually, this also involves the available retarder or engine brake for wear-free deceleration.

Due to the configuration of ACC as a comfort system, the deceleration calcu-

Figure 2: Basic structure of ACC system



lated by the controller is limited nowadays to approx. 2 to 3 m/s^2. Should this be insufficient due to the current traffic situation (e.g. vehicles in front braking sharply), a visual and audible signal is issued to the driver indicating that he or she must assume control. The driver must then initiate the corresponding braking deceleration via the standard brake. The ACC does not include safety functions such as emergency braking.

If necessary, with ACC activated, the stabilizing systems Antilock Brake System or driving-dynamics control are activated in the usual manner. Depending on the parameterization of ACC, stabilizing interventions from the Antilock Brake System or driving-dynamics control cause ACC to shut off.

Display
The driver must be provided with at least the following information:
– Display of the desired speed
– Indication of the switch-on status
– Indication of the required time gap selected by the driver
– Indication of the follow-up mode, which informs the driver as to whether the system is controlling the distance to a detected target object or not.

The information can be displayed, for example, in the instrument cluster or in a head-up display (Figure 3).

Figure 3: Information shown in the head-up display
1 Present speed,
2 Desired speed,
3 ACC status (Adaptive Cruise Control).

Control algorithms

Control modules
As a general principle, the control system for cars as well as for trucks consists of three control modules.

Cruise control
If the radar sensor has not detected any vehicles in front, the system maintains the vehicle's speed at the cruising speed set by the driver.

Tracking control
The radar sensor has detected vehicles in front. Control essentially maintains the time gap to the nearest vehicle at a constant setting.

Cornering control
When negotiating tight bends, the radar sensor can "lose sight" of the vehicle in front because of the limited width of its field of vision. Until the vehicle comes in sight of the radar again, or until the system is switched to normal cruise control, special measures come into effect. Depending on the vehicle manufacturer, the speed, for example, is kept constant, current lateral acceleration is adapted or ACC is switched off.

Object detection and lane allocation
The central task of the radar sensor and its integrated electronics is to detect objects and allocate them either to the same lane as the one on which the truck is traveling, or to a different lane. This lane allocation requires both exact detection of vehicles ahead (high angle resolution and accuracy) and exact knowledge of the vehicle's own movement. The decision as to which of the detected objects is used as the reference for adaptive cruise control is essentially based on a comparison between the positions and motion of the detected objects and the motion of the system's own vehicle. Here, in particular in the case of commercial vehicles, it is not always necessarily the next vehicle ahead that is selected. Under certain circumstance, it makes better sense to use the next vehicle but one, e.g. when a passenger car filters in from

the slip lane and continues rapid acceleration to change quickly to the fast lane.

Electronic structure
Apart from the data transmitted by sensors (Figure 2), ACC requires additional data from the engine, retarder (for commercial vehicles), transmission and driving-dynamics control units, and which are transmitted via the CAN data bus. Conversely, these control units convert the accelerations requested by ACC into drive and braking torques. The coordination of the actuators (e.g., distribution of the required braking torque to the available brakes) can take place both in the driving-dynamics control unit and in a guidance computer or in the ACC control unit itself.

Adjustment
The radar sensor is fitted in the frontal area of the vehicle. Its radar lobe scans are aligned relative to the vehicle longitudinal axis. This is done by means of the adjustment screws in the mounting area of the sensor. If it is moved out of alignment by physical force, e.g. deformation of the mounting due to accident damage or any other effect, realignment must be carried out. Small degrees of misalignment are automatically corrected by the permanently active alignment routines implemented in the software. If manual realignment is required, this is indicated to the driver.

Area of application and functional expansions

Use in passenger cars
The use of Adaptive Cruise Control is bound to the availability of driving-dynamics control. This is a requirement for active brake intervention without action on the part of the driver.

Use in commercial vehicles
Requirements
Some of the general conditions for a commercial vehicle ACC differ significantly to those for a passenger car ACC:
– Regulation of braking and acceleration must take account of the widely variable parameters of payload and engine size.
– Overtaking and merging maneuvers follow a dynamic pattern that is slower on trucks than on cars, and therefore result in different control requirements and settings.
– The control dynamics must be capable of handling a situation where several vehicles equipped with ACC are driving in a convoy (trucks drive in a line at nearly the same speed).
– A degree of simplification is provided by the fact that trucks have a more limited speed range than cars.
– The commercial deployment of trucks means that the focus during configuration is placed more on economy than on sports and comfort. Fuel consumption and wear must be at least as good with ACC as with an average driver.

As a general principle, the same type of ACC system can be used for buses, trucks and tractor units. The requirements with regard to drive and braking systems, manual, semi-automatic or fully automatic transmissions are also very similar in buses and trucks. Only with the configuration of the system are there heightened requirements in buses with regard to comfort.

System design
The system architecture of ACC for commercial vehicles is barely different at all from that of ACC for passenger cars. However, the range of the sensors can be shorter owing to the lower speeds involved. The environmental and service-life requirements imposed on the components in this respect are much higher.

ACC control is configured in commercial vehicles for optimum consumption and wear performance. Thus, for example, the service-brake system is activated only when the available retarder is no longer able to decelerate the vehicle in the manner requested by the ACC controller. Brake wear caused by ACC is therefore for the most part at the same level as that caused by an average driver. The same applies to fuel consumption, in which case a positive effect compared with an average driver can also be discerned thanks to ACC.

As well as these ACC systems, there are for commercial vehicles also predictive ACC systems which, on the basis of route-topology information that is learned or stored in maps, optimize the driving speed in such a way as to achieve the lowest possible fuel consumption. The systems achieve this for example by no longer accelerating ahead of humps in the road or on downhill stretches with a subsequent uphill gradient by better utilizing the kinetic energy through increased speed. The proven savings are, even when compared with good drivers, in the range of 5 to 10 %.

In some countries, e.g., the USA and Canada, there are even ACC systems which on account of the simpler brake architecture influence solely the engine torque or the continuous braking torque. The driver must therefore intervene manually more often.

ACCplus
First generation ACC systems had limitations in their range of functions resulting from the limited functionality of sensors and actuators. The limited object-sensing range and the limited horizontal resolution capacity only permitted operation above 30 km/h. Therefore ACC could not initially be used down to low speeds and at a standstill. The ACCplus system (in series production since 2009) has a further-developed radar sensor with wider angular coverage (±15°) and improved detection properties, and thus permits braking to a standstill and restarting by driver intervention. Pressing the accelerator pedal within a predetermined time limit is sufficient to reactivate the system.

Thanks to its greater reliability in destination selection and its even better ability to detect objects at close range, ACC can now also be used in traffic-jam situations.

ACC with low-speed following
During low-speed following (ACC Stop & GO, ACC LSF, Low Speed Following), the data from the long-range radar sensor is combined with the data from the medium or short-range sensors (short-range radar sensors or ultrasonic sensors) in order to provide an exact measurement of objects in front of the entire vehicle.

It operates in a speed range of 0 to 200 km/h, brakes the vehicle to a standstill, and automatically restarts within a predetermined time limit.

Sensor-data fusion with a video camera
Object measurement and object classification can be performed by means of sensor-data fusion with a video camera. This enables robust control over the vehicle with regard to stationary objects.

By combining with video sensor technology, it will be possible for low-speed following to perform full linear guidance at all speed ranges and also in urban traffic in the future (FSR, full speed range). ACC has also provided the basis for developing assistance systems which automatically intervene in critical driving situations to avoid accidents or to mitigate the consequences of accidents. Further developments are geared towards automatic evasive maneuvering by automatic steering intervention.

Current ongoing developments

Electronic horizon

The quality of the ACC function is being improved based on digital maps. The navigation system determines the position of the vehicle and estimates the expected path that the vehicle will travel (most probable path, MPP). A wide variety of predictive information is provided along this path by accessing digital navigation maps (electronic horizon). Examples of this include the road class, the geometric shape of the road, expressway exits and on ramps, speed limits and the gradient of the road. Manufacturer-specific protocols or the ADASIS standard [4] using CAN bus are used to provide the electronic horizon to the ECU.

The ACC system can access this information to improve its function. For example, the predictive course of the road can be used to more reliably assign oncoming radar specifically to a lane (reducing adjacent lane interference). The acceleration of the vehicle can be prevented when approaching an expressway exit if an oncoming radar object is lost when switching to the deceleration lane. The set speed can be reduced automatically before coming to a very tight curve.

In the future, the increased enhancement of the digital map with data and improvement in data quality will enable innovative assistance functions in combination with the ACC system, including predictive, fully automated specification of the set speed. The driver no longer has to enter the intended speed manually; the ACC system determines it automatically by communicating with the navigation system.

This allows the ACC system to implement predictive driving strategies in combination with the engine control unit, which minimize CO_2 emissions. If the ACC "sees" a speed limit or curve in advance via the electronic horizon, the vehicle can roll or coast to it with optimal fuel consumption. The gradient of the road is also taken into account when initiating the rolling or coasting procedure.

Networking with the cloud

The higher the ACC function's degree of automation, the greater the requirements are on the timeliness, precision and reliability of the data in the electronic horizon. To increase the data quality of the digital map, the vehicle itself will contribute to recording street environment data using its sensors. The function: Information such as traffic signs or the cornering speed are recorded by the vehicle's sensors, supplemented with data from the navigation system (e. g. position) and sent to the server (cloud) via mobile communications. In the central server, the incoming signals from many vehicles are processed, compiled and prepared for retrieval. The server information can be requested by vehicles with navigation systems. This ensures that the most recent information is always available. The incoming data from the server is applied to the local navigation map as new knowledge and provided to the ACC system immediately via the electronic horizon.

Information and warning systems

Rearview-camera system

Function

Modern vehicles often offer the driver only a limited view of the vehicle's immediate surroundings. Increasingly smaller side and rear windows, combined with a vehicle shape that is strongly influenced by aerodynamics and pedestrian protection, is making safe and precise maneuvering difficult. The rearview-camera system assists the driver when reversing by displaying a real-time image of the rear driving area in the radio or navigation-system display. The rearview-camera system offers the driver when reversing an unobstructed view of the vehicle's immediate surroundings (Figure 1).

Rearview cameras were already first introduced some time ago in Japan, but did not become prevalent in Europe due to the heavily distorted picture of the super-wide-angle lens. The breakthrough in Europe didn't come until there were systems to correct the image distortion.

Operating principle of the rearview-camera system

The near-range camera in the vehicle's rear automatically becomes active as soon as the reverse gear is engaged. The camera image displays the area behind the vehicle (detection range up to 180°, Figure 2). This enables the driver to determine in real time whether the way is clear. Optionally, the vehicle's path can be shown dynamically on the camera image with the aid of colored lines. These display the vehicle's trajectory according to the current steering-wheel position and indicate when the steering wheel must be turned. This makes accurate maneuvering possible.

In combination with the ultrasonic-based parking aid, for example, distances measured by the ultrasonic sensors are displayed as colored bars in the camera image. This means that all relevant information is available to the driver at a glance.

System benefits for the car driver

- The rearview-camera system allows for safe and comfortable parking and maneuvering,
- it allows for quicker and easier parking maneuvers,
- it is easy to use,
- the display of the surroundings is easy to understand thanks to intelligent image processing (no fish-eye effect),
- it reduces the risk of material damage and the associated costs.

Figure 1: Driver assistance with rearview camera

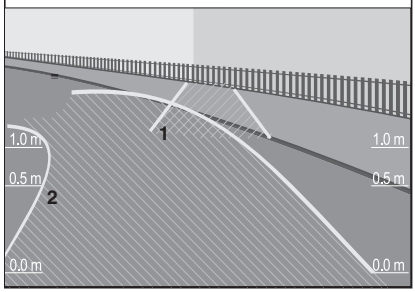
2 Trajectory calculated from the current steering angle.



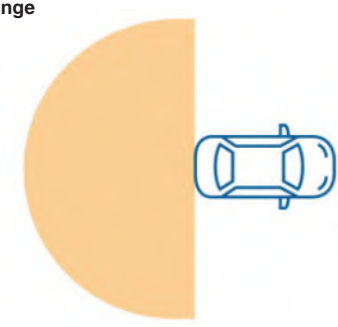


Figure 2: Reversing-camera detection range

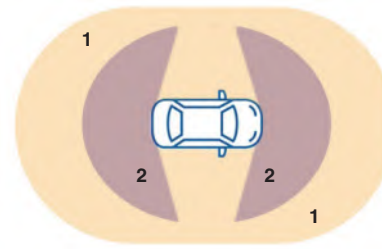
Multi-camera system

Features
Parking and maneuvering are among the activities most likely to be associated with accidents, so every centimeter counts. The multi-camera system offers the driver a 360° surround view to ensure easy, safe, and comfortable parking and maneuvering. The option to switch between perspectives makes it possible to line up precisely with lines, curbs, and walls. Safe maneuvering is possible through better orientation and visibility of the vehicle's complete surroundings, including obstacles and curbs.

Properties of the multi-camera system
The 3D surround view of the multi-camera system offers various advantages thanks to its highly complex video-based object detection. The 360° view (Figure 3) and the automatic, real-time tracking shot always provide the driver seamlessly with the best perspective. In addition, the multi-camera system generates a realistic, animated 3D vehicle model that provides the driver with an impressive, detailed image of the vehicle's surroundings. Moreover, the 3D visualization automatically adapts while maneuvering to an environment model based on sensor-data fusion to provide the best view of critical situations. This makes automated parking and parking-assist functions easier and safer.

The modular approach of this multi-camera system covers the various performance requirements with only one ECU, near-range cameras with a resolution of one to two megapixels, and optional ultrasonic sensors. Light system variants integrate two to four near-range cameras, depending on the resolution.



Automated and assisted parking functions can be robustly realized with the aid of the multi-camera system since sensor-data fusion increases the understanding of the vehicle's surroundings and thus improves parking functions like the (remote-controlled) parking assistant or the home-zone parking assistant. The multi-camera system also supports the driver when parking and maneuvering with a trailer. It simplifies coupling the trailer by providing a specific view of the trailer tow hitch and supports the driver when reversing with the trailer by taking over lateral guidance of the vehicle.

Operating principle of the multi-camera system
The multi-camera system consists of four near-range cameras. One faces forward, another rearward, while the two side cameras are integrated in the exterior mirrors. Each with an aperture angle of 190°, they capture the vehicle's complete surroundings. The system also includes an ECU, which merges the camera images to form a 360° view and – if desired – combines them with distance information from ultrasonic sensors.

Using these data, the system generates a dynamic 3D wireframe around the virtual vehicle model; the shape of that frame is adjusted to match to match the changing surroundings. The real-time images from the near-range cameras are projected onto the wireframe. In contrast to 2D systems, this method allows objects that rise up to be represented more realistically.

A new technical feature of the multi-camera system is the seamless, distortion-free merging of the camera images in real time: Depending on the perspective, the system dynamically adjusts the borders of the images. The result is a homogeneous image with no distracting frames

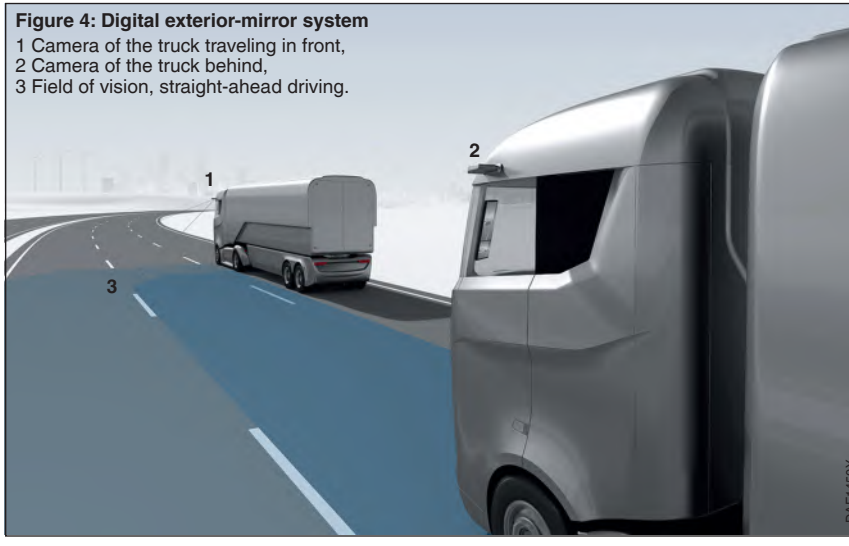
Figure 3: 360° surroundings detection with the multi-camera system with four near-range cameras
1 Detection range of the front camera, rearview camera, and cameras in the exterior mirrors,
2 Detection range of the optionally used ultrasonic sensors.

or overlaps. Objects remain optimally visible at all times.

The multi-camera system offers different modes and perspectives. It supports the driver by affording them an exact view of the vehicle's surroundings which are relevant at that very moment to enable the drive to maneuver and park safely and comfortably. The system uses 3D visualization techniques which are also used in cinema films for a highly realistic image.

System benefits for the car driver

– The multi-camera system facilitates more precise parking and maneuvering the visible of the vehicle's complete surroundings including lines and obstacles,
– different perspectives make it possible to line up precisely with lines, curbs, and walls,
– it helps to avoid collisions and reduce parking stress.



Digital exterior-mirror system

Large side mirrors on commercial vehicles are an extremely important safety feature and are essential for ensuring the driver has a good rear view. But, due to their size, they restrict forward visibility and also generate high aerodynamic drag. The digital exterior-mirror system replaces the large side mirrors with two monitors integrated in the driver's cab and two exterior cameras that are mounted above the driver's cab (Figure 4). The aerodynamic design reduces aerodynamic drag and with it fuel consumption. At the same time, the system increases safety by significantly improving the driver's all-around visibility and reducing the blind spot.

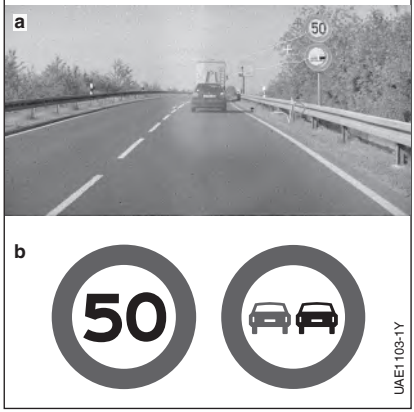
Replacing the two exterior side mirrors provides additional advantages with the innovative technology. The technology of the digital exterior-mirror system furthermore makes it possible to provide a situation-specific display:

– on expressways and highways the driver can see further behind the vehicle,
– in towns and cities the viewing angle increases to expand the driver's field of view,
– at night the enhanced contrast improves visibility.

Figure 4: Digital exterior-mirror system
1 Camera of the truck traveling in front,
2 Camera of the truck behind,
3 Field of vision, straight-ahead driving.

Road-sign recognition

Features
Another function that makes use of the information from the video sensor is road-sign recognition. This system is capable of recognizing and interpreting road signs (e.g., speed limit or no-overtaking signs). A video camera takes over 20 images per second and transmits these in the form of a video signal to the image-processing computer. While the vehicle is moving, the system searches for objects which on the basis of their external shape could be road signs (object detection). When such an object is found, it is tracked until it is close enough to be picked up by the video camera as a specific object (object classification). These can be road signs which show for example speed limits, the start and end of stretches where passing (overtaking) is prohibited, and also no entry. Stop, right-of-way, and road-works signs are also recognized. Road-sign recognition also classifies relevant supplementary signs, such as time limits, signs applicable only to specific vehicle types, and turn arrows. The system reliably detects road signs, whether they are sited on actual signs, variable message systems or gantries. Road-sign recognition presupposes that the sample designs to be recognized have previously been taught into the image-processing computer.



When the system detects a relevant road sign, it shows this as an icon in the instrument cluster's graphic display (Figure 5). If the driver for example fails to observe the detected speed limit, the system can issue an additional acoustic or haptic warning. The driver can also be warned against passing (overtaking) on a stretch where such maneuvers are prohibited and when stop and no-entry signs have been overlooked.

Reliable road-sign recognition is now possible at speeds of up to 160 km/h and also in conditions of rain and road spray.

Application In assistance functions
Recognized road signs are increasingly being used in a variety of assistance functions. For example, navigation maps can be updated with recognized road signs and the adaptive cruise control system can in a further expansion stage maintain the vehicle's speed at the identified speed limit.

When a pedestrian is identified as an object class, the function can become active for active pedestrian impact protection if there is an imminent danger of a collision (see Active pedestrian protection).

Figure 5: Road-sign recognition
a) Road image,
b) Icons in instrument-cluster graphic display.

Driver-drowsiness detection

Problem
Fatigue and microsleep at the wheel are often the cause of serious accidents. However, the initial signs of fatigue can be detected before a critical situation arises. The steering behavior can provide an indication of the onset of driver drowsiness.

Operating principle
Using information from the steering-angle sensor, the drowsiness-detection algorithm analyzes the driver's steering behavior and recognizes changes that occur over the course of long trips and in response to driver fatigue. Typical signs of waning concentration are phases during which the driver is barely steering, combined with slight, yet quick and abrupt steering interventions to keep the car on track. Already small steering deviations that are barely perceptible to the driver are typical signs of waning concentration. Based on the frequency of these steering corrections and other parameters, among them the length of the trip, blinking behavior, and the time of day, the function calculates a fatigue index. If this index exceeds a certain value, an icon such as a flashing coffee cup in the instrument cluster alerts the driver to take a break.

This drowsiness-detection system has already successfully been on the market for a few years. Because it is purely a software solution in combination with the steering-angle sensor, the function can be integrated with minimal effort and outlay in existing vehicle platforms. The function helps to fulfill the upcoming legal requirements.

A more sophisticated realization of driver-drowsiness detection is based on camera-based interior monitoring.

Rear cross-traffic warning

Features
Backing out of a parking space (Figure 7) can often be a challenge, especially when the driver's view of the traffic passing behind their own vehicle is obstructed. Rear cross-traffic warning makes this reversing parking maneuver easier by warning the driver of crossing vehicles. Rear cross-traffic warning can detect crossing vehicles up to 50 m away.

Operating principle of rear cross-traffic warning
The system utilizes two corner radar sensors in the rear of the vehicle, Figure 6 shows the detection range. They measure and interpret the distance, speed, and anticipated driving path of detected vehicles in the cross-traffic.

When the function detects other vehicles crossing from the left or right at a distance of up to 50 meters, it warns the driver acoustically or visually of an imminent danger of collision.

Figure 6: Detection range of rear cross-traffic warning

System benefits for the car driver
– Rear cross-traffic warning warns the driver of crossing vehicles when backing out of parking spaces,
– it facilitates safe and stress-free reversing out of parking spaces, even with limited visibility.

Turn collision warning for trucks

Features
Driving heavy commercial vehicles can be a challenge, especially at intersections. Cyclists and pedestrians are particularly at risk in such situations. Turn collision warning promptly detects pedestrians and cyclists in the commercial vehicle's blind spot (Figure 8), warns the driver acoustically or visually of potential dangers before the vehicle turns, and thereby helps to avoid accidents. The side radar sensors can not only facilitate this function, but can also more than satisfy the legal requirements.

Figure 7: Backing out of a parking space with cross-traffic

Figure 8: Turn collision warning for heavy trucks

Operating principle of turn collision warning

Radar sensors installed on the side of the vehicle promptly detect pedestrians and cyclists on the co-driver's side. These sensors cover the entire area alongside the vehicle and trailer, from the immediate area in front of the vehicle reaching into the intersection to just behind the end of the trailer. If the side-mounted radar sensors detect other road users in these areas, the system outputs a visual signal to notify the driver of their presence. In this situation, the vehicle's predicted route is tracked against the road users detected.

If a person is situated in the critical area alongside the vehicle and the driver initiates a turning maneuver, the driver receives a further visual or acoustic warning. This enables the driver to react in good time to avoid a collision with a pedestrian or cyclist. The system helps to increase road safety and prevent accidents between heavy commercial vehicles and more vulnerable road users. With these side-mounted radar sensors, the legal requirements for protecting pedestrians and cyclists during turning maneuvers contained in regulation UN ECE R151 [1] for “blind-spot information systems” can be more than satisfied.

System benefits for the vehicle driver

– Turn collision warning increases road safety by displaying warnings of hard-to-see road users or persons obscured by the vehicle,
– it assists the driver with acoustic or visual warning signals.

Moving-off information system for heavy commercial vehicles

Features

Maintaining a clear view in heavy commercial vehicles can be a challenge, especially in urban traffic. Cyclists and pedestrians are particularly at risk in such situations. The moving-off information system helps to avoid collisions. It detects objects and people within close range of the front of the vehicle (Figure 9), issues the driver with acoustic or haptic warnings of potential dangers, and therefore helps to prevent accidents. The side radar sensors can not only facilitate this function, but can also more than satisfy the legal requirements.

Operating principle of the moving-off information system

The moving-off information system is a cornerstone for integrative, near-range safety functions and helps to avoid collisions with other road users. It provides the driver with an assistance system that detects people and obstacles close to the front of the vehicle in situations involving moving off and low-speed maneuvers. Side-mounted radar sensors at the front of the cab constantly monitor the vehicle's immediate surrounding in such situations.

If the sensors detect objects or road users and recognize a potential risk of collision, the system promptly provides the driver with an acoustic or haptic warning. This enables the driver to react swiftly and brake in good time. The visual or acoustic warning ceases when there is no further risk of collision. With these side-mounted radar sensors, the legal requirements of the General Safety Regulation (GSR) can be more than satisfied.

Figure 9: Moving-off information system for heavy trucks

System benefits for the vehicle driver

– The moving-off information system increases road safety by displaying warnings of hard-to-see road objects or objects obscured by the vehicle,
– it assists the driver with acoustic or haptic warning signals,
– it increases safety for all road users.

Wrong-way driver warning

Motivation

In Europe there are more than 4,000 accidents every year caused by wrong-way drivers on expressways/highways. This amounts to around 5 % of all the fatal accidents on expressways/highways. The aim of cloud-based wrong-way driver warning is to avoid the often serious accidents involving wrong-way drivers on expressways/highways. This function thus makes an important contribution to increasing road safety.

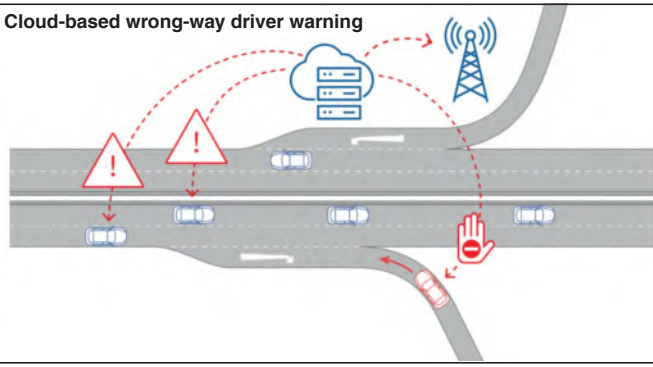
Technical implementation

In order to reach a very large number of road users as quickly as possible with the service, an approach was chosen which called for solely connectivity and GPS (Global Positioning System). The function can be integrated both in mobile end devices such as smartphones and directly in the vehicle's central communication unit (head unit). To this end, all that needs to be integrated is a “Software Development Kit” (software comprising tools and libraries), which contains the coordinates of all the relevant highway entrance ramps and the necessary algorithms for performing the steps described in the following.

Functioning principle

As soon as a networked vehicle reaches the area of a high entrance ramp, the end device starts to send the position and acceleration data in one-second intervals to the back end. Here the actual direction of travel is compared with the permitted direction of travel. The data required for this purpose are available in the cloud in the form of a map with direction-of-travel details. A warning is sent if the two sets of information clash. This warning is sent to all the connected vehicles. Only then is a check made in the end device as to whether the individual vehicle is affected by the warning and this warning must be displayed to the user accordingly. It is up to the customer to organize the nature and the content of the warning. Bosch in its proposal is orientated to the recommended actions of the German motoring association ADAC.

Performance



In this way, it is possible to warn not only the wrong-way driver themselves but also quite specifically those road users who are driving towards the wrong-way driver.

With a warning time of under 10 seconds with a “true positive rate” of 93 % (actual wrong-way drivers detected) and a “false positive rate” of just 0.0004 % (incorrect warnings are issued in only four out of every one million cases) this solution is more efficient than other approaches to preventing wrong-way driving incidents.

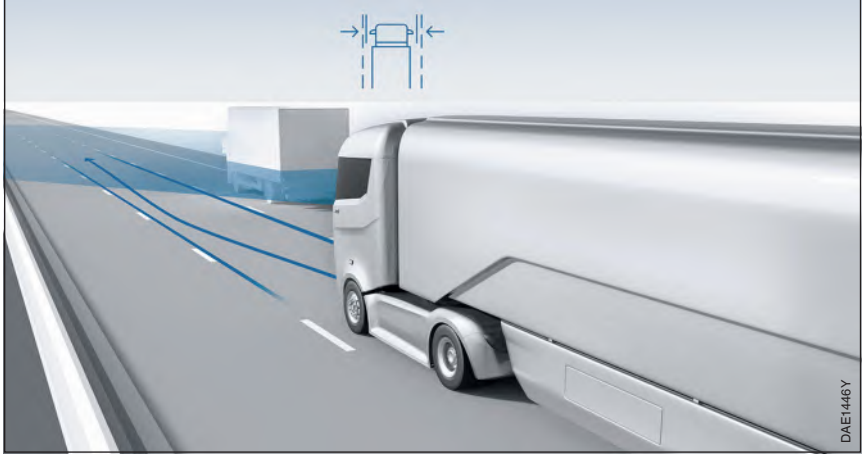
Figure 1: Cloud-based wrong-way driver warning

Lane assistance

Drifting from the lane unintentionally frequently leads to serious accidents. It is caused for the most part by the driver being distracted or tired (e.g., microsleep). Lane departure warning (LDW) is designed to help avoid such accidents by detecting the lane markings ahead and warning the driver if there is a danger of a lane marking being crossed without the direction-indicator lamp (turn signal) having been activated. The lane-keeping support system (LKS) also actively intervenes in vehicle guidance (Figure 1).

Assistance systems that afford the driver further lateral-guidance support on expressways/highways with roadworks (roadworks assistant) or in urban traffic (bottleneck/constriction assistant) are currently in development.



Lane departure warning

Lane detection

Lane-departure warning systems use video cameras to detect the lanes ahead of the vehicle and can have both mono and stereo video designs. A stereo video sensor offers advantages when the road surface exhibits more pronounced gradients, as is typical for example of many country roads. Here the stereo video sensor helps to estimate the surface profile. Knowledge of the surface profile simplifies in the next stage the detection of lane markings and extends the detection range. There are no advantages for lane detection on expressways/highways as here only slight changes in the surface profile are permitted by statutory requirements. In good weather conditions and with good lane markings, the range is in the region of up to 100 m.

Figure 2 shows the principle of video-based lane detection. The image-processing system searches for lane markings by analyzing differences in contrast between the road surface and the lane markings. Figure 2a shows the camera image with search lines, Figure 2b shows a detailed view. The crosses in Figure 2a

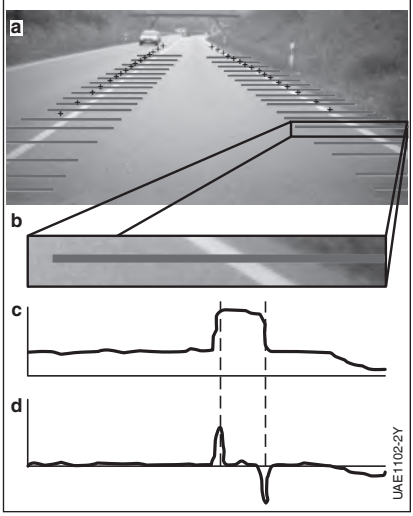


Figure 1: Lane-keeping support for heavy trucks

mark the course of the lane which have been calculated by the image-processing computer. In order to detect a line, the luminance signal (brightness) inside the search line is analyzed (Figure 2c). The limits of the lane markings are detected by high-pass filtering (Figure 2d). The lane covered by the system vehicle can be detected on the basis of the limiting lane markings. A brief absence of lane markings can be compensated for in the currently available systems. No lane assistance can be offered if the markings are absent over wide areas.

The lane-detection algorithm of the camera detects and classifies all the common variants of lane markings up to a distance of around 60 meters (in good visibility conditions round 100 meters), regardless of whether they are continuous, dashed, white, yellow, red or blue. Even “Botts‘ Dots” (round, non-reflective, raised lane markers) can be detected by the camera.

Figure 2: Principle of lane detection
a) Camera image with search lines,
b) Detailed view with search line,
c) Luminance signal (high level for light lane marking),
d) Edge information by high-pass filtering of luminance signal (peaks at light/dark transitions).

Research is currently being conducted into systems which are intended to detect the roadsides even without markings on the basis of the surface structure and color. The attributes of the last road driven on are also utilized as models. When such systems are market-ready in a few years, lane-assistance systems will also be available on unmarked roads.

Driver warning
A warning for the driver can be derived on the basis of the detected lanes in the event of the vehicle drifting out of lane. Different forms of warning are conceivable here. The first systems used an acoustic warning from the vehicle speaker in the form of a warning sound or “rumblestrip rattling”; a stereo sound can additionally convey a direction here. However, the systems that have become the most widely used since then feature warning the driver via the haptic sensory channel by vibrating the steering wheel or subjecting the steering to a slight counter-torque. The advantage of issuing the warning through the steering wheel lies in the driver directly associating the danger with the movements on the steering wheel.

Regulations and standards
Together with the mandatory introduction of the automatic emergency-braking system for heavy commercial vehicles (8 t and upwards) the Lane Departure Warning System (LDWS) has been prescribed for this vehicle class in the EU (European Union LDWS Regulation (EU) 351/2012 [1]). Here too the introduction was conducted incrementally from 1 November 2013 initially for vehicles to be newly homologated and from 1 November 2015 for all new vehicles brought onto the roads.

Lane-keeping support

Supporting interventions
Lane-keeping support is a functional enhancement of lane departure warning in that it not only warns the driver against drifting unintentionally from the lane, but also actively supports him in maintaining course. If the vehicle drifts too far from the lane, lane-keeping support makes a course correction, either by means of an active steering intervention or an asymmetrical braking intervention. In this way, the system supports the driver in keeping his vehicle on course and at the same time helps to increase road safety by avoiding accidents caused by drifting unintentionally from the lane.

However, lane-keeping support itself cannot assume full lateral guidance of a vehicle, but is instead intended to support the driver in maintaining course. The system does not relieve the driver of his responsibility to follow and react to the traffic conditions attentively and to drive the vehicle consciously and deliberately. A system intervention can be overridden by the driver at any time.

To prevent misuse, the lane-keeping support system is fitted with a device which monitors whether the driver has both hands on the steering wheel and is actively steering the vehicle. If the driver is driving with no hands, an instruction is promptly issued to the driver to take control of the vehicle and the assistance afforded by lane-keeping support is terminated with an accompanying visual or acoustic warning.

Applications
Lane-keeping support is designed primarily for use on expressways/highways and well developed highways. Like lane departure warning, lane-keeping support is dependent on detecting lanes ahead of the vehicle. Short-term failures in lane detection, caused for example by hidden or faded lane markings, are compensated for by the system. However, lane-keeping support is deactivated if no lane information is received for an extended period of time.

Lane centering assist for heavy trucks

Application
Tiredness and distraction are the most frequent causes of a driver unintentionally drifting over lane markings, especially on long and monotonous journeys. Event just a fleeting moment of inattention can lead a driver to depart from their lane. Lane centering assist prevents this by actively keeping the vehicle in the center of its lane (Figure 3), bringing both driver and load to their destination safely and comfortably.

Lane-keeping support actively steers the vehicle in the center of its lane.

Operating principle of lane centering assist
Lane centering assist uses a video camera to detect lane boundaries – including road markings or structural boundaries – alongside the vehicle and compare these with the position of the vehicle in the lane. Then the system aligns the vehicle via the electrohydraulic steering system to keep it on track, making active interventions to ensure that it stays in the center of its lane.

The function can be activated while driving and – if necessary – can be overridden by the driver at any time. In this way, the driver remains responsible for the vehicle.

The smart combination of components makes driving heavy commercial vehicles safer and brings a noticeable improvement in driving comfort. Damage to the load caused by jerky steering maneuvers is avoided.

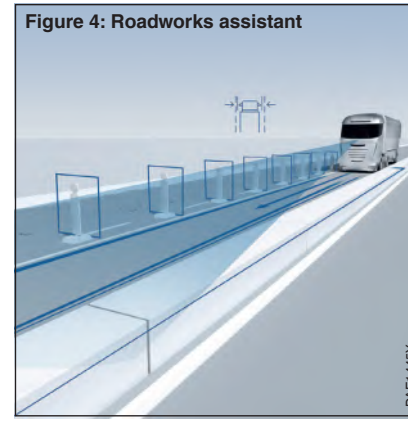
Figure 3: Lane centering assist for heavy trucks

Emergency lane-keeping support for heavy trucks

Application
Long, monotonous stretches of road can cause drivers to become tired and inattentive. On occasion, this can make them unintentionally drift over the lane markings. Things get particularly dangerous when unprotected, steep embankments or verges line the edge of the road. If the driver starts to drift away from the drivable road surface and fails to react promptly, emergency lane-keeping support actively steers the vehicle back into the correct lane.

Operating principle of emergency lane-keeping support
Emergency lane-keeping support uses a camera to detect the edge of the road, i.e., the boundary of the surface that can be safely driven on, and compares this with the vehicle's position. The function intervenes if it determines that the vehicle is failing to maintain a defined minimum distance to the boundary of the road surface.

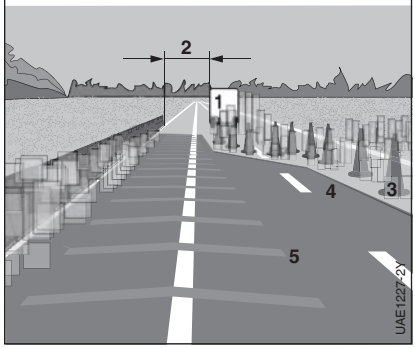
Emergency lane-keeping support makes a noticeable steering correction in the opposite direction with the electrohydraulic steering system to keep the vehicle on track and thereby avoid the serious consequences of the vehicle departing the road. It increases safety through early correction of driving mistakes.



Roadworks assistant

Applications
When roadworks are taking place on the roads, there is often very little space between the vehicles in the adjacent lane and the crash barriers. Roadworks assistant and bottleneck/constriction assistant are further developments of lane-keeping support. In addition to lane markings, these systems also detect raised objects and obstacles and take them into consideration in lateral guidance (Figure 4). The help drivers maintain a lateral safety distance to vehicles in the adjacent lane and safety curbs or crash barriers when driving in a narrow lane.

The roadworks assistant supports the driver in negotiating roadworks on expressways/highways and thus extends the lane-keeping support system to include this special scenario.



Types of support
The type and the extent of support provided can vary greatly. The system can run through all the stages of a cascade of intervention, from the visual, acoustic or haptic warning right up to interventions in vehicle guidance. An intervention in vehicle guidance can involve interventions both in the lateral vehicle dynamics (steering torque or asymmetrical braking intervention) and in the longitudinal dynamics (deceleration). Automatic deceleration can help to keep the vehicle in lane if it drives too fast into a roadworks chicane.

Figure 4: Roadworks assistant

Detection of lane restrictions
Because roadworks are more complex in their structure than the typical expressway/highway environment, the roadworks assistant detects roadworks-specific lane restrictions (traffic beacons, cones, safety barriers) in addition to the regular lane markings. The sensor functions are typically performed by a front-end stereo video camera and side-mounted ultrasonic sensors. These sensors enable the system to distinguish between static objects (e.g., roadside structures) and dynamic objects (e.g., vehicles). In this way, the system can take the necessary collision-avoidance action in the event of lane constrictions at roadworks caused by traffic in neighboring lanes. This in turn affords the driver support to suit the situation as he or she drives through expressway/highway roadworks and as a result offers the best support possible for maintaining a sufficient safety distance.

Figure 5: Bottleneck/constriction assistant – visualization of calculation results
1 Inflatable obstacle (balloon car),
2 Bottleneck/constriction,
3 Collision-relevant objects (e.g., cones, safety curbs),
4 Available road width,
5 Predicted corridor.

Bottleneck/constriction assistant

Applications
The bottleneck/constriction assistant extends the roadworks assistant with regard to the typical speed range in urban areas (0 to 60 km/h) and with regard to the supported radii of bends. Collision-avoiding steering assistance is offered in urban bottlenecks/constrictions accordingly.

Functionally negotiable bottlenecks/constrictions can also be caused by objects traveling in the same direction or by oncoming objects. The bottleneck/constriction assistant provides automatic steering interventions so that a sufficient safety distance from side obstacles is maintained when passing through tight spaces (bottlenecks, constrictions). It also ensures that an early warning is issued to the driver and an automatic brake intervention is effected if there is not enough space for the vehicle to be able to pass.

As with lane-keeping support, the intensity of the steering and brake interventions is restricted. The interventions can be easily overridden by the driver so that potentially motiveless interventions remain fully non-critical and thus without consequences.

The feasibility of the functional idea was demonstrated by the implementation of an in-vehicle prototype as part of the publicly funded UR:BAN project concluded in 2016 [2]. The prototype's system response in a typical urban scenario is shown in a video in [3]. The bottleneck/constriction assistant is currently in the advance-development stage. The date of a series launch is still open.

Environment detection
A functional requirements analysis reveals that a forward-mounted stereo video camera and alternatively side-mounted ultrasonic sensors or monocular video sensors must be used. The stationary environment and moving objects (those traveling in the same direction and oncoming objects) must be represented within the framework of environment modeling. An occupancy grid presents itself for the stationary environment. An occupancy grid is a metric grid of the vehicle's environment.

Typical cell sizes range between 10 cm and 20 cm. If an object exists in the system vehicle's surrounding environment, the affected grid cells are marked as occupied. Dynamic objects are pictured by way of object models with various function-related attributes (position, width, length, speed, and acceleration).

Evaluation of the traffic situation

The situation analysis must make an assessment of the collision risk in accordance with the planned trajectory of the vehicle and the moving objects, and incorporating the stationary environment. Criticality measurements which are used in the function module to detect critical situations where action is required are typically calculated for this purpose. A typical criticality measurement of this type is the braking-time reserve (also called "time to brake"), which specifies how much time the driver still has to avoid, through a self-initiated brake intervention, a collision for example in an unpassable bottleneck/constriction. If the driver is no longer able to react (i.e., the braking-time reserve is zero or negative), a collision-mitigating system response is authorized.

Response model

The function module checks, aside from the criticality measurements mentioned, that the system limits are observed (e.g., whether the maximum supported bend is exceeded) and activates where necessary steering and brake assistance or issues an early warning to the driver.

Figure 5 visualizes some central calculation results by the bottleneck/constriction assistant in a test scenario with a passable bottleneck/constriction while using typical test equipment (safety curbs, cones, balloon car). The rectangles represent detected collision-relevant objects. The gray area (in the graphic on the left of the pictured boundary line) codes the available road width in the bottleneck/constriction. The stripes on the level show the predicted corridor for the vehicle.

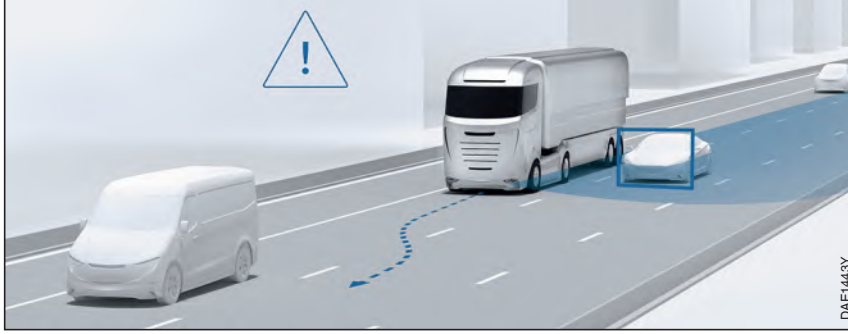
Lane-change assistant

The number of passenger-car accidents caused by inappropriate lane changing was in the past years regularly in the range of between 6 % and 8 % [1]. Here, the incidence of accidents is mainly centered on highways and expressways/highways. Drivers initiate a lane change and fail to notice other road users either next to or behind their vehicle. In the first case, the other road users are outside the field of vision of the side mirrors (blind spot, see Figures 1 and 2). On expressways/highways the colliding vehicles are typically driving at similar speeds, i.e., are traveling parallel or slowly passing (overtaking). In the second case, a lane change is made in front of a vehicle that is approaching from the rear at high speed. A typical outcome here is a rear-end collision.

Subfunctions which can address the two types of accident mentioned are described in the following. The functions described are available for trucks and motorcycles as well as for passenger cars. The principle of operation is the same, regardless of the vehicle type.

Blind-spot assistant



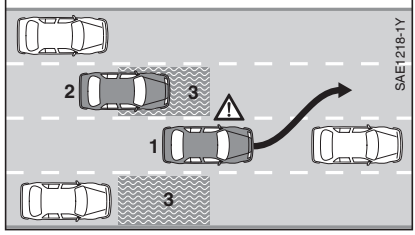
The blind-spot assistant helps to avoid the first type of accident mentioned.

Environment detection

There are various sensor concepts, differing in terms of costs and performance. In order to avoid this type of accident, only the area directly next to or just behind the system vehicle is relevant. What all the sensor concepts have in common is that the range to the rear extends only a short distance beyond the rear end of the vehicle.

There are systems that utilize the ultrasonic sensors (also used for the parking aid) at the rear corners of the vehicle. As a result, small objects (e.g., scooters) which are situated directly next to the system vehicle cannot be measured, since these are outside the ultrasonic sensor's field of vision. Another solution available on the market utilizes mono cameras in the side mirrors. In a third variation, short-range radars to the sides are used. In the last two cases mentioned even smaller objects at the sides of the vehicle can be detected by sensors. It is to be noted that the sensors mentioned can be used again by the vehicle manufacturers in a value-added approach for a variety of functions (e.g., parking aid, turning assistance, integral safety).

Figure 1: Blind-spot detection in a truck – the entire area alongside the trailer is detected



Sensor-related challenges arise in driving maneuvers that involve high transverse dynamics (turning operations). Here the manufacturers typically set system limits (e.g., thresholds for lateral acceleration, yaw rate, radius of curve which when exceeded deactivate the system) in such a way that incorrect object measurements and consequently false system warnings are avoided.

Response model
The following warning cascade will run if the sensor system detects a vehicle in the neighboring lane.

In a first stage, only slightly perceptible driver information is provided in the form of a side-specific activation of visual symbols or light elements in the side mirrors. If the driver additionally signals a lane-change request (e.g., by activating the direction-indicator lamp or on the basis of the measured driver steering torque on the steering wheel), the visual display can flash, followed by a supplementary acoustic warning or even a slight intervention in lateral guidance. The latter steering intervention can actively prevent or impede the lane change. Automatic steering intervention can be easily overridden and is comparable in terms of intervention intensity with that of lane-keeping support.

Figure 2: Blind-spot detection in a passenger car
1 Vehicle pulling out,
2 Vehicle in the detection range of vehicle 1,
3 Detection range of vehicle 1.

Lane-change assistant

As described above, the blind-spot assistant, on account of the limited sensor field of vision to the rear, cannot react to vehicles approaching at high speed from the rear (with the typical outcome of a rear-end collision). Here, the function of the lane-change assistant supplements the range of functions of the blind-spot assistant, i.e., simultaneously monitors the space to the sides of the vehicle as well.

Environment detection
In contrast to the blind-spot assistant, exclusively mid- or long-range radars are used here; these are mounted on a passenger car at the rear corners below the bumper. If a truck is fitted with a lane-change, this is typically positioned under the side mirror.

In particular for passenger cars the radar-antenna radiation pattern is typically set out in such a way that the radar sensor with a smaller radar lobe of low range also covers the area next to the vehicle. The radar sensors use attain a range of up to 100 m to the rear.

Response model
Unlike with the blind-spot assistant, an object prediction is now conducted on the basis of the object list created in environment detection. The system therefore measures whether at a given system-vehicle speed the object approaching from the rear would enter into a critical situation, i.e., would have to brake sharply, if the system vehicle changes lane. The braking-time reserve (time to brake, see Bottleneck/constriction assistant) of the approaching object is determined as the criticality measurement for this purpose. If a lower threshold is undershot (typically <2 to 3 seconds), the lane change is assessed as critical and the escalation cascade passes, as with the blind-spot assistant, into the second stage. The actual response model now corresponds to that of the blind-spot assistant.

Evasive steering support

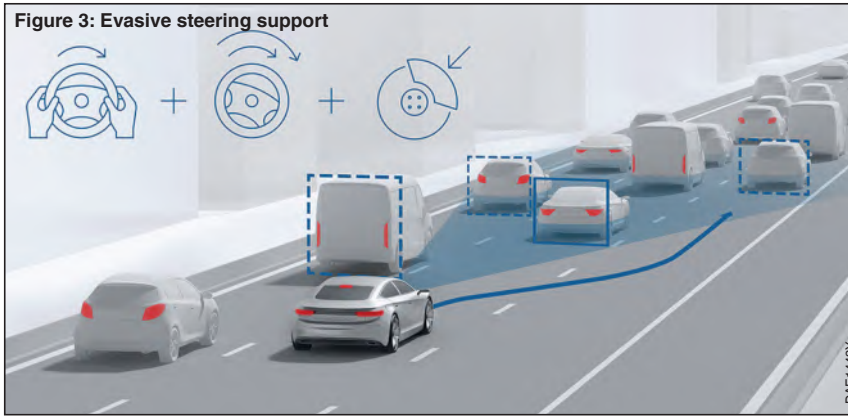
Features
Evasive steering support actively supports the driver during a critical evasive maneuver by means of a supporting steering torque. The helps the driver to circumnavigate an obstacle in order to avoid an accident. The maximum steering angle is reached faster with the assistance of evasive steering support.

Evasive steering support becomes active when the system detects an impending collision and the driver initiates an evasive maneuver. Once the driver begins steering, the system assists the driver with torque interventions in the power steering in order to guide the vehicle around the obstacle (Figure 3).

Using the data from the video camera and radar sensor, the system instantaneously computes a suitable path, taking into account distance, width and offset of the vehicle traveling in front. The collected data from the radar and the camera are merged in an ECU for a better and more robust understanding of the scene.

System benefits for the car driver
– Evasive steering support reduces the risk of collisions with objects and thus associated injuries,
– it supports the driver in maintaining a safe evasive path,
– it maintains driving stability.

Further developments



Automation of the lane-change operation – particularly on expressways/highways – is conceivable with the above-mentioned lane-change assistant. Such systems are currently in development.

Here the system indicates to the driver the possibility of a safe lane-change maneuver provided the system vehicle is following another slower vehicle. The driver enables the maneuver and can gently place his or her hands on the steering wheel. The system performs the lane change automatically. In combination with Adaptive Cruise Control (ACC) the system would speed up the vehicle and then after the overtaking operation is completed get the vehicle back in lane in front of the passed (overtaken) vehicle.

Since the radar sensor monitors the traffic behind the vehicle, such a maneuver can only be initiated if there is no risk of a side collision. This significantly increases overall safety. Most of the accidents that currently occur due to driver error when changing lanes could thereby be avoided.

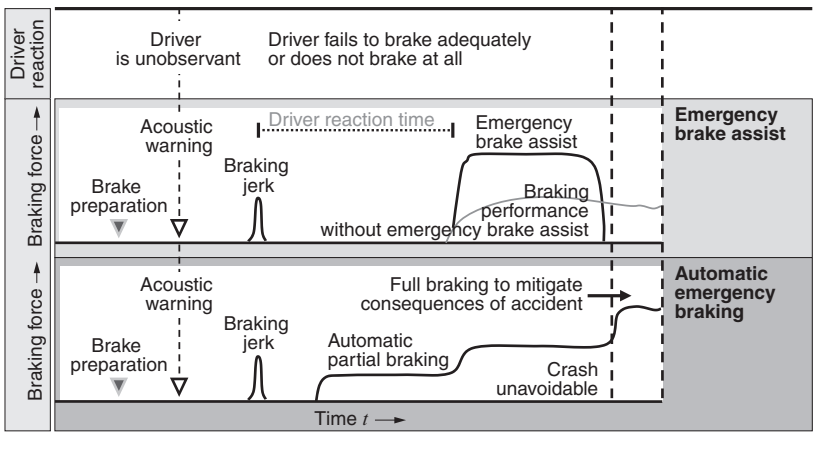
Figure 3: Evasive steering support

Emergency-braking systems

Emergency-braking systems in longitudinal traffic

Emergency brake assist and automatic emergency braking

A significant number of road accidents are the result of collisions between vehicles driving in the same direction, i.e., rear-end collisions. Driver-assistance systems which can avoid such accidents or at least mitigate their consequences have been in series production for some years now. A simple feature is the brake assistant (see Brake-assistance functions). Systems that use sensor technology to observe and interpret the vehicle's surroundings have a particularly high potential [1]. This enables such a system to make the necessary anticipatory intervention in vehicle guidance in order for example to avoid an accident with emergency braking.



Environment detection

To be able to avoid rear-end collisions, it is necessary to observe the vehicle traveling in front and its movement. If the system detects that a collision is imminent, it can take appropriate action, for example by issuing a warning to the driver or by performing emergency braking.

Various sensors are suitable for observing the vehicle environment. Their range and sensing range constitute an important function-relevant feature. The required look-ahead distance of the sensors is derived above all from the speed range in which the function is to be active. Radar sensors are used predominantly used for long ranges which are required at high driving speeds. Mono and stereo video sensors typically achieve medium look-ahead distances. Lidar sensors can be used for both medium distances and close range.

Several sensors are frequently combined for a automatic emergency-braking system. This offers two advantages: Firstly, the strengths of the individual measurement concepts complement each other, providing for a more accurate measurement of vehicles traveling in front. Secondly, system reliability is enhanced in that possible faults in individual sensors can be detected. In particular, unjustified system responses can be avoided. It is also possible, albeit with a loss in per-

Figure 1: Braking-response model of Emergency Brake Assist and Automatic Emergency Braking for an unobservant driver who fails to brake adequately or does not brake at all

formance, to realize emergency-braking systems which are based merely on the data from a single sensor.

Attributes of objects traveling in front such as position, speed, acceleration, and object size and type are assessed on the basis of the environment-sensor data and taking into account the motion of the driver's own vehicle. These object attributes are then used to evaluate the traffic situation with regard to its criticality.

Evaluation of the traffic situation
Different measures have become established that describe how critical the current traffic situation is, i.e., how probable it is that a collision with a vehicle traveling in front is imminent (criticality measurements). Assumptions regarding the future motion both of the vehicle traveling in front and of the driver's own vehicle are made for this purpose. This is possible since only very short prediction horizons are required for emergency-braking systems. It can be assumed for instance that the driver of the actual vehicle will still try by means of an avoidance maneuver to avoid the collision. Assuming maximum transverse dynamics for this avoidance maneuver, the last possible moment when the driver can still avoid the collision by evasive maneuver can be calculated. The time remaining until this moment is called the "time to steer" (TTS). Similarly, a "time to brake" (TTB) can be calculated, i.e., the time remaining to the driver to still avoid the imminent collision by means of a braking maneuver. The shorter these times, the more critical the traffic situation. There are many more criticality measurements, e.g., the probability of a collision in the future "time to collision" (TTC). To be able to calculate these, it is necessary to make assumptions about probability distributions for the future motion of the vehicles involved.

Response model
Different system responses can be initiated if a collision is imminent and this is detected when the above-mentioned criticality measurements are undershot. The time sequence of an exemplary system response is illustrated in Figure 1. The following system-response stages exist in standard systems:

Brake preparation
If the probability of an imminent collision increases, the brake system can be prepared by driving-dynamics control (Electronic Stability Control, ESC) in such a way (prefill) that any subsequent braking (by the driver or by the system) can be effected more rapidly.

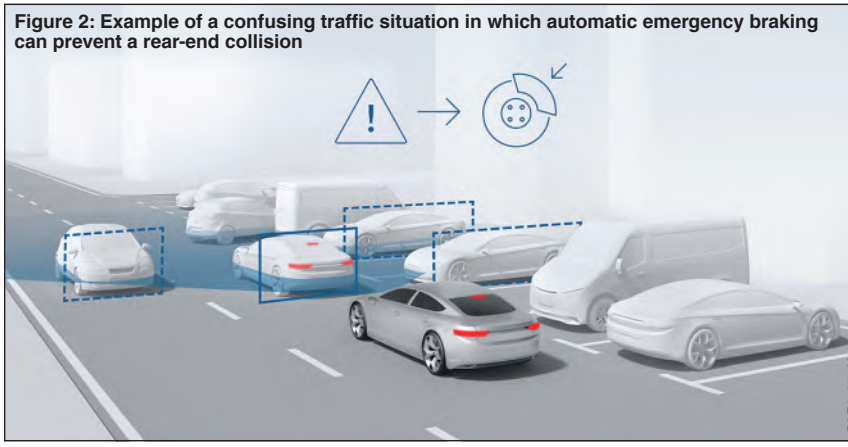
Warning
The driver can be warned in the event of a heightened collision risk. A warning is suitable to force the driver into a tried-and-tested response, especially if he has not yet recognized the danger. An accident can thus be avoided by the driver himself if the advance-warning time is long enough.

However, when configuring a warning function, it is important not to set the advance-warning time at too long; in such a case the warning would frequently be issued already in easy-to-control, non-critical situations and would thus be perceived to be unjustified.

Braking jerk
The braking jerk constitutes a further warning escalation stage. Here the brake system is automatically activated for a brief period and then released again immediately. This has two advantages: Firstly, the driver is warned by haptics of the danger; secondly, the driving speed is already slightly reduced.

Partial braking
Partial braking works along similar lines to the braking jerk. Here a slight deceleration is automatically set, but unlike the braking jerk is not released again immediately.

Brake assistant
Frequently the driver will react to the critical situation by initiating a braking operation that is too weak to avoid the accident. In this event the system can boost the braking force requested by the driver so as to bring the vehicle to a stop in good time before the obstacle and avoid the accident.



Full braking
If the system responses described above are not sufficient or the driver fails to react appropriately to avoid the imminent collision, the above-described criticality measurements do not decrease sufficiently – the situation therefore remains critical. In this case, automatic full braking is initiated at the last moment. A possible criterion for activating emergency braking is for example a “time to brake” which is virtually zero or negative. Automatic full braking will frequently prevent an accident entirely, but at least will greatly reduce the impact speed.

Regulations and standards
Emergency-braking systems for passenger cars
Since 2014 automatic emergency braking when driving in the same direction has been part of the Euro NCAP assessment (European New Car Assessment Program). Emergency-braking systems are assessed by reference to standardized collision scenarios which are recreated on a test track. Here, both the avoidance of collisions by an emergency-braking system and a reduction of the impact speed are positively assessed. The effectiveness of the emergency-braking system installed in each case finally affects the number of NCAP stars that a vehicle can achieve.

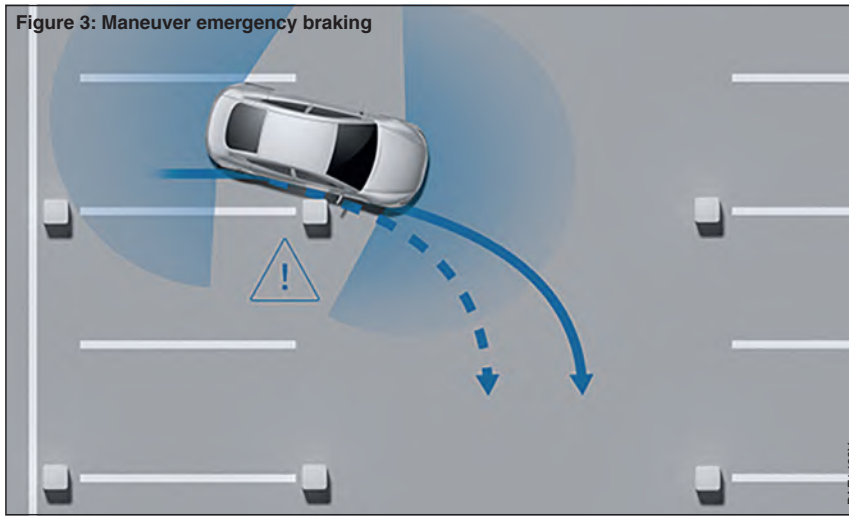
Emergency-braking systems for commercial vehicles
An automatic emergency-braking system (AEBS, Advanced Emergency Braking Systems) has since been prescribed in the EU for heavy commercial vehicles weighing 8 t and upwards (European Union AEBS Regulation (EU) 562/2015, [2]). The introduction was conducted incrementally from 1 November 2013 initially for vehicles to be newly homologated and from 1 November 2015 for all new vehicles brought onto the roads. In a further step the requirements with regard to reducing the speed in respect of moving and stationary targets were tightened from 2016.

Available systems
Various systems are currently available which can significantly reduce speed in critical situations and frequently avoid the collision entirely. However, an automatic emergency-braking system can involve the additional risk of a rear-end impact and in the event of unjustified deployments give rise to acceptance problems. Suitable measures must therefore be taken within the framework of system development to ensure that no unauthorized emergency braking occurs (see “Test and hedging”).

Figure 2: Example of a confusing traffic situation in which automatic emergency braking can prevent a rear-end collision

Statutory requirements
With the front radar sensor and optionally the multifunction camera the legal requirements of UN-ECE R131 [3] regarding the Advanced Emergency Braking System (AEBS) and a large number of regional legal requirements can be satisfied.

Maneuver emergency braking



When maneuvering in tight and complex driving situations and when attempting to maneuver the car into a parking space, maneuver emergency braking prevents the vehicle from bumping into posts, pillars, and neighboring vehicles.

Operating principle of maneuver emergency braking
The assist function constantly monitors the vehicle's surroundings by means of ultrasonic sensors. Using steering angle and driving speed, the system calculates the car's intended path and identifies any obstacles that could get in the way while maneuvering into the parking space (Figure 3).

In the event of an imminent collision, the assist function automatically applies the brakes promptly until the car comes to a stop, thereby preventing dents or scratches.

System benefits for the car driver
– Maneuver emergency braking supports the driver when maneuvering in tight driving situations,
– it helps to prevent accidents when parking and maneuvering and thus avoid damage to the sides of the vehicle.

Automatic emergency braking for unprotected road users

Active pedestrian protection

Motivation

The protection of vulnerable road users, particularly pedestrians, has increasingly taken center stage in recent years. Initially this increased focus resulted in the improvement of passive safety systems for pedestrian protection (e.g., specific design of the vehicle front end to mitigate the consequences of collisions with pedestrians). Now, increasingly, active systems – i.e., systems which clearly act against potential collision – are also going into series production.

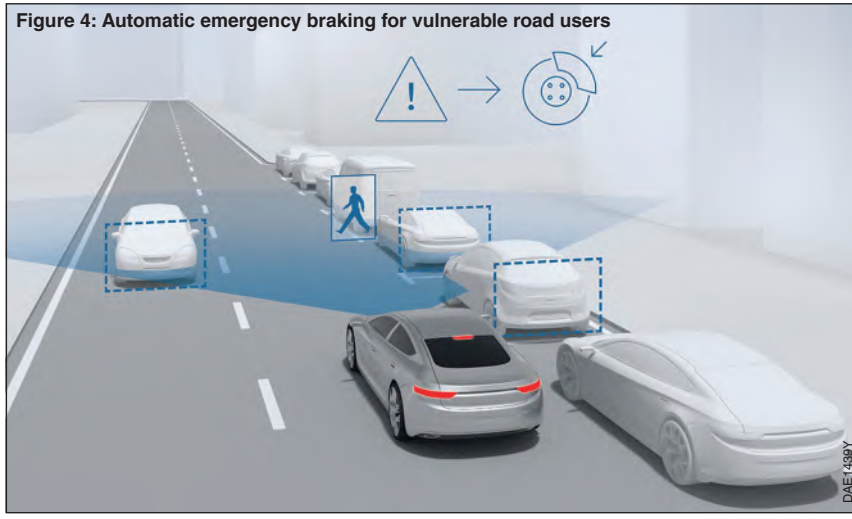
Active pedestrian-protection systems react similarly to emergency-braking systems for vehicles traveling in the same direction. However, the environment-sensing requirements are different; this can be identified in an analysis of the frequently occurring types of accident.

Causes of accidents

The majority of pedestrian accidents involve persons who cross the road while the vehicle is driving straight ahead. The pedestrian steps out from the side in front of the moving car (Figure 4), often from a concealed position (i.e., the pedestrian is initially hidden behind another object).

Another significant number of pedestrian accidents happen at intersections, particularly when vehicles are turning.

Comparison with emergency-braking systems for vehicles traveling in the same direction



System responses

As already mentioned, the system responses for active pedestrian protection are comparable with emergency braking for vehicles traveling in the same direction. The system responds to an imminent collision with a pedestrian with a warning to the driver together with partial and full braking. As pedestrians frequently step out unexpectedly from a concealed position into the road, often only part of the response cascade, i.e., only the partial and full braking for example, is activated.

Environment detection

Pedestrians usually step out from the side into the road. Therefore, when compared with emergency-braking systems for vehicles traveling in the same direc-

Figure 4: Automatic emergency braking for vulnerable road users

tion, a wider area in front of the vehicle must be monitored by the sensor system. To make the correct decision on deployment, the sensor system must be able to measure precisely the lateral velocity of pedestrians in particular. Because pedestrians often step out onto the road from a concealed position, sensors must furthermore be able to detect those pedestrians very quickly (i.e., within a few sensor measurement cycles). This is the only way of ensuring a punctual system response (e.g., full braking).

Various sensor configurations for active pedestrian protection are in series production. In this case, both systems which are based on a single sensor and systems which fuse the information from a number of sensors are used. Sensors used are for example mono video cameras, stereo video cameras, or radar sensors.

Situation analysis

To assess the traffic situation, assumptions must be made about the future movement of the road users involved – i.e., here that of the pedestrian and of the driver's own vehicle. In this way, the system can calculate whether an imminent collision situation can still be averted by the driver or whether an activation of automatic emergency braking is necessary. This prediction is performed in all emergency-braking systems (e.g., emergency-braking systems for situations with vehicles driving in the same direction), but is particularly challenging in the case of active pedestrian protection. Pedestrians can very abruptly stop in their tracks, start to run, or change direction. These movement possibilities must be taken into account in the system in order to avoid unauthorized system interventions. For example, so as not to risk a rear-end collision with the following traffic, the system is not permitted to initiate emergency braking for a pedestrian who steps out onto the road but then stops in time.

Assessment standards

Since 2016 automatic emergency braking for pedestrians has been part of the Euro NCAP assessment (European New Car Assessment Program). Emergency-braking systems are assessed by reference to standardized collision scenarios which are recreated with dummy pedestrians on a test track. Three basic collision scenarios are tested, with the tested vehicle driving straight ahead at different speeds in all the cases:

– an unconcealed pedestrian crossing from the opposite side of the road (in right-hand traffic therefore from the left),
– a pedestrian crossing from the same side of the road (in right-hand traffic therefore from the right), and
– a pedestrian crossing from behind a parked vehicle.

In the last case the dummy pedestrian is the height of a child. The dummy pedestrians are able to move their legs and thus realistically mimic a real walking pedestrian. This is necessary since the movement of the legs is sometimes an important attribute in classifying the detected object as a pedestrian, without which automatic emergency braking would not be initiated. Radar sensors detect for example the leg movement of pedestrians via the micro-Doppler effect. This is characterized by a minimal oscillation of the pedestrian's measured speed signal.

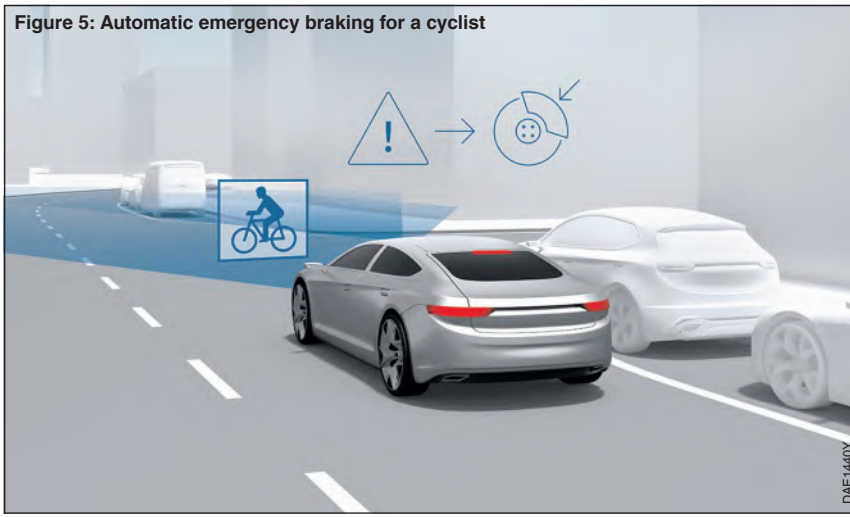
Emergency braking for vulnerable road users traveling in the same direction

Rear-end collisions are among the worst – especially if pedestrians or cyclists are involved (Figure 5). The predictive pedestrian-protection system can prevent such collisions entirely or at the very least significantly mitigate their impact.

Up to 60 km/h the system can trigger automatic emergency braking in order to prevent frontal collisions with pedestrians or at the very last mitigate their impact.

Operating principle

In order to trigger automatic emergency braking before an accident occurs, the vehicle must know at all times if there are any objects in the danger zone in front of the vehicle. Radar sensors installed in the vehicle are on the one hand able to detect objects and other road users thanks to radar sensor technology with chirp-sequence modulation with a high level of reliability and accuracy, even in adverse weather conditions and poor visibility. On the other hand, cyclists and pedestrians can be detected promptly thanks to their wide aperture angle. In addition, the direction of travel and speed of the vehicle are constantly compared with the data of the pedestrian or cyclist. If the system detects a dangerous situation for pedestrians or cyclists, it can warn the driver and automatically initiate emergency braking if the driver fails to react. In this way, a collision with the endangered road user can be avoided or the vehicle's speed can at least be reduced as much as possible prior to impact if a collision is inevitable. This significantly minimizes the risk of serious injury.



Reverse automatic emergency braking

Backing out of a parking space can be a challenge if the driver fails to adequately observe the surroundings behind the vehicle. A fleeting moment of inattention is enough to overlook a pedestrian passing behind a vehicle (Figure 6). Reverse automatic emergency braking for pedestrians reduces this risk as the system monitors the surroundings behind the vehicle and warns of an impending collision. If the driver does not react in time, the system automatically brakes the vehicle. This makes backing out of parking spaces safer and more comfortable.

Environment sensing

With the combined use of ultrasonic sensors and near-range cameras, the sensor data can be merged in the ECU and a 3D surround view created for a better and more robust understanding of the scene. Other road users, objects, and

Figure 5: Automatic emergency braking for a cyclist

parking-space markings can be detected and understood by means of data fusion. This makes parking functions and automatic emergency braking for vulnerable road users even more reliable and safer.

Thus, for example, while the vehicle is being backed out of a parking space, the system detects when a pedestrian is walking past behind the vehicle and relays this information to the brake control system, which then triggers automatic emergency braking.

Safety

The predictive pedestrian-protection system complies with the NCAP requirements regarding automatic emergency braking.

Intersection assistant

Motivation

Cause of accidents
Around 26 % of all accidents involving injury in Germany occur when crossing intersections and turning [1]. Driver-assistance systems which are designed to prevent this common type of accident are called intersection assistants. This covers safety functions with the aim of avoiding accidents or mitigating their severity. To achieve this, the driver is alerted at an early stage to an imminent accident or an automatic braking of the vehicle is performed.

Environment sensing
Other road users are detected with radar sensors, video cameras or lidar sensors and their distance, speed and direction of movement are determined. The information is processed by the microcomputer of an ECU and evaluated in the form of an object list in software.

Situation assessment
An imminent accident is predicted whereby the future position of the vehicles is predicted from the measured positions and speeds of other road users and the motion status of the driver's own vehicle. In the next step the system checks whether the predicted vehicles coincide, which would correspond to an imminent collision. It is however necessary to take into account in this respect that the measured positions and speeds are invalidated by measuring errors. It is furthermore not known exactly how the vehicles will move in future, i.e., whether they will for example brake or steer. Therefore, when it comes to predicting the situation development, driving maneuvers which would avoid an accident must also be taken into account. The less these avoidance maneuvers are possible, the more critical the situation. The situation where an accident cannot be avoided or can only be avoided with difficulty by means of normal handling is called an acute collision risk.

It is particularly difficult to distinguish between critical and non-critical situations in intersection scenarios as the vehicles have a large freedom of movement in several direction and the turning behavior of the vehicles involved would have to be predicted several seconds in advance. This is almost impossible, especially when the vehicles involved are being driven in a sporty style. For this reason, an imminent accident can only be unequivocally detected just before the collision.

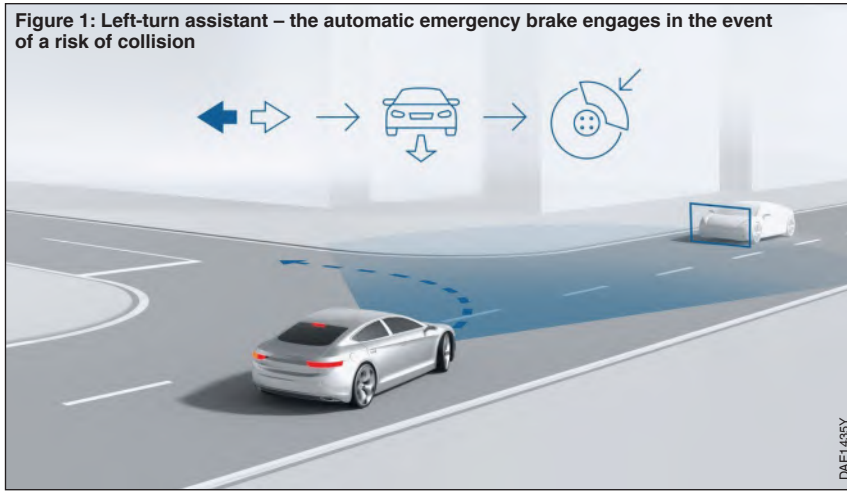
Unauthorized brake interventions must be avoided without fail as firstly they would not be accepted by the driver and secondly they constitute a potential danger to the following traffic. In certain situations, therefore, automatic emergency braking cannot be activated or can only be activated with a delay. Accident prevention is then no longer possible in some circumstances. If, for example, the driver's vehicle is traveling at high speed, an accident-avoiding braking operation would as a rule have to be initiated very early, but this is not possible due to the situational uncertainties and the risk of incorrect deployments.

But even if the system cannot avoid an accident in an individual case, it can mitigate the consequences of the accident through an automatic braking intervention since the impact speed is reduced and the point of impact favorably shifted under certain circumstances.

A distinction is made between the intersection-assistance systems described in the following.

Left-turn assistant

Causes of accidents
The left-turn assistant is designed to prevent accidents which happen when turning left in the face of oncoming traffic (Figure 1). The accident is usually caused by the driver incorrectly judging the speed of the oncoming vehicle – the accident perpetrator turns although there is no longer enough time to complete the maneuver.



Environment sensing
The multifunction camera used in addition to the front radar sensor helps to increase the availability of the AEB functions (automatic emergency braking). Objects can be detected, classified, and tracked more reliably thanks to the fusion of the sensor data from the radar and the camera. This creates an extremely detailed and reliable "image", which is the basis of a robust interpretation of the vehicle's surroundings.

System response
When turning, the driver must not only keep an eye on crossing traffic, but also on oncoming traffic. Disregarding or misjudging the speed of an oncoming vehicle can quickly develop into a dangerous situation (Figure 1). Here automatic emergency braking engages for turning scenarios. An imminent left-turn maneuver by the driver can be detected by an evaluation of turn signal, accelerator-pedal position, and steering angle.

When the vehicle is stationary in preparation for making a turn and the driver tries to make the turn even though there is a real danger of collision, the driver is warned in a first stage. If there is an acute risk of collision, automatic braking or start prevention is finally initiated. The driver is prevented from moving off until the danger has passed. If the vehicle has already been set in motion despite the risk of collision, the system recognizes the dangerous situation and warns the driver. The driver is then responsible for reacting appropriately.

To avoid the situation where the vehicle in the event of an incorrect response cannot be moved in a potentially dangerous situation, the driver can override the start prevention by means of a kickdown.

Figure 1: Left-turn assistant – the automatic emergency brake engages in the event of a risk of collision

Cross-traffic assistant

Causes of accidents
The cross-traffic assistant is designed to prevent accidents which happen when crossing intersections and turning in the face of vehicles that are themselves crossing (Figure 2). Because passengers involved in side collisions are much less adequately protected than in head-on collisions due to the lack of crumple zones, the risk of injury is particularly high.

Obscurations/obstructions are frequent causes of accidents as well as distracted and inattentive drivers.

Environment sensing
As with the left-turn assistant, crossing vehicles are detected by environment sensors. Compared to the left-turn assistant, however, the field of vision to be covered is much wider (≥180°), meaning that generally several sensors must be used. Radar sensors mounted at the front corners of the vehicle enhance the vehicle's horizontal field of vision and enable the system to detect crossing vehicles even earlier and faster, even those traveling at higher speeds. These radar sensors are ideally designed for detecting and differentiating between relevant objects, particularly in hectic and confusing urban traffic.

System response
If while the vehicle is entering a blind intersection the system detects a crossing vehicle approaching, the driver is alerted in an initial stage to the presence of a potentially dangerous traffic situation (e.g., visually by way of a neutral indication in the head-up display). If the driver attempts to enter the intersection even though another vehicle will shortly be crossing the lane and a safe crossing of the intersection is no longer possible, the system prevents the vehicle from moving, for example by cutting the fuel supply or engaging the brakes. As with the left-turn assistant, start prevention can be overridden by means of a kickdown. At faster speeds a warning (conspicuous visual or acoustic indications) is issued first in the event of an imminent collision with cross-traffic. If the driver fails to react, the system initiates an automatic brake intervention in the event of an acute collision risk.

Outlook
Because obscurations/obstructions caused for example by parked vehicles are frequently encountered in intersection situations, presumably car-to-car communication (C2C) will also play an important role in the future. Here the vehicles exchange information by radio signal on their position, speed, and steering angle, and can thus detect potential conflicts at an advanced stage and take countermeasures. The position of the vehicle is determined beforehand by satellite positioning. However, extremely accurate locating of the vehicles is required to enable the information from a safety-critical function like the cross-traffic assistant to be used. This is not possible however with the precision of GPS that is currently used by commercially available navigation devices. This is caused by for example atmospheric interference. In the case of Differential GPS (DGPS) a second GPS receiver, whose exact position is known, is used. This generates a correction signal which can be used by other GPS units in the immediate surroundings to correct the interference. Centimeter-perfect locating is thus theoretically possible. However, this system is currently still very expensive and therefore cannot be used for series introduction in vehicles. Furthermore, the GPS receiver must be in direct radio contact with a larger number of satellites, which is often not the case in urban canyons.

Traffic-light and stop-sign assistants

Causes of accidents
Unlike the left-turn and cross-traffic assistants, the traffic-light and stop-sign assistants are designed not to prevent an imminent collision with other road users, but to prevent the driver from accidentally running a red light or a stop sign. This is intended to prevent accidents which happen as a result of these traffic violations.

Environment sensing
A video camera equipped with image-recognition algorithms scans the vehicle environment for traffic lights and road signs (see Road-sign recognition), whereupon their status and their meaning are interpreted. To reduce the risk of erroneous detections, digital maps can be used in which the positions of road signs are marked.

An alternative is offered by car-to-infrastructure communication (C2I). Here, the traffic light for example communicates its status by radio signal to vehicles equipped with special receivers in the surrounding area. Furthermore, the associated stop line must be detected to enable the system response to be sensibly configured in terms of time.

System response
If the driver is on the point of not stopping at a red light or a stop sign, a warning is issued first. If the driver then fails to react appropriately, the vehicle can also, depending on the system design, be automatically braked.

A sensible response to the yellow phase is only possible if there is still sufficient distance for a comfortable stopping operation or if the remaining duration of the yellow phase is known for example via C2I.

Another type of traffic-light assistance pursues the objective of optimally utilizing the green phases and avoiding unnecessary braking and acceleration phases. Aside from the fluid and comfortable driving style, this is also intended to lower fuel consumption. In this system the traffic lights ahead transmit their traffic-light phase and the time until the phase change to approaching vehicles. The speed at which the next traffic light is reached on green is displayed in the instrument cluster.

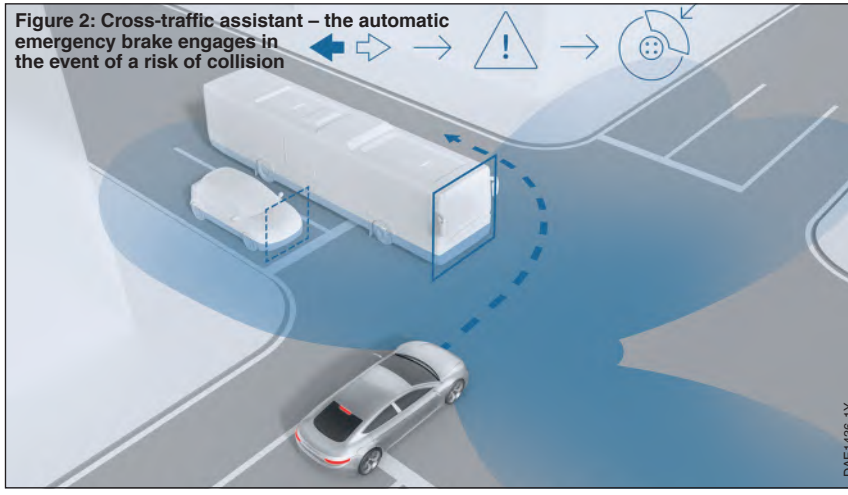

Figure 2: Cross-traffic assistant – the automatic emergency brake engages in the event of a risk of collision

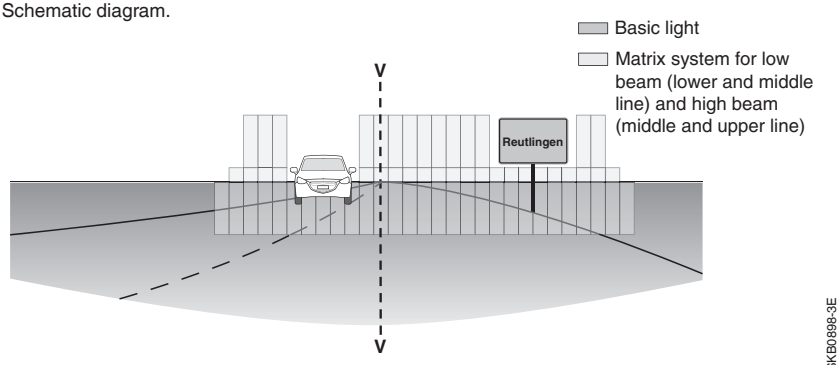
Intelligent headlamp control

Motivation

Statistics show that people are exposed to a significant risk of being involved in a serious accident when driving at night. A typical driver when driving at night for the most part does not switch on the high beam and drives on low beam even though activating the high beam is perfectly possible. Some drivers do not engage the high beam at all and continuously drive on low beam. A system with a high-beam assistant activates the high beam much more frequently than the typical driver who activates manually and thereby significantly improves the illumination of the road compared to the low beam. The figures from the statistics are very much dependent on the traffic density – the lower the density, the greater the use of the high beam. It has also been established that fatigue and lack of concentration causes drivers not to manually turn off the high beam reliably and thus to dazzle other road users.



An automatic system offers a dramatic improvement for all road users. The driver of a vehicle with a high-beam assistant experiences a noticeable reduction of the burden and, thanks to automatic activation, a more frequent improvement in illumination. Automatic deactivation of the high beam ensures that drivers of oncoming vehicles are not dazzled.

System designs

The high-beam assistant automates the process of switching between low beam and high beam. It detects vehicles driving in front and oncoming vehicles and automatically switches the high beam on or off to suit the traffic situation. This significantly increases safety and comfort when driving at night, mainly on highways and expressways.

Basic version
The system consists of a light-sensitive sensor or a camera, combined with an ECU which controls the headlamps. The camera is either integrated in the rearview mirror or installed in a standalone sensor assembly on the windshield. The camera detects and distinguishes between vehicles and stationary street lights. The system detects oncoming vehicles up to a distance of 600 m and tail lamps of vehicles driving in front up to a distance of 400 m. The positions of detected objects are transmitted to the headlamp ECU, with the data being transmitted via the CAN bus used in the vehicle. The headlamp ECU calculates from the position data whether an object is in the headlamp's beam range and dazzling can occur. The high beam is automatically deactivated if the sensor system detects an object that can be dazzled. If the sensor system does not detect an object, the high beam is automatically activated. The high beam is deactivated even in the presence of street lights for example in urban areas which the system detects and can distinguish from other objects.

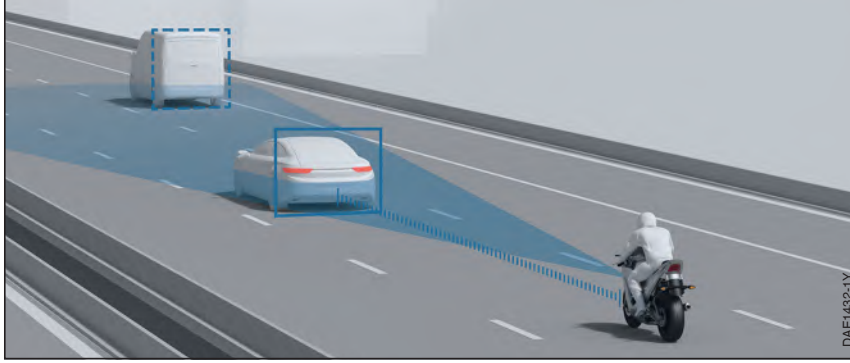
Figure 1: Matrix headlamps
Schematic diagram.

Further expansion stages
The range of the low-beam or high-beam lights can be automatically adjusted using video data.

The next stage of intelligent headlamp control facilitates adaptive high-beam control. This not only controls the range of the light, but also adapts the width of the beam to the traffic conditions. This can, for example, illuminate curves in advance or in urban traffic deliver a wider light cone which can effectively illuminate the edges of the road, ultimately helping the driver to spot any potentially vulnerable pedestrians.

With a further expansion stage of headlamp control the driver can drive with the high beam permanently on. Oncoming traffic or traffic ahead and its position are detected on the basis of camera-image analysis. The system is based on horizontally and vertically swiveling headlamps or full LED headlamps in which the entire light distribution is controlled in segments so that on the one hand road users who could potentially be dazzled are not exposed to the light cone (matrix headlamps, Figure 1), while on the other hand the remainder of the area can be optimally illuminated by the high beam (“Glare-free high beam”). The light distribution from the high beam remains virtually unchanged, while the driver's visual range is increased considerably. Most of the high beam can thus remain switched on and contribute to the driver’s safety and comfort without dazzling other road users.

Advanced rider-assistance systems for two-wheelers



Assistance systems such as the antilock braking system (ABS) and motorcycle stability control (MSC) have already made riding on two wheels considerably safer. Advanced rider-assistance systems (ARAS) can make a further contribution to increasing safety. The electronic assistants are always vigilant and, in emergencies, they respond more quickly than humans can. The technology underpinnings these systems is a combination of radar sensor, braking system, engine management, and HMI (Human Machine Interface). Giving motorcycles radar a "sensory organ" makes these new assistance and safety functions for two-wheelers possible while providing a accurate picture of the vehicle's surroundings. As a result, these assistance functions not only increase safety, they also enhance enjoyment and convenience by making life easier for riders.

– With ARAS the rider can concentrate better on the current traffic situation,
– the system supports the rider in critical situations and helps to avoid accidents,
– more comfortable and relaxed riding,
– the electronic assistants are always vigilant and, in emergencies, they respond more quickly than humans can.

Adaptive cruise control

Riding in heaving traffic and maintaining the correct distance to the vehicle in front takes a great deal of concentration and is exhausting over longer periods. Adaptive cruise control (ACC) adjusts the vehicle speed to the flow of traffic and maintains the necessary safe following distance to the vehicle in front (Figure 1, see also Adaptive cruise control). ACC can effectively prevent rear-end collisions caused by insufficient distance to the vehicle in front. And not only does ACC offer riders more comfort and convenience, for example when riding in convoy, it also allows them to concentrate more on the current traffic situation.

Figure 1: Adaptive cruise control
The motorcycle adapts the speed to the vehicle in front.

Forward collision warning

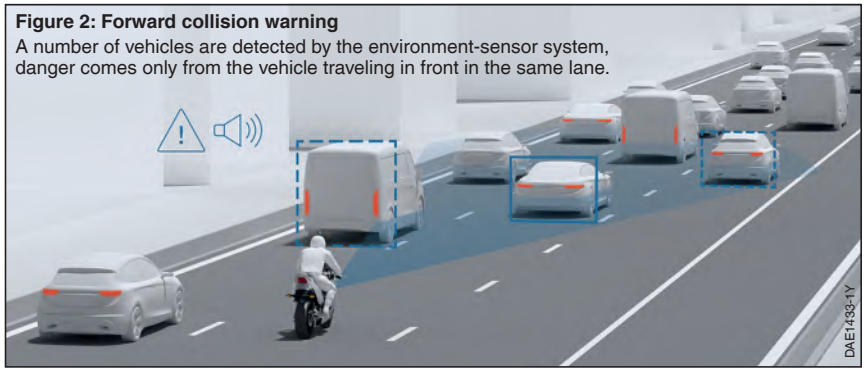
In road traffic, even the briefest lapse in concentration can have serious consequences. The forward collison warning for motorcycles reduces the risk of a rear-end collision or at the very least mitigates it impact. The system is active as soon as the vehicle starts and it supports the rider in all relevant speed ranges. If the system detects that a vehicle in front is dangerously close and the rider fails to react to the situation, it warns the rider by way of an acoustic or visual signal (Figure 2).

Forward collision warning alerts the rider promptly to the danger of a rear-end collision so that the rider is able to react in time.

Blind-spot detection

Blind-spot detection helps motorcycle riders change lanes safely. A radar sensor acts as the system's electronic eye, detecting objects in hard-to-see areas. Whenever there is a vehicle in the rider's blind spot, the technology warns the rider with a visual signal, for example in the rearview mirror (Figure 3).

Figure 2: Forward collision warning
A number of vehicles are detected by the environment-sensor system, danger comes only from the vehicle traveling in front in the same lane.



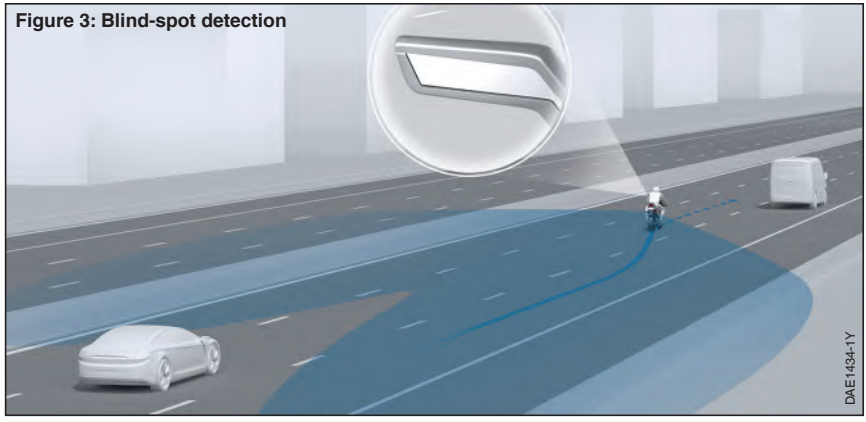


Figure 3: Blind-spot detection

Interior-monitoring systems

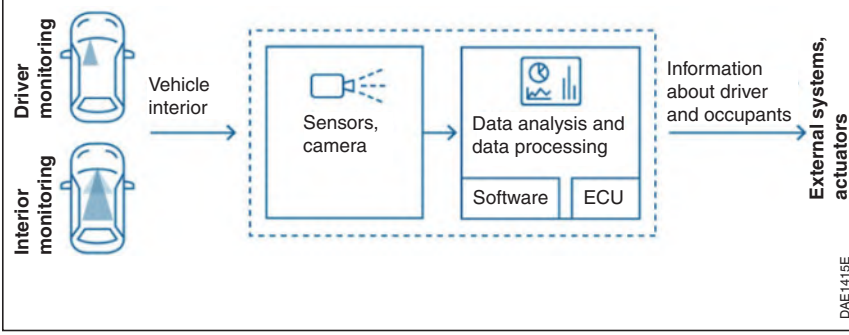
Interior monitoring enhances safety, comfort, and convenience for all vehicle occupants. The system for monitoring the vehicle interior from Bosch is able to detect signs of distraction or drowsiness and even whether a child has been left behind in the vehicle, and alerts the driver to critical situations. Safety systems, such as for example the seat-belt alert function, are further enhanced by information acquired from the vehicle interior. Besides the various safety-relevant applications, the system also provides a range of innovative interaction options, like gesture control for distraction-free operation of the infotainment system. Vehicle interior-monitoring systems will in future be absolutely essential in automated vehicles for ascertaining whether the driver is able is able to take control of the vehicle in a particular situation.

Camera-based interior monitoring

The modular system provides vehicle manufacturers with a high degree of flexibility when adapting the system to different requirements and vehicle types.

It means the tailored solutions can be implemented quickly and cost-effectively, and it allows other systems, such as automated driving, passive safety, and infotainment, to be integrated seamlessly.

Driver monitoring



Driver-drowsiness detection

The driver-monitoring camera (Figure 1) monitors the alertness and state of the driver. It can detect distraction, drowsiness, and microsleep and alerts the driver promptly.

Driver identification

Facial recognition makes it possible for the system to identify the driver with absolute certainty. Using the stored driver profile, the system can then automatically adjust personal comfort and convenience settings such as optimal seat and mirror positions, favorite radio station, or preferred interior temperature.

Figure 1: Camera-based interior monitoring

Interior and occupant monitoring
With the interior-monitoring system, it is not just the driver who is the focus of attention. The camera is positioned in such a way that all seats are in its field of vision. The system can detect the presence of any other occupants and can then provide more specific reminders to fasten seat belts.

The system is also able to identify whether the front passenger seat is occupied and can thus deactivate the airbag if, for instance, a child safety seat is present.

Rising temperatures in the vehicle can quickly become dangerous for a child left behind on the back seat. The system warns the driver in this case too in order to prevent a critical situation like this occurring in the first place.

Safety and convenience
The interior-monitoring system makes it possible to implement innovative interaction interfaces, such as gesture control. This enables the driver, for instance, to skip to the next song with a simple hand movement without looking away from the road. This reduces distraction and at the same time enhances the “user experience”.

Driver monitoring for automated driving
In future automated vehicles it will be necessary to know whether the driver is able in critical situations to assume control of the vehicle again.

In automated driving situations the driver can adopt a more relaxed posture because they no longer have to control the vehicle permanently. In dangerous situations the system can determine the seat position and move the occupant into a safe position so that they are afforded optimal protection in the event of a collision.

Future of automated driving

Automation levels

Driving a car can be fun, but can also be tiring or even dangerous. Driver-assistance systems support drivers in difficult driving situations or relieve them of tiresome and monotonous driving tasks.

A trend that has been observed in recent years is the increasing degree of automation of the systems on the market. This trend will continue in the future [1], [2].

Levels according to SAE
The definitions of the SAE (SAE J3016 [3]) have gained acceptance as the standard worldwide when it comes to classifying the driving functions of continuous automation. There are five different levels.

Level 1
An assistance system assumes lateral or longitudinal control of the vehicle in a specific application. The driver is supported, but remains responsible.
Examples: Lane-keeping systems, adaptive cruise control (ACC).

Level 2
The system assumes longitudinal and lateral control in a specific application. The driver is supported, but remains responsible. The driver monitors the system constantly and takes on the delegated tasks where necessary.
Example: Highway assistant.

Level 3
The system takes on the entire driving task in a specific application. The driver no longer has to monitor the system constantly, but must be able to take over the driving task again at any time within a short period of time following a takeover request.
Example: Traffic-jam pilot section.

Level 4
The system takes on the entire driving task in a specific application. In the event of a fault, responsibility remains with the system, which brings about a safe state; it does not send a takeover request to the driver.
Examples: Driverless city taxi, automated valet parking.

Level 5
The system takes over the entire driving task in all applications, for instance in cities, on ordinary roads or expressways/highways. The user simply inputs a destination and the vehicle navigates to this destination all by itself. In the event of a fault, responsibility remains with the system, which brings about a safe state.
Example: Vehicle can drive autonomously at any time and under all conditions.

Autonomous driving
The logical extension of this development is therefore a system that can permanently perform all the driving tasks without the driver having to monitor the system. The driver becomes a passenger and can use the journey time for other activities, such as for example reading, working or even sleeping.

Further applications would include the vehicle independently looking for a parking space (see Automated valet parking), driving to the garage or taking the children to school without a driver actually having to be in the vehicle. Last but not least, it is hoped to reduce the number of accidents in that a computer-controlled system can essentially react faster and more reliably than a person and unlike the driver does not get tired.

Obstacles to automated driving

The idea of driverless driving has been pursued for several decades in numerous research projects. As early as 1986 Professor Dickmanns (University of the Federal Armed Forces, Munich) introduced a “robot vehicle” which was able to drive under automated conditions on expressways/highways at speeds of up to 96 km/h. In 1995 Professor Dickmanns’ team drove another vehicle from Munich to Copenhagen and back (covering a distance of 1,758 km) with automatic longitudinal and lateral guidance. The system was available for 95 % of the journey time.

In 2004 the US Department of Defense organized the DARPA Grand Challenge (DARPA, Defense Advanced Research Projects Agency), the first competition over a longer distance for autonomous vehicles.

The DARPA Urban Challenge organized in 2007 involved the autonomously driving vehicles having to perform a range of tasks in quasi-urban traffic in a former air-force base.

As the various research projects have shown, today it is perfectly possible to build a Level 4 or Level 5 prototype vehicle. But before such vehicles can be put into series production, some technical and non-technical obstacles have to be overcome.

Since 2011 Robert Bosch GmbH has been joining various vehicle manufacturers and other suppliers in working on the technologies that are required for automated driving. Since 2013 Bosch has also been running test vehicles in public traffic.

Technical obstacles

The technical aspects involved are, from a functional standpoint, essentially environment detection, understanding of the situation, and the behavior planning derived from them.

Environment detection

With regard to environment detection, all aspects of the vehicle’s surroundings as are a matter of course to a human driver must be sensed and detected. These aspects include detecting other road users and detecting the road, obstacles that cannot be driven over, and the traffic infrastructure (e.g., road markings, road signs and traffic lights).

Understanding of the situation

In the final analysis, the gestures of other road users and traffic police officers must also be interpreted. Both the reliable measurement at all times of all these aspects and the processing of the data supplied by these environment sensors are currently still stretched to their limits.

Behavior planning

A further functional challenge is to derive appropriate actions (behavior planning) in real time. Traffic situations are often highly complex, particularly in urban environments, due to the fact that a multitude of road users, traffic regulations and special situations has to be taken into account. A number of pilot projects are already addressing the urban sphere, e.g., in the low speed range. These systems are however not yet available in production vehicles.

Outlook

With the inexorable advances in development (e.g., with increasing computing capacity, powerful learning algorithms) it appears that these functional obstacles can be surmounted in the foreseeable future.

As for a further technical obstacle, the validation of functional reliability, there is as yet no general solution approved by legislators for series production: A fully automated vehicle naturally may not jeopardize its occupants or other road users in any situation through failures/faults. The failure rate will therefore have to satisfy extremely stringent requirements for a

series-production launch. To ensure this, many millions of kilometers would have to be completed in test drives, which is currently not economically feasible and necessitates the use of simulations.

Legal obstacles
Finally, there are also legal (non-technical) obstacles that need to be removed. It is unclear for instance who is liable for the damage/injury caused by a vehicle at automation level 3 or higher when the driver no longer has responsibility for vehicle handling.

Aside from the question of liability, Level 3 and higher automated driving functions in public traffic are currently not legal in many countries. Often there are no binding approval criteria for vehicles with systems at higher automation levels. Furthermore, the regulatory legislation needs to be adapted because driving strategy and behavior in traffic are determined no longer by the driver, but by the algorithms of a technical system.

The responsibilities for the legislation are regulated differently worldwide, resulting in a fragmentation of the requirements. The UNECE (United Nations Economic Commission for Europe) has a central role in the goal of harmonizing the requirements.

Stages on the road to autonomous driving

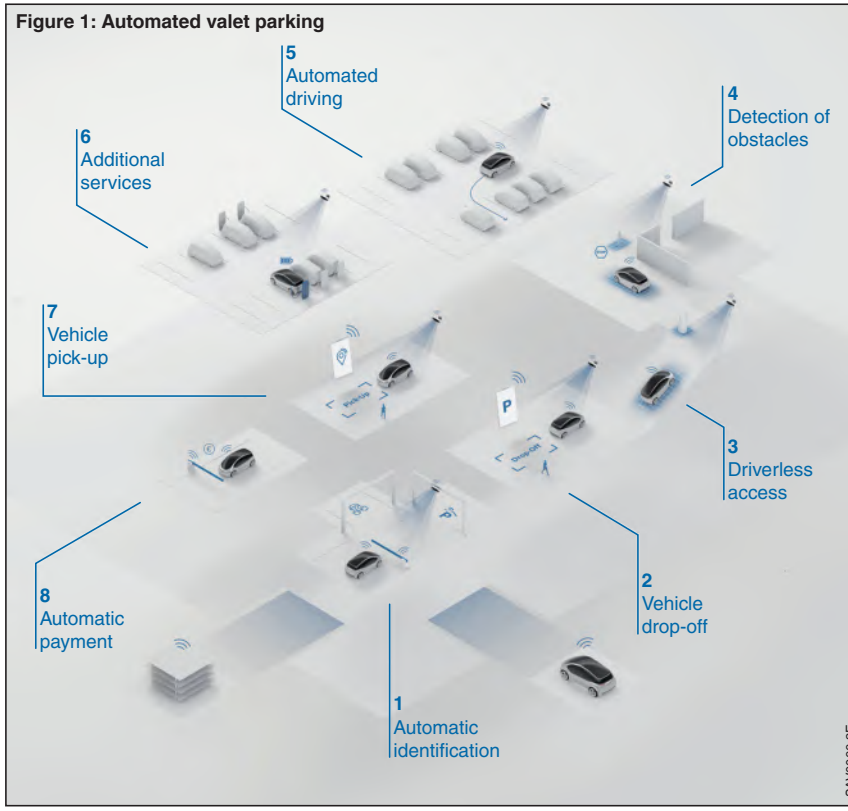
Autonomous driving (Level 5) will not be introduced suddenly, but instead will come in stages. In other words, initially systems at a lower automation level (Level 2), which are confined to specific use-cases, will be brought into series production. These can be for example:
– expressway/highway situations, due to the more simply structured and less complex environment,
– traffic-jam, parking and maneuvering situations, since they typically occur in the low-speed range, the sensors involved only need to have a short range, and the vehicle can be brought to a stop very quickly and with only a minimal stopping distance.

Combinations are naturally also conceivable, such as the traffic-jam pilot described in the next section.

Development of assisting driving functions
Assisting driving functions such as adaptive cruise control (ACC), lane-keeping support, and parking assistant have been established on the market for some years now. And also Level 2 functions such as the traffic-jam assistant are now available on the market.

Traffic-jam assistant
Here the system performs lateral and longitudinal guidance completely in traffic-jam situations. At low speeds the driver depending on the functionality does not have to keep his hands on the steering wheel, but does have to monitor the system and intervene if necessary. The traffic-jam assistant as a rule functions in a speed range up to 60 km/h.

Highway assistant
The highway assistant assumes longitudinal and lateral control at typical expressway/highway speeds (e.g., combined system of ACC and lane-keeping support). But ultimate responsibility remains with the driver. He must monitor the system so that he can intervene at any time. Depending on the functionality, the highway



assistant can also contain the traffic-jam assistant function.

Traffic-jam pilot and highway pilot
The next level of automation (Level 3) includes for example the traffic-jam pilot, which assumes complete responsibility for vehicle handling/guidance in traffic jams. To realize the follow-on highway pilot, it is necessary to provide the emergency stop subfunction, which can bring the vehicle to a safe stop on the hard shoulder (emergency lane) if the driver is unable to re-assume responsibility for driving. Unlike the highway assistant, the highway pilot assumes responsibility for vehicle handling/guidance. The driver can perform secondary activities, but must where necessary be able to take over the driving task from the system again within a few seconds.

Automated valet parking
On top of the expressway/highway functions, the parking and maneuvering functions are also subject to ever-increasing automation. Systems which drive the vehicle independently under human supervision into a parking space are already available (see Parking and maneuvering systems).

Automated valet parking goes one step further. A smart parking-garage infrastructure works hand in hand with the technology in the vehicle to handle the entire parking operation in the parking garage under fully automated conditions (Figure 1). The necessary parking-garage infrastructure includes cameras which detect vacant parking spaces in the parking garage, monitor the driving corridor and its surroundings, and detect unexpected obstacles or persons in the lane so that

Figure 1: Automated valet parking

the vehicle can react immediately. The technology in the vehicle converts the infrastructure's commands into driving maneuvers. The data acquired by the cameras are processed by the parking-garage IT technology to compute the routes and satisfy all the safety requirements. A technical unit which communicates with the vehicle and a cloud connection for interacting with the back end are also required.

Once the driver has parked their vehicle in a drop-off area in front of the parking garage, the vehicle is safely and efficiently navigated by the system into a vacant parking space. The parking operation comprises the following individual stages (see Figure 1):

1. Automatic identification
Because an “automated valet parking” space has already been reserved through an app on the smartphone or by the in-car infotainment system, the smart infrastructure already identifies the vehicle at the entrance.

2. Simple vehicle drop-off
The driver comfortably parks their vehicle in the drop-off area, gets out, and activates the valet service by smartphone command. From this moment on, the “automated valet parking” infrastructure is in constant communication with the vehicle and navigates the vehicle to a vacant parking space.

3. Driverless access
The cameras installed in the parking garage detect vacant parking spaces and monitor the driving corridor and its surroundings.

4. Detection of obstacles
If unexpected obstacles such as persons or objects are detected in the surrounding area by the smart “automated valet parking” infrastructure, the vehicle is immediately brought to a stop.

5. Automated driving
The vehicle maneuvers itself into the tightest parking space thanks to the “automated valet parking” infrastructure.

6. Additional services
Automated valet parking extends the range of possible services, such as for example driverless battery charging while the vehicle is parked in the parking garage.

7. Simple vehicle pick-up
As soon as the driver is ready to pick up, they activate their vehicle by smartphone and the smart parking-garage infrastructure directs the vehicle automatically to the pick-up area.

8. Automatic payment
Payment is taken automatically at the exit. Depending on the business model, all the partners involves share the parking charge.

Bosch and Daimler have in this connection reached a milestone on the road to automated driving. In summer 2019 the two companies received the approval of the relevant authorities for the automated parking system in the parking garage of the Mercedes-Benz Museum in Stuttgart/Germany. It is therefore the world's first fully automated and driverless parking function in compliance with SAE Level 4 officially approved for everyday use.

Long-term goal – autonomous driving
The logical extension of development is an automation level 5 vehicle that can take the passengers from door to door like a taxi. Here the vehicle must be able to drive autonomously at any time and under all conditions.

Such fully automated systems are also already in development. They are, on account of the absence of driver supervision and thus the absence of a human fallback level, based on a completely different system architecture from classic driver-assistance systems.

Thus Level 4 and 5 automated and autonomous systems must have a redundant design. As well as a failsafe power supply for safety-relevant system components and redundant actuators (e.g., steering intervention by power steering or asymmetrical intervention of driving-dynamics control), redundant sensor concepts must be used. The goal is therefore to compensate for technological weaknesses in the

various sensors. For example, a video sensor as an individual sensor can be dazzled by bright sunlight. A redundant sensor concept is based accordingly on the combined use of sensors that use independent measuring principles (e.g., radar, video, and lidar), but also overlap with regard to their sensing range.

In addition, a new central system component is introduced in fully automated systems with high-precision digital maps. This is required to provide information for representing the surrounding environment which cannot be measured with environment sensors (e.g., course of a road after the bend/curve).

Another new component is the behavior planner, which assumes the job of tactical maneuver planning which was previously performed by the human driver. Examples are the recognition of the need for a lane change, a slipping-in maneuver or an overtaking maneuver, to name just a few.

Exact vehicle locating is necessary to enable the data supplied by the environment sensors to be correctly associated with the digital map. The purpose of locating is, on the basis of the GPS position (Global Positioning System), the vehicle-motion data (e.g., the driving speed) and striking environmental features (e.g., trees, houses, city-limit signs), to pinpoint the exact position of the vehicle on the digital map. This is the only way of ensuring correct data association between environment sensors and map data.

As well as the pure measurement of stationary and moving objects in road traffic, a fully automated system must be able to understand and utilize all the paths of communication between road users (e.g., gestures and eye contact with a pedestrian on a zebra crossing, hand signals by cyclists, traffic signs carried by police officers or road workers). While technical solutions for communication between vehicles and infrastructure already exist with Vehicle2X, research is currently still being conducted into robust solutions to gesture recognition in road traffic.

The development of these systems is constantly progressing. In a few years these systems will leave their prototype status behind and will be adopted in our everyday lives.

Belt pulleys, belt drives 722
Belt run, belt drives 721
Belt slack, occupant-protection systems 1418
Belt-driven starter generator, hybrid drives 995
Belt-force limiter, occupant-protection systems 1419
Belt-pulley profile, belt drives 722
Belt-reminder system, safety systems in the motor vehicle 1410
Belt-run forces, belt drives 721
Belt-run lengths, belt drives 728
Belt-tensioning systems, belt drives 724, 729
Bending stress, material parameters 262
Bending stress, mechanics 52
Bernoulli equation, flow mechanics 58
Bernoulli's Law, flow meters 1746
Bessel functions, wave optics 78
Bevel crown wheel, differentials 626
Bevel-gear differential, differentials 626
Bevel-gear pinion, differentials 626
Bifuel vehicles, engines fueled by natural gas 894
Bifuel-Motronic 805
Bi-Litronic, lighting equipment 1351
Bimorphous spring element, acceleration sensor 1753
Binary classifier, sensor-data fusion 1866
Binary system, mathematics 204
Bingham bodies 538
Biodiesel, diesel fuel 575
Bioethanol, gasoline 568
Biofunctional filters, cabin filters 1397
Biogas, engines fueled by natural gas 894
Biomass-to-Liquid, fuels 577
Biomethane, engines fueled by natural gas 894
Biomethane, natural gas 580
Bipolar transistors, electronics 144
Bit stuffing, CAN 1696
Bitstream, FlexRay 1700
Bi-turbo supercharging, complex supercharging systems 784
Black malleable cast iron, metallic materials 277
Blank, radial tire 1172
Bleeding, lubricants 538
Blend components, diesel fuel 575
Blend components, gasoline 568
Blending chamber, climate control 1393
Blending-flap system, climate control 1393
Blends, plastics 315
Blind rivet, riveting 458
Blind-spot detection, advanced rider-assistance systems for two-wheelers 1931
Block copolymers, plastics 315
Block diagram 1546
Blocking converter, DC-DC converters 1595
Blow-off valve, exhaust-gas turbocharger 779
Bodies submerged in a fluid flow, flow mechanics 59
Body acoustics 534
Body mass, motor-vehicle dynamics 489
Body natural frequency, motor-vehicle dynamics 489
Body shock absorbers, chassis systems 1136
Body springs, suspension 1124
Body structures, vehicle bodies, commercial vehicles 1329
Body types of passenger cars, overall motor-vehicle system 30
Boiling curve, gasoline 565
Boiling range, diesel fuels 570
Boiling range, fuels 562
Boiling temperature, material parameters 258
Bolt connections, positive or form-closed joints 428
Bolt loosening torque, threaded fasteners 441
Bolt tightening torque, threaded fasteners 441
Bolt-through design, reciprocating-piston engine 681
Bond angle, chemical bonds 190
Bond-frame module, inverters 1591
Boost converter, DC-DC converters 1595
Boost pressure, exhaust-gas turbocharging 672
Booster heater, climate control 1393
Booster heaters, auxiliary heater systems 1402

Booster voltage,
high-pressure fuel injector 850
Booster voltage,
solenoid-valve injector 933
Boost-pressure control,
Electronic Diesel Control 913
Boost-pressure control,
exhaust-gas turbocharger 781
Boot, exhaust-gas system 796
Borderline pumping temperature,
lubricants 539
Bore, radial shaft seal 401
Boron treatment, heat treatment 338
Bosch process, DRIE process 1720
Bottleneck/constriction assistant,
lane assistance 1910
Bottom dead center, charge cycle 664
Bottom-feed principle, LPG injector 891
Bottom-up approach, architecture
of electronic systems 1679
Boundary descriptor, MOST 1708
Brake booster,
passenger-car brake system 1217
Brake by wire,
electrohydraulic brake 1225
Brake by wire, mechatronics 1641

Control of electric drives,
electrification of drive 984
Control of shift quality,
transmission control 633
Control on the high-pressure side,
common rail 926
Control process,
antilock braking system 1261
Control rod, natural-gas pressure-control
module 899
Control strategy, inverters 1588
Control structure, ESC 1275
Control task, control engineering 244
Control valve, steering 1196
Control-based operating strategy,
control of a hybrid drive 1012

Control-blade independent wheel suspension, wheel suspensions 1152
Controlled braking, automatic brake-system operations 1294
Controlled system, control engineering 242, 245
Controlled variable, control engineering 242
Controller Area Network, buses in motor vehicles 1692
Controller design, control engineering 245
Controllo Stabilità e Trazione, driving-dynamics control system 1287
Convection, thermodynamics 96
Convective heat transfer, thermodynamics 96, 99
Convenience lamps, lighting equipment 1367
Conventional batteries, starter batteries 1483
Conventional radio tuner 1797
Conventional wiper blade, windshield, rear-window and headlamp cleaning systems 1386
Convergent lens, geometric optics 76
Conversion coatings, deposits and coatings 353
Conversion range, hydrodynamic torque converter 604
Conversion rates, catalytic converter 879
Conversion, catalytic converter 874
Converter increase, hydrodynamic torque converter 604
Converter lockup, transmission control 633
Converters, inverters 1582
Convex lens, geometric optics 76
Coolant circuit, reciprocating-piston engine 689
Coolant cooling, water cooling 737
Coolant expansion tank, water cooling 739
Coolant heaters, auxiliary heater systems 1399
Coolant temperature, reciprocating-piston engine 689
Coolant, reciprocating-piston engine 688
Coolant, water cooling 737
Coolant-cooled intercoolers 744
Coolants for internal-combustion engines 553
Coolant-temperature regulation, water cooling 741
Coolant-temperature sensor 1763
Cooler types, inverters 1592
Cooling circuit, exhaust-gas cooling 745
Cooling circuit, water cooling 737
Cooling module, engine cooling 747
Cooling, aerodynamics 521
Cooling, electric final-drive unit 1021
Cooling, electrical machines 1580
Cooling, electronic control unit (ECU) 1636
Cooling, inverters 1591
Cooling, reciprocating-piston engine 688
Cooling-air fan, water cooling 739
Cooling-down phase, flame start system 960
Cooling-system technology, engine cooling 748
Cooperatively regenerative braking system, electrification of drive 976
Coordinate systems, mathematics 211
Coordination Engine, Motronic 804
Copolymers, plastics 307
Copper alloys, nonferrous metals 277
Copper-nickel alloys, nonferrous metals 277
Cords, radial tire 1171
Core-back technique, two-component seals 410
Coriolis acceleration 1743
Coriolis force, yaw-rate sensor 1744
Cornering headlamps, lighting equipment 1355, 1356
Cornering lamps, lighting equipment 1363
Cornering resistance, running resistances 465
Cornering stiffness, motor-vehicle dynamics 484
Correcting variable, control engineering 242
Correction functions, common rail 928
Corresponding acid-base pairs 199
Corrosion inhibitors, diesel fuel 574
Corrosion inhibitors, gasoline 568
Corrosion processes, corrosion and corrosion protection 340
Corrosion protection, brake fluids 558
Corrosion protection, corrosion and corrosion protection 344
Corrosion protection, deposits and coatings 348
Corrosion testing, corrosion and corrosion protection 342

Corrosion, corrosion and corrosion protection 340
Corrosive attack, corrosion processes 340
Corrugated pipe, exhaust-gas system 796
Corrugated tubing, wiring harnesses 1520
Cosine function, mathematics 208
Cotangent function, mathematics 209
Coulomb force, electrical engineering 125
Coulomb friction, mechanics 53
Coulomb, electrical engineering 104
Coulomb, SI units 34
Coulomb's law of sliding friction, mechanics 53
Counterflow cylinder head, reciprocating-piston engine 683
Countershaft, step-up gear units 615
Countersunk-head rivet, riveting 458
Coupler, hydraulic coupler 935
Coupler, piezo high-pressure fuel injector 852
Couplers, electrical engineering 129
Coupling lever, reciprocating-piston engine 682
Coupling, vibrations and oscillations 61
Coupling-shaft link, wheel suspensions 1148
Course setting, ACC 1891
Covalent bonds, chemical bonds 189
Cracking, reciprocating-piston engine 679
Cradle to grave, energy demand for drives 514
Crank pin, reciprocating-piston engine 680
Crankcase scavenging, 2-stroke cycle 666
Crankcase ventilation, air-intake system 760
Crankcase, reciprocating-piston engine 676, 681
Crankcase-ventilation gases, air-intake system 766
Crankshaft assembly, reciprocating-piston engine 691
Crankshaft drive, reciprocating-piston engine 676
Crankshaft main bearing 680
Crankshaft starter generator, hybrid drives 995
Crankshaft throw, reciprocating-piston engine 681
Crankshaft vibration damper 689
Crankshaft web 693
Crankshaft, reciprocating-piston engine 677, 680
Crankshaft-assembly design, reciprocating-piston engine 691
Crankshaft-assembly kinetics, reciprocating-piston engine 692
Crankshaft-drive kinematics, reciprocating-piston engine 691
Crankshaft-speed sensor 1741
Crash recorder, safety systems in the motor vehicle 1411
Crash, safety systems in the motor vehicle 1411
CRC Field, CAN 1695
CRC sequence, CAN 1696
Creaking, locking systems 1434, 1437
Creep behavior, plastics 309
Creeping function, control of electric drives 986
Crevice corrosion, types of corrosion 341
Crimping process, plug-in connections 1523
Critical driving situations, driver-assistance systems 1804
Critical point, water 193
Critical speeds in curves, motor-vehicle dynamics 485
Critical stress intensity factor, material parameters 262
Criticality measurements, driver-assistance systems 1917
Cross product, coriolis acceleration 1743
Cross product, mathematics 214
Crossflow cylinder head, reciprocating-piston engine 683
Cross-linking, adhesive technologies 455
Cross-member, vehicle bodies, commercial vehicles 1328
Cross-over body shapes, vehicle bodies, passenger cars 1313
Cross-ply tires 1171
Cross-section, O-ring 386
Cross-traffic assistant, intersection assistant 1926
Cruise control, ACC 1891, 1892
Cruise control, Electronic Diesel Control 913
Crystal structure, electrical steel strip 292
CTS system, wheels 1158, 1167

Cubic coefficient of thermal expansion, material parameters 258
Cumulative shield, inverters 1585
Cup, radial shaft seal 399
Curie point, material parameters 259
Curie temperature, magnetic materials 290
Curie temperature, material parameters 259
Current characteristic, alternators 1498
Current density, electrical engineering 105
Current intensity, electrical engineering 104
Current law, electrical engineering 110
Current output capability, starter batteries 1483
Current, electrical engineering 104
Cushioning seal, pneumatic seals 406
Customer code area, motor sport 884
Customer-specific extra-small series, motor sport 885
Cutter FID, exhaust-gas measuring techniques 1083
CVD coatings, deposits and coatings 352
CVO process, high-pressure fuel injector 850
CVS dilution procedure, exhaust-gas measuring techniques 1079
CW phase measurement method, lidar-sensor system 1833
Cycle count, FlexRay 1699
Cycle direction, thermal engines 643
Cycle stability, 12 V vehicle electrical system 1459
Cycle stability, starter batteries 1483
Cycles, thermodynamics 91
Cycles, vehicle communication networks 1686
Cyclic redundancy check, Serial Wire Ring 1714
Cyclic redundancy check, vehicle communication networks 1691
Cyclic variations, gasoline engine 653
Cyclical variation, vehicle electrical systems for hybrid and electric vehicles 1564
Cyclone principle, air-intake system 759
Cyclone, air-intake system 769
Cylinder arrangements, reciprocating-piston engine 690
Cylinder charge, management for spark-ignition engines 812
Cylinder head, reciprocating-piston engine 677, 683
Cylinder shutoff, cylinder charge 817
Cylinder-bank shutoff, cylinder shutoff 817
Cylinder-charge movement, diesel engine 659
Cylinder-head gasket, reciprocating-piston engine 684
Cylinder-head gaskets, flat seals 395
Cylinder-head identification, reciprocating-piston engine 683
Cylindrical coordinates, mathematics 212
Cylindrical interference fit, frictional joints 430
Cylindrical rolling bearing, rolling bearings 378

D

Daisy-chain topology, vehicle communication networks 1690
Damped natural frequency, motor-vehicle dynamics 488
Dampers, shock absorbers 1137

Photometric characteristic quantities, lighting quantities 79
Photometric quantities, legal units 39
Photometrical terms and definitions, lighting equipment 1345
Photometry, lighting quantities 79
Photon energy 1776
Photonic-crystal fiber, optical fibers/waveguides 83
Photoresistors 1776
Phototransistors 1777
Photovoltaic effect, sensors 1777
Physical characteristic quantities, lighting quantities 79
Physical layer, vehicle communication networks 1684
Physical material parameters 258
Physical vapor deposition, deposits and coatings 352
Pi filter, inverters 1585
Piezo actuator, piezo high-pressure fuel injector 851
Piezo high-pressure fuel injector, mixture formation 851
Piezo inline injector, common rail 933
Piezoceramic element, knock sensor 1755
Piezoelectric acceleration sensors 1753
Piezoelectric effect, acceleration sensor 1752
Piezoelectric knock sensor 1755
Pilot control, transmission control 640
Pilot injection, axial-piston distributor pump 950
Pilot injection, unit injector 945
Pin connections, positive or form-closed joints 428
Pin-fin concept, inverters 1592
Pinhole-camera model, video sensors 1847
Pipe threads, threaded fasteners 446
Piston bearing surface, reciprocating-piston engine 682
Piston clearance, reciprocating-piston engine 712
Piston guidance, rod and piston sealing systems 413
Piston normal force, reciprocating-piston engine 692
Piston recess, reciprocating-piston engine 676
Piston ring, reciprocating-piston engine 677, 701
Piston seal, O-ring 391
Piston seals, pneumatic seals 406
Piston seals, seals 413
Piston shapes, reciprocating-piston engine 676, 678
Piston speed, reciprocating-piston engine 713
Piston stroke, reciprocating-piston engine 706
Piston, reciprocating-piston engine 676, 684
Piston-pin force, reciprocating-piston engine 692
Piston-ring shapes, reciprocating-piston engine 679
Piston-surface geometry, reciprocating-piston engine 676
Piston-travel function, reciprocating-piston engine 692
Pitch angle, threaded fasteners 437
Pitch angle, vehicle motion 463
Pitch axis, chassis systems 1118
Pitch axis, yaw-rate sensor 1743
Pitch, acoustics 71

Pitch, belt drives 727
Pitch, threaded fasteners 437
Pitch, vehicle motion 463
Pitch-circle diameter, wheels 1156
Pitching moment, vehicle motion 463
Pitot-tube flow meters, sensors 1746
Pitting corrosion, types of corrosion 341
PK profile, belt drives 722
Plain bearings 371
Planar technology, electronics 157
Planck's quantum of action 83
Plane of oscillation, wave optics 78
Plane system of forces, mechanics 49
Plane triangle, mathematics 210
Plane wave,
vibrations and oscillations 62
Planetary gear,
starters for passenger cars 1508
Planetary gears, step-up gear units 610
Planetary-gear set, steering 1201
Planetary-gear set,
step-up gear units 610
Planning, artificial intelligence 254
Plasma discharge,
lighting equipment 1348
Plasma, substances 192
Plastic flow behavior, lubricants 542
Plastic wheel, wheels 1160
Plasticity, control of a hybrid drive 1018
Plastics, materials 306
Plate capacitor,
electrical engineering 108
Plate straps, starter batteries 1478
Plate, finite-element method 237
Plate-cone measuring system,
lubricants 541
Platform software, automotive
software engineering 1647
Platinum resistors,
temperature sensor 1762
Platinum, catalytic converter 874
Plausibility check, diagnostics 1091
Plenum chamber, air-intake system 763
Plenum chamber,
intercooling (charge-air cooling) 743
Plug-in connections 1520
Plug-in connections,
electronic control unit (ECU) 1636
Plug-in hybrid,
electrification of the drive 971
Plug-in hybrid, hybrid drives 998
Plunger-and-barrel assembly,
electric fuel pump 827
PMOS transistors, electronics 148
pn junction, semiconductor 139
PN PEMS, exhaust-gas
measuring techniques 1084
Pneumatic actuators,
air-intake system 766
Pneumatic brake assistant, automatic
brake-system operations 1292
Pneumatic seals, Seals 406
Point cloud, lidar-sensor system 1825
Point of interest,
vehicle navigation 1874
Poisson distribution,
technical statistics 228
Poisson's ratio,
material parameters 260
Polar coordinates, mathematics 211
Polar substances, lubricants 541
Polarization curve, fuel cell 1032
Polarization, electrical engineering 117
Polarization, wave optics 77
Polarization-resistance measurement,
corrosion testing 342
Pollutant dispersion system,
wind tunnels 527
Pollutant emissions, diesel engine 661
Pollutant emissions,
gasoline engine 655
Pollutant formation, diesel engine 661
Pollutant formation,
gasoline engine 655
Pollutant reduction inside the engine,
diesel engine 661
Pollutant reduction, diesel engine 661
Pollutant reduction,
gasoline engine 655
Pollutants, exhaust-gas emissions 716
Pollutants, gasoline engine 655
Poly ellipsoid system,
lighting equipment 1348
Polyacrylic rubber,
elastomer materials 416
Polyester resins, plastics 319
Polyester, plastics 325
Polygon effect, chain drives 732
Polygon ring, high-pressure pump,
common rail 938
Polymer bearings, friction bearings 376
Polynomial, mathematics 205
Polytetrafluoroethylene, lubricants 541
Polytropic curve change of state,
thermodynamics 91
Polyurethane adhesive,
adhesive technologies 456
Polyurethane, plastics 325
Polyurethanes, elastomer materials 417
Poly-α-olefins, lubricants 543

Poor-weather light, lighting equipment 1356
Porosity, material parameters 262
Porous lead dioxide, starter batteries 1479
Porous silicon, micromechanics 1722
Portable emission measuring devices, exhaust-gas measuring techniques 1084
Position detection, electrical seat adjustment 1408
Position determination, GPS 1872
Position lamps, lighting equipment 1360
Position sensors for transmission control 1731
Position sensors 1724
Positional tolerance, tolerances 356
Position-controlled acceleration sensor 1751
Positioning, vehicle navigation 1872
Position-measuring systems, acceleration sensors 1750
Positive belt drives, internal-combustion engines 725
Positive feedback, operational amplifiers 150
Positive grids, starter batteries 1479
Positive or form-closed joints, detachable connections 426
Positive-displacement pump, electric fuel pump 827
Positive-displacement supercharger, mechanical superchargers 773
Positive-locking grip, tire grip 1178
Positron, elements 186
Post-heating phase, preheating systems 955
Post-ignitions, spark plug 868
Postprocessor, finite-element method 234
Potential energy, mechanics 47
Potential energy, thermodynamics 87
Potential-free housing, starters for heavy commercial vehicles 1517
Potentially susceptible devices, electromagnetic compatibility 1526
Potentiometric measurement methods, hydrogen sensors 1775
Potentiostat, corrosion testing 342
Pour point, lubricants 541
Powder composite materials, magnetic materials 294
Power balance, lidar-sensor system 1828
Power coupling procedure, electromagnetic compatibility 1531
Power curve, supercharging 672
Power Density Line, alternators 1505
Power diodes, electronics 141
Power in the alternating-current circuit, electrical engineering 126
Power output per liter, reciprocating-piston engine 703
Power smoothing, on-board charger 1604
Power supply unit, motor sport 884
Power switches, inverters 1583
Power take-up elements, drivetrain 600
Power yield, gasoline engine 656
Power, legal units 37
Power, mechanics 49
Power-assisted steering system, steering 1193
Power-assisted steering systems for commercial vehicles, steering 1203
Power-assisted steering systems for passenger cars, steering 1196
Power-assisted steering systems with modulation capability, steering 1196
Power-factor correction, on-board charger 1603
Power-neutral downsizing, hybrid drives 993
Power-socket consumption, energy demand for drives 511
Power-split hybrid, hybrid drives 1005
Power-steering pump, steering 1198
Power-steering system, steering 1193
Power-sunroof drives, sunroof systems 1406
Power-supply rejection ratio, operational amplifier 151
Power-window systems 1404
Prandtl number, thermodynamics 99
Preamble, Ethernet 1704
Prebraking time, motor-vehicle dynamics 475
Prechamber, wind tunnels 525
Precipitation hardening, heat treatment 336
Pre-crash detection, safety systems in the motor vehicle 1411
Pre-Crash Positioning, integral safety 1427
Pre-engaged-drive starter, starters for passenger cars 1509
Pre-excitation circuit, alternators 1494
Prefilling, automatic brake-system operations 1294

Prefix symbol, SI units 33
Preheating phases,
preheating systems 955
Preheating software,
preheating systems 955
Preheating systems,
start-assist systems 954
Preheating time,
flame start system 960
Pre-heating, preheating systems 955
Pre-ignition, ignition 859
Pre-ignition, spark plug 868, 871
Preliminary detent,
locking systems 1432
Preload forces, threaded fasteners 441
Preloaded bearing arrangement,
rolling bearings 380
Premium lock, locking systems 1434
Premixed combustion,
diesel engine 658
Preprocessor,
finite-element method 234
Press fit, frictional joints 430
Press-fit force, frictional joints 432
Pressure build-up time, brakes 1209
Pressure build-up time,
motor-vehicle dynamics 476
Pressure control, common rail 926
Pressure generation, common rail 926
Pressure increase, gasoline engine 651
Pressure modulator,
electrohydraulic brake 1225
Pressure on the face of a hole,
mechanics 51
Pressure ratio, thermodynamics 95
Pressure reduction, natural-gas
pressure-control module 898
Pressure regulator, brake systems,
commercial vehicles 1234
Pressure sensors 1756
Pressure tank, fuel supply 825
Pressure vessel, flow mechanics 58
Pressure vs. volumetric-flow map,
supercharging 673
Pressure-backing, unit injector 945
Pressure-compensated valve,
common rail 931
Pressure-control module,
engines fueled by natural gas 898
Pressure-control modules, electronically
controlled brake system 1245
Pressure-control valve,
gasoline direct injection 833
Pressure-control valve,
low-pressure diesel fuel supply 920
Pressure-control valve,
traction control system 1270
Pressure-control valve,
transmission control 637
Pressure-drop phase,
antilock braking system 1261
Pressure-increase ratio,
thermodynamics 93
Pressure-indicated cycle power,
thermal engines 644
Pressure-loaded ball valve,
common rail 930
Pressure-relief valve, natural-gas
pressure-control module 899
Pressure-retention phase,
antilock braking system 1261
Pressure-rise phase,
antilock braking system 1261
Pressure-wave superchargers,
turbochargers and
superchargers 772
Pressure-wave supercharging 673
Prestress, threaded fasteners 438
Prestroke, unit injector 945
Pretensioning force, belt drives 721
Primary address,
Serial Wire Ring 1713
Primary detent, locking systems 1432
Primary quantum number,
periodic table 185
Primary retarder, continuous-operation
brake systems 1247
Primary shoe, drum brake 1257
Primary winding, ignition coil 862
Principal maxima, wave optics 79
Priority control, vehicle
communication networks 1687
Prismatic hardcase cell, batteries
for electric and hybrid drives 1611
Prisms, geometric optics 76
Process assessment, automotive
software engineering 1653
Process capability characteristic value,
technical statistics 233
Process capability,
technical statistics 233
Process description models, automotive
software engineering 1650
Process evaluation models, automotive
software engineering 1651
Process variables, thermodynamics 86
Process, thermodynamics 86
Processing methods, plastics 322
Product Specifications, tolerance 354
Production date, tire designation 1183

Profiled shaft-hub connections, positive or form-closed joints 427
Program memory, electronic control unit (ECU) 1629
Projection system, headlamps, lighting equipment 1346
Prometheus, driver-assistance systems 1804
Prompted troubleshooting, ECU diagnostics 1106
Propagation of sound, acoustics 67
Properties, finite-element method 237
Property classes, threaded fasteners 438
Proportional solenoid, transmission control 639
Protection against misuse, starters for heavy commercial vehicles 1517
Protocol, MOST 1708
Protocols, vehicle communication networks 1682
Protolysis, acids in water 198
Protons, elements 182
Pseudo-first-order reaction, reaction kinetics 197
Pseudo-Hall sensors 1735
PSI5, buses in motor vehicles 1705
Psychoacoustics, vehicle acoustics 535
PTC thermistor 1760
PTC, temperature sensor 1760
PTFE, lubricants 541
Pull-in winding, starters for passenger cars 1508
Pulsation, acoustics 70
Pulse detection, lidar-sensor system 1830
Pulse supercharging, exhaust-gas turbocharger 780
Pulse time-of-flight method, lidar-sensor system 1829
Pulse wheel, rpm sensors 1738
Pulses in the vehicle electrical system, electromagnetic capability 1525
Pump cell, λ sensors 1767
Punch riveting, riveting 458
Puncture detection, tire-pressure monitoring systems 1188
Purely electric driving, hybrid drives 993
Push voltage, preheating systems 955
Pushbelt, step-up gear unit 622
Push-rod piston, passenger-car brake system 1220
PVD coatings, deposits and coatings 352
PWM activation, DC-DC converters 1598
PWM inverter, vehicle electrical systems for hybrid and electric vehicles 1561
PWM valves, transmission control 636
PWR inverters, inverters 1582
Pyrometer 1760

Q

Quad-headlamp system, lighting equipment 1340
Quadratic temperature coefficient, PTC 1762
Quality assurance, automotive software engineering 1654
Quality control, gasoline engine 656
Quality factor, vibrations and oscillations 61
Quantities used in atom physics, legal units 40
Quantities, quantities and units 32
Quantity control, gasoline engine 656
Quantity of heat, legal units 37
Quantity of light, lighting quantities 81
Quantum numbers, periodic table 182
Quarter-vehicle model, motor-vehicle dynamics 488
Quartile, Technical statistics 227
Quenching and drawing, heat treatment 335
Quenching, spark plug 869
Queue, Serial Wire Ring 1714

R

“Restored-signal recognition”, diagnostics 1091
R12, refrigerants 591
R-1234yf, climate control 1396
R1234yf, refrigerants 592
R134a, climate control 1396
R134a, refrigerants 591
R-744, climate control 1396
Rack travel, chassis systems 1119
Rack, steering 1195
Rack-and-pinion steering, steering 1195
Radar-antenna radiation pattern, lane-change assistant 1913
Radar-sensor system, driver assistance and sensor system 1816
Radial crushing strength, material parameters 262
Radial engine, reciprocating-piston engine 690

Radial play, rolling bearings 379
Radial run-out, radial shaft seal 401
Radial seal, plug-in connections 1521
Radial shaft seal, seals 398
Radial tire 1171
Radial vee-form filter,
gasoline filter 826
Radial-piston distributor pumps 951
Radial-piston pump,
gasoline direct injection 832
Radian, SI units 34
Radiance, lighting quantities 80
Radians, mathematics 207
Radiant energy, lighting quantities 79
Radiant excitance,
lighting quantities 80
Radiant flux, lighting quantities 79
Radiant intensity, lighting quantities 80
Radiation quantities,
lighting quantities 79
Radiation thermometer 1760
Radiator core, water cooling 737
Radiator design, water cooling 742
Radiator designs, water cooling 737
Radiator protection agents
containing silicate, coolants 554
Radiator protection agents,
coolants 553
Radiator tank, water cooling 738
Radio and TV reception 1794
Radio Data System,
radio and TV broadcasting 1799
Radio Data System,
traffic telematics 1801

Reaction kinetics,
reactions of substances 196
Reaction progression,
chemical thermodynamics 195
Reaction time, brakes 1209
Reaction time,
motor-vehicle dynamics 475
Reactions of substances 195
Reactive power,
electrical engineering 127
Reactive-power compensation,
electrical engineering 127
Readiness codes,
on-board diagnostics 1097
Real gas, thermodynamics 90

Real numbers, mathematics 204
Real Road PEMS Tests, test cycles for heavy commercial vehicles 1070
Real-time capable, software 1646
Rear cross-traffic warning, information and warning systems 1900
Rear fog warning lamps, lighting equipment 1362
Rear reflectors, lighting equipment 1361
Rear underride guard, vehicle bodies, commercial vehicles 1333
Rear wiper drives, windshield, rear-window and headlamp cleaning systems 1389
Rear wiper systems, windshield, rear-window and headlamp cleaning systems 1388
Rear-axle steering, steering 1192
Rear-end collision, integral safety 1426
Rear-engine drive, drivetrain with internal-combustion engine 599
Rearview camera, parking and maneuvering systems 1886
Rearview-camera system, information and warning systems 1896
Rear-wheel drive, drivetrain with internal-combustion engine 598
Rear-wheel lift-up control, Motorcycle Stability Control 1298
Rebound resilience, elastomer materials 422
Rebound stage, shock absorbers 1141
Reception problems, radio and TV broadcasting 1795
Recessive state, CAN 1692
Reciprocating-piston engine types 690
Reciprocating-piston engine 676
Recirculated-air mode, climate control 1392
Recirculating-ball gear, steering 1200
Recirculating-ball steering, steering 1196
Recoil permeability, material parameters 259
Recording of air charge, cylinder charge 815
Recrystallization annealing, heat treatment 335
Rectification value, vibrations and oscillations 62
Rectification, alternators 1493
Rectifier diode, electronics 141
Rectilinear motion, mechanics 46
Recuperation level, control of electric drives 986
Recuperation torque, control of electric drives 986
Recuperation, 12 V vehicle electrical system 1464
Recuperation, alternators 1497
Recuperation, hybrid drives 992
Redox reaction, chemistry 203
Reduced stress, mechanics 52
Reduction equations, catalytic converter 874
Reduction gear, starters for passenger cars 1508
Reduction gear, steering 1199
Reduction, chemistry 202
Redundancy, brake systems for passenger cars 1228
Reference belt length, belt drives 722
Reference mark, rpm sensors 1741
Reference variable, control engineering 242
Reference-vacuum chamber, pressure sensors 1758
Reflectance factor, electrical engineering 128
Reflected image, night vision systems 1877
Reflection coefficient, geometric optics 76
Reflection headlamps, lighting equipment 1347
Reflection mufflers, exhaust-gas system 794
Reflection system, headlamps, lighting equipment 1346
Reflector focal length, lighting equipment 1346
Reflector illuminated area, lighting equipment 1346
Reflectors, geometric optics 77
Refractive index, geometric optics 75, 76
Refrigerant circuit, climate control 1395
Refrigerant cooling, batteries for electric and hybrid drives 1614
Refrigerant, climate control 1395, 1396
Refrigerants, operating fluids 591
Refueling emissions, evaporative-emissions test 1089
Refueling test, evaporative-emissions test 1089
Regeneration of the particulate filter, catalytic exhaust-gas treatment, gasoline engine 881

Regeneration of the particulate filter, exhaust-gas treatment, diesel engines 963
Regeneration, NO_x storage catalytic converter 875
Regeneration, particulate filter 793
Regeneration-air tank, brake systems, commercial vehicles 1234
Regenerative braking system, electrification of drive 976
Regenerative braking system, electrification of the drive 972
Regional programs, emission-control legislation for heavy commercial vehicles 1066
Regroovable, tire tread 1174
Regulated preheating system, start-assist system 957
Regulation of climate control 1394
Reinforcement additives, friction bearings 376
Reinforcement learning, artificial intelligence 251
Relative frequency, technical statistics 227
Relative permeability, electrical engineering 121
Relative-pressure sensors 1756
Relaxation behavior, plastics 309
Relaxation, springs 364
Relay-station attack, locking systems 1431
Release angle, snap-on connections 448
Release force, snap-on connections 448
Release of ammonia, exhaust-gas treatment, diesel engines 969
Release torque, threaded fasteners 441
Reliability, sensors 1717
Remagnetization losses, electrical engineering 124
Remanence point, electrical engineering 122
Remanence, electrical engineering 122
Remote frame, CAN 1695
Remote key, locking systems 1431
Remote welding, welding 453
Remote-controlled parking assistant, parking and maneuvering systems 1888
Renewable-energy gas, engines fueled by natural gas 894
Repeater, vehicle communication networks 1689
Replacement of wheel-torque distribution by brake and engine-control interventions 1306
Replacing the battery, starter batteries 1489
Replay attack, vehicle immobilizer 1446
Representative sinor, inverters 1587
Requirement management, architecture of electronic systems 1678
Requirement model, architecture of electronic systems 1675
Research octane number, gasoline 565
Reset function, tire-pressure monitoring systems 1189
Residual exhaust gas, cylinder charge 812
Residual gas, charge cycle 664
Residual ripple, electromagnetic compatibility 1525
Residual speed, wet braking 1175
Resilient clips, snap-on connections 447
Resilient snap-on hooks, snap-on connections 447
Resistance measurement 1761
Resistance projection welding, welding 450
Resistance spot welding, welding 450
Resistance to flow, flow mechanics 59
Resistance to seizing, friction bearings 372
Resistance to wear, friction bearings 372
Resistance welding, welding 450
Resistance, electrical engineering 106
Resistance-based measurement principle, hydrogen sensors 1775
Resistivity, electrical engineering 106
Resolving capacity, wave optics 79
Resonance chamber, air-intake system 764
Resonance flap, air-intake system 764
Resonance plenum, air-intake system 764
Resonance sharpness, acceleration sensor 1751
Resonance sharpness, vibrations and oscillations 61
Resonance, vibrations and oscillations 61

Electronic Diesel Control 913
Roadworks assistant,
lane assistance 1909
Robustness, control engineering 245
Rocker arm,
reciprocating-piston engine 685
Rockwell hardness, heat treatment 328
Rod guides,
rod and piston sealing systems 412
Rod seal, O-ring 392
Rod seal, pneumatic seals 406
Rod seals, seals 411
Rod shape, rpm sensors 1739

Roll angle, vehicle motion 463
Roll axis, chassis systems 1116
Roll behavior,
motor-vehicle dynamics 485
Roll pole, chassis systems 1116
Roll steer, driving dynamics - commercial vehicles 493
Roll, vehicle motion 463
Roll-back effect, disk brake 1251
Roller electrodes, seam welding 451
Roller race,
starters for passenger cars 1510
Roller sun blind, sunroof systems 1406
Roller tappet,
gasoline direct injection 830
Roller-cell pump, electric fuel pump 827
Roller-type chain, chain drives 730
Roller-type overrunning clutch,
starters for passenger cars 1510
Rolling bearings, machine parts 378
Rolling elements, rolling bearings 378
Rolling friction, mechanics 54
Rolling moment, vehicle motion 463
Rolling pairs,
reciprocating-piston engine 701
Rolling radius, chassis systems 1121
Rolling resistance,
running resistances 464
Rolling resistance, tires 1180
Rolling-contact pressure,
reciprocating-piston engine 701
Rolling-resistance coefficient,
tires 1180
Rollover Mitigation Function, ESC 1281
Rollover prevention, ESC 1281
Rollover protection,
occupant-protection systems 1421
Root function, mathematics 205
Roots supercharger,
mechanical superchargers 773
Rope friction, mechanics 54
Rotary drive, windshield,
rear-window and headlamp cleaning systems 1384
Rotary drives, windshield,
rear-window and headlamp cleaning systems 1382
Rotary motion, mechanics 46
Rotary oscillator, yaw-rate sensor 1744
Rotary seal for tire-pressure control,
tires 1190
Rotary table, two-component seals 409
Rotary-magnet actuator,
distributor injection pump 949
Rotating load, rolling bearings 381
Rotating mass, mechanics 47
Rotating-field generation,
three-phase current system 179
Rotational impulse, mechanics 49
Rotational motions, vehicle motion 463
Rotational speed, mechanics 46
Rotocap,
reciprocating-piston engine 686
Rotor shapes, rpm sensors 1739
Rotor, alternators 1492
Roughness values,
reciprocating-piston engine 701
Round filters, air-intake system 770
Route computation,
traffic telematics 1802
Route computation,
vehicle navigation 1874
Route guidance,
vehicle navigation 1875
Route recommendations,
vehicle navigation 1874
Route-guidance systems,
traffic telematics 1802
Routing, vehicle communication networks 1685
rpm sensors 1738
Rubber compound, belt drives 721, 726
Rubber compounds, plastics 316
Rubber elasticity, plastics 316
Rubber elements,
suspension systems 1124
Rubber friction, tires 1179
Rubber lip, windshield, rear-window and headlamp cleaning systems 1387
Rubber springs, suspension 1126
Rubber, plastics 316
Run length, chain drives 733
Run-flat tires 1171
Run-in performance,
friction bearings 372
Running resistance, drivetrain with internal-combustion engine 596
Running resistances,
vehicle physics 464
Running-loss test,
evaporative-emissions test 1088
Run-time environment, automotive software engineering 1649
Rust level, corrosion testing 343

S

Sacrificial anode,
corrosion protection 345
Sacrificial layer, micromechanics 1721

SAE viscosity grades,
lubricants 543, 547
Safe function, locking systems 1438
Safety element, air-intake system 770
Safety functions, ESC,
commercial vehicles 1291
Safety functions, locking systems 1438
Safety labyrinth cover,
starter batteries 1483
Safety margin,
motor-vehicle dynamics 476
Safety requirements, batteries
for electric and hybrid drives 1611
Safety strategy, transmission control 634
Sailing operation, hybrid drives 1001
Salts, chemical bonds 189
Sample size, technical statistics 227
Sample, technical statistics 228
Sanding waves,
vibrations and oscillations 62
Sandwich injection molding,
two-component seals 408
Satellite positioning system GPS 1872
Saturation detection, catalytic exhaust-
gas treatment, gasoline engine 881
Saturation detection, exhaust-gas
treatment, diesel engines 964
Saturation polarization,
electrical engineering 122
SC03 cycle, test cycles 1058
Scalability, electric final-drive unit 1027
Scalar product, mathematics 214
Scan tool,
on-board diagnostics 1093, 1097
Scavenge efficiency, charge cycle 664
Scavenging pumps, 2-stroke cycle 666
Scavenging, cylinder charge 814
Scavenging,
engines fueled by natural gas 897
Schematic diagram 1546
Schottky diode, electronics 142
Scleroscope hardness,
heat treatment 331
SCR method, exhaust-gas treatment,
diesel engines 966
Screw/bolt, threaded fasteners 437
Screw-type supercharger,
mechanical superchargers 774
Scrub radius, chassis systems 1119
Seal seat, spark plug 867
Seal technology, machine parts 384
Sealed-beam design,
lighting equipment 1344
Seal-glass bonding,
micromechanics 1722
Sealing caps, seals 396
Sealing compounds, plastics 323
Sealing compounds, properties 324
Sealing cup, radial shaft seal 399
Sealing gap, molded seal 394
Sealing gap, O-ring 387
Sealing geometry,
natural-gas injector 898
Sealing lips, plug-in connections 1521
Sealing-edge rings,
rod and piston sealing systems 411
Seals, machine parts 384
Seam welding, welding 451
Seat adjustment,
electrical seat adjustment 1408
Seat Belt Reminder, safety systems
in the motor vehicle 1410
Seat belts,
occupant-protection systems 1418
Seat reference point,
vehicle bodies, passenger cars 1318
Seat-occupancy mat,
occupant-protection systems 1422
Secant modulus,
snap-on connections 448
Second law, thermodynamics 88
Second, SI units 32
Secondary brake system 1206
Secondary braking effect, brake
systems, commercial vehicles 1230
Secondary Collision Mitigation,
occupant-protection systems 1417
Secondary groups, periodic table 182
Secondary hardening,
heat treatment 334
Secondary lock,
plug-in connections 1522
Secondary maxima, wave optics 79
Secondary retarder, continuous-
operation brake systems 1248
Secondary shoe, drum brake 1257
Secondary winding, ignition coil 862
Secondary-air injection,
catalytic-converter heating 877
Secondary-air pump,
catalytic-converter heating 878
Secondary-air valve,
catalytic-converter heating 878
Secondary-brake system, brake
systems for passenger cars and
light utility vehicles 1217
Secondary-brake system, brake
systems, commercial vehicles 1232
Second-order reaction,
reaction kinetics 197

Section designation, circuit diagrams 1549
Security, vehicle immobilizer 1446
Seebeck coefficient, electrical engineering 131
Seebeck effect, electrical engineering 131
Segment sensor, rpm sensors 1740
Seiliger cycle, thermodynamics 93
Seismic mass, acceleration sensor 1753
Seismic mass, knock sensor 1755
Seizing, reciprocating-piston engine 699
Selection criteria, rolling bearings 379
Selective catalytic reduction, exhaust-gas treatment, diesel engines 966
Select-low control, antilock braking system 1263
Self-aligning rolling bearing, rolling bearings 378
Self-augmenting effect, drum brake 1257
Self-caused dirtying 523
Self-cleaning temperature, spark plug 867
Self-discharge, starter batteries 1483, 1487
Self-excitation, 12 V vehicle electrical system 1455
Self-excitation, alternators 1491
Self-induction, electrical engineering 121
Self-inhibiting effect, drum brake 1257
Self-lubricating bearings made of metal 374
Self-lubricating bearings made of plastic 376
Self-protection function, electronic control unit (ECU) 1635
Self-stabilization, Motorcycle Stability Control 1296
Self-steering effect, motor-vehicle dynamics 481
Self-test, diagnostics 1090
Semiconductor devices, electronics 141
Semiconductor memories, electronic control unit (ECU) 1628
Semiconductor technology, electronics 138
Semiconductor technology, micromechanics 1720
Semiconductors, electrical engineering 110
Semicrystalline thermoplastics, plastics 307
Semi-finished, electrical steel strip 292
Semi-hollow rivet, riveting 458
Semi-independent axles, wheel suspensions 1149
Semi-rigid axles, wheel suspensions 1148
Semi-synthetic filter media, air-intake system 757
Semi-synthetic oils, lubricants 544
Sensor classification, sensors 1718
Sensor flap, flow meters 1746
Sensor redundancy concept, architecture of electronic systems 1672
Sensor shapes, rpm sensors 1739
Sensor space, sensor-data fusion 1860
Sensor-data fusion, ACC 1894
Sensor-data fusion, driver assistance and sensor system 1860
Sensor-data fusion, driver-assistance systems 1809
Sensors, automotive electronics 1716
Sensotronic brake control, passenger-car brake system 1224
Separate motor-generator, electrical machines 1571
Separators, starter batteries 1478
Sequence control in the master, Serial Wire Ring 1714
Sequential supercharging, complex supercharging systems 785
Serial testing, emission-control legislation 1043
Serial Wire Ring, buses in the motor vehicle 1711
Series combinations, springs 363
Series hybrid, hybrid drives 1003
Series-based ECUs, motor sport 884
Series-parallel hybrid, hybrid drives 1005
Service brake system 1206
Service Information System, diagnostics 1106
Service-brake system, brake systems for passenger cars and light utility vehicles 1216
Service-brake system, commercial vehicles 1230
Service-brake system, tractor vehicle 1230
Service-brake system, trailer 1231
Service-brake valve, brake systems, commercial vehicles 1237

Service-brake valve, electronically controlled brake system 1244
Servo unit, steering 1199
Servomotor, steering 1199
Setpoint time gap, ACC 1891
Settling chamber, wind tunnels 525
SFTP cycles, test cycles 1058
Shaft, radial shaft seal 401
Shafts, axles and shafts 359
Shakers, vehicle acoustics 532
Sharpness, acoustics 71
SHARX, receivers 1800
Shear layer, aerodynamics 522
Shear modulus curve, plastics 309
Shear rate, lubricants 541
Shear stress, flow mechanics 57
Shear stress, lubricants 541
Shear stress, material parameters 262
Shear stress, mechanics 52
Shear viscosity, lubricants 541
SHED, evaporative-emissions test 1087
Shedding, aerodynamics 517
Shedding, starter batteries 1484
Shell elements, finite-element method 235
Shell model, finite-element method 237
Shell-type mufflers, exhaust-gas system 795
Shift-point control, transmission control 632
Shock-absorber characteristic curves, shock absorbers 1138
Shock-absorber piston, shock absorbers 1136
Shore hardness, elastomer materials 419
Short-circuit scavenging, 2-stroke cycle 666
Short-circuiting-ring sensor 1726
Short-range radar, radar-sensor system 1822
Short-term loads, 12 V vehicle electrical system 1451
Short-time performance, electric final-drive unit 1026
Shoulder-belt pretensioner, occupant-protection systems 1418
Shrink fit, frictional joints 433
Shrinking process, spark plug 866
Shutoff valve, LPG operation 893
SI units, quantities and units 32
Side airbag, occupant-protection systems 1421
Side electrode, spark plug 867
Side force, aerodynamics 518
Side member, vehicle bodies, commercial vehicles 1328
Side-marker lamps, lighting equipment 1361
Side-view assistant, lane-change assistant 1912
Sidewall markings, radial tire 1172
Sidewall, radial tire 1171
Siemens, SI units 34
Sievert, SI units 34
Sign function, mathematics 206
Signal conditioning, electronic control unit (ECU) 1632
Signal lamps, lighting equipment 1359
Signal path, diagnostics 1091
Signal processing, electronic control unit (ECU) 1634
Signal Range Check, on-board diagnostics 1100
Signal transmission, radio and TV broadcasting 1794
Signal types, electronic control unit (ECU) 1634
Signal-to-noise ratio, radio and TV broadcasting 1796
Silica, starter batteries 1478
Silica, tires 1181
Silicon semiconductor resistors 1763
